

ARO 49th MidWinter Meeting

PUERTO RICO CONVENTION CENTER
FEBRUARY 7-11, 2026

Abstract Book

**SAN JUAN,
PUERTO RICO**

Friday, February 6, 2026

gEAR Session: Beginner Workshop - Introduction to gEAR

7:00 p.m. - 9:00 p.m.

Meeting Room 208ABC, Floor 2

Presenters:

Joshua Orvis, *Institute for Genome Sciences*

Daniel Lesperance, *Institute for Genome Sciences, University of Maryland, Baltimore*

Session Overview: This introductory workshop provides a hands-on tour of the Gene Expression Analysis Resource (gEAR). Participants will learn how to create an account, navigate the user dashboard, and search across gEAR's growing library of datasets. We'll cover the basics of finding and viewing gene expression profiles, organizing results into lists, and exploring curated dataset collections.

Shifting then to more advanced applications, we will focus on tools like the single-cell workbench, spatial displays, and epigenomic browser and projection, where users can dive deeper into their multi-omic data. You'll learn how to visualize clusters, compare cell populations, and quickly identify expression patterns across tissues and developmental stages. By the end of the session, attendees will have the tools to confidently begin using gEAR to support their own research questions.

This workshop includes a gEAR binder with all the instructional materials, and snacks and refreshments for the long session.

Saturday, February 7, 2026

Presidential Symposium: The Power of Collaboration - Part 1

Chair: Ronna Hertzano, *National Institutes of Health*

8:00 a.m. - 9:30 a.m.

Ballroom B, Floor 3

Session Overview: This year's Presidential Symposium celebrates the transformative impact of collaboration, how breaking boundaries, sharing expertise, and building trust create a synergy in which the whole becomes greater than the sum of its parts. Inspired by breakthroughs in single-cell analysis and accelerated progress in clinical trials across our field, the symposium, *The Power of Collaboration*, is organized into two thematic parts. Each segment opens with an inspiring plenary lecture, followed by a panel of concise, high-impact presentations that exemplify collaborative science in action.

A Community Standard Cell Type Atlas of the Brain: The Brain Initiative Cell Atlas Network

Mike Hawrylycz*¹

¹*Allen Institute for Brain Science*

Individual Abstract: Single-cell genomics has revolutionized our ability to construct comprehensive cellular atlases of the brain, enabling researchers to systematically characterize the molecular diversity of individual neurons and glia at unprecedented resolution. Cell type atlases and databases allow the creation of molecular reference standards akin to the pangenome, a standardized representative sequence derived from the genomes of multiple individuals that act as a genetic baseline for comparison. This paradigm underpins the work of the BRAIN Initiative Cell Census Network (BICAN), which is creating a standardized and integrated cell atlas of the human, macaque, marmoset and mouse brain as a new community standard to serve as a unifying reference for the mammalian brain. Brain atlases have now been generated for diverse species, regions, and disease states and form invaluable resources for studying cell types and their perturbations. Through this work and active consortia such as BICAN, the Human BioMolecular Atlas Program (HuBMAP) and the Human Cell Atlas (HCA) we are rapidly proceeding toward a comprehensive reference map of all human cell types—including their molecular profiles, spatial locations, developmental trajectories and inter-cellular interactions. The brain and the ear are closely connected through the auditory and vestibular systems and with connections to the primary and peripheral nervous system the ear has essential links to healthy brain function. A single-cell ear atlas would transform hearing and balance research by defining every molecular cell type, linking genotype to function and pathology, and providing a reference framework for regenerative and therapeutic innovation, much as brain and retinal atlases have done for their respective systems. In this presentation we survey the techniques and accomplishments of cell type characterization in the brain and peripheral nervous system highlighting opportunities for a constructing detailed map of the auditory and vestibular systems.

Gearing up for Regeneration

Lisa Goodrich*¹, John V. Brigande², Alain Dabdoub³, Albert Edge⁴, Andrew K. Groves⁵, Ksenia Gnedeva⁶, Stefan Heller⁷, Ronna Hertzano⁸, Tatjana Piotrowski⁹, David W. Raible¹⁰, Yehoash Raphael¹¹, Litao Tao¹², Mark Warchol⁵, Seth A. Ament¹³

Individual Abstract: With the introduction of out-of-the-box methods to generate high-quality genomic data even from rare cell populations, inner ear researchers now have access

to many large datasets that can be used to answer a wide range of experimental questions and generate hypotheses. However, it can be challenging to access or analyze data effectively, especially when methods and quality vary across labs. The Hearing Restoration Project (HRP) was founded on the core principle that collaboration will accelerate and improve the field's efforts to find molecular entry points for stimulating hair cell regeneration. To lower the barrier for everyone, HRP has produced a large number of single cell and single nucleus datasets from all hair cell bearing organs from four species across development and after damage. 13 laboratories are currently working together to develop and apply cutting edge bioinformatic approaches that can be used to identify key nodes of gene expression and mechanisms of regulation, to develop standardized methods for screening candidate pathways in vivo and in organoids, and to test directly how manipulation of candidate pathways can improve the number and maturity of hair cells regenerated from supporting cells. Efforts to date have revealed cohorts of genes that are enriched in hair cells relative to supporting cells across species or that are associated with key steps in regeneration. Data generated by HRP researchers is freely available through gEAR, where you can directly query the results of our analysis to further your own research goals.

Towards a High-Resolution Spatiotemporal Transcriptomic Atlas of the Vestibular Utricle

Rachel Honeyghan-Williams^{*1}, Jimena Perez Lloret², Valeria Castagna¹, Marcela Lipovsek¹

¹*University College London*, ²*University College London Ear Institute*

Individual Abstract: The cellular composition of vestibular sensory epithelia has been extensively explored using histological and electrophysiological methods, identifying two major types of hair cells, type I and type II, and two distinct areas on the epithelium, the striola and extrastriola. Single cell transcriptomics has been able to match overall gene expression signals to this wider cell type and spatial definitions. However, due to the challenges inherent to the preparation of single cell suspensions, the transcriptomic profiling has been, with few exceptions, low-throughput and focused on early postnatal stages.

Here, we present a novel tissue collection and freezing strategy that, coupled with the preparation of single nuclei suspensions and combinatorial barcoding sequencing libraries, allowed us to generate, in an experimentally flexible and cost-effective way, a high-resolution dataset that profiles the mouse utricle from embryonic to adult stages, encompassing 17 timepoints and ~120,000 cells.

By implementing non-linear dimensionality reduction and visualisation tools, cluster stability evaluation and non-negative matrix factorisation for gene module analysis we have reached robust and granular transcriptomic definitions of the cell types and subtypes that make up the vestibular utricle. Moreover, trajectory and RNA velocity analysis are allowing us to study in detail the maturational process of individual cell types and their subcellular functional modules.

We will discuss how this in-depth exploration of the cell types and subtypes present in the mouse utricle can be exploited to further our understanding of the functional maturation and potential for sensory hair cell regeneration in inner ear sensory epithelia.

HIEDRA: A Human Inner Ear Development Single-Nucleus RNA Atlas

Heiko Locher^{*1}

Individual Abstract: The human inner ear comprises a diverse array of highly specialized cell types that enable hearing and balance. Recent studies have advanced our understanding of their development, yet human-specific mechanisms are still being uncovered. This gap limits our ability to interpret how genetic variants cause inner ear disorders and to develop targeted therapies.

To address this, we generated HIEDRA (Human Inner Ear Development RNAseq Atlas), a high-resolution single-nucleus RNA-sequencing atlas of the developing human inner ear spanning fetal weeks 7 to 15, capturing both auditory and vestibular domains. HIEDRA identifies many transcriptionally distinct cell populations, including sensory and non-sensory epithelia, neuronal, and mesenchymal cells. Among these are previously under-characterized secretory cells such as the marginal cells of the stria vascularis and the vestibular dark cells, crucial for endolymph homeostasis and inner ear function.

HIEDRA was validated using newly generated data from manually separated cochlear and vestibular tissues (fetal week 12), publicly available mouse cochlear and ampullary datasets (E16), and pseudotime analyses revealing temporal expression of established gene markers. By integrating disease gene annotations, we mapped known deafness and balance disorder genes to specific cell types, revealing selective cellular vulnerabilities of sensory and secretory cell types. We further defined developmental trajectories and gene regulatory networks underlying sensory and secretory lineage specification.

To demonstrate HIEDRA's utility as a discovery platform, we applied its insights to human inner ear organoids, aiming to induce the formation of secretory cells, cell types normally absent in this model. We found that suppression of Hedgehog signaling is essential for secretory cell fate acquisition. Targeted Hedgehog inhibition successfully promoted formation of vestibular dark cells and cochlear marginal cells, enhancing organoid complexity and establishing a more physiologically relevant in vitro model for studying disease mechanisms and testing therapeutic interventions.

Altogether, HIEDRA offers a human-specific framework for understanding inner ear development and disease, serving as an open resource for the research community.

Comap – A Single Cell “Omic” Atlas of the Cochlea Across the Life Span

Matthew Kelley*¹, Tessa R. Sanders¹, Elizabeth C. Driver¹, Beatrice Milon¹, Christopher Shults¹, Amanda Bonczkowski¹, Rafal Olszewski¹, Wei Song¹, Nachiket Kelkar¹, Katherine Fernandez¹, Lisa Cunningham¹, Ran Elkon¹, Michael Hoa¹, Robert Morell¹, Ronna Hertzano¹

¹*NIH/NIDCD*

Individual Abstract: Background: The cochlear duct is a remarkable structure. While small in size (30 mm long in human, 6 mm long in mice), the cochlea successfully detects and processes sounds across a wide range of frequencies and sound intensities. The cochlea's exceptional performance is achieved, in part, through its highly diverse population of cell types, which are distributed in stereotypical patterns within the duct. Despite the importance of these varied cell types for auditory function, the small size of the cochlea and its high cellular diversity have prevented a full characterization of their gene expression and epigenetic states.

Methods: To address this challenge, we will combine spatial transcriptomics with single cell RNA and ATAC sequencing at different time points to create an omic atlas of the developing, adult, and aging cochlea. The resulting data will be posted to the gEAR website in a user-friendly format that will allow researchers to easily determine gene expression and epigenetic state for cells located in specific locations within the cochlea.

Results: Using the CBA/CaJ mouse line, which does not experience premature age-related hearing loss, we are collecting data from 5 embryonic and early post-natal time points prior to the onset of hearing. In addition, we will collect cochleae at P14, P30 and > P365 to characterize omic profiles during normal function and aging. As a first step, we have generated and posted on gEAR the data for cochleae at post-natal day 1.

Conclusions: Cellular diversity, function, and degeneration are all, ultimately, driven by the expression or lack of expression of specific genes or gene isoforms. By creating an in-depth single cell atlas of cochlear gene expression and epigenetic states throughout the mouse lifespan, we plan to provide a baseline dataset that can be used to characterize genetic changes underlying both known and unknown causes of auditory dysfunction.

NIDCD's Human Temporal Bone Resources

Amy Poremba*¹, Janet Cyr¹, Troy Hackett¹

¹*NIH-NIDCD*

Individual Abstract: As the delicate inner ear is encased within the temporal bone, one of the hardest bones of the body, detailed study of the human inner ear relies on post-mortem temporal bones to understand underlying pathophysiology which is critical for illumination of how humans process hearing and balance information. At NIDCD (National Institute on Deafness and Other Communication Disorders), we have formed a three-part resource for studying the human temporal bone/inner ear tissue: 1) The National Hearing and Balance Organ Donor Program to coordinate a list of potential consented donors, and then procure and distribute the inner ear tissues to be processed for researchers. This resource is managed by the Human Tissues and Organs for Research Resource through the National Disease Research Interchange; 2) The National Human Ear Resource Network for tissue processing, case analysis, method optimization, and data and specimen sharing. There are five currently NIDCD funded laboratories across the nation that comprise this collaborative Network and human inner ear resource. These laboratories are located at Johns Hopkins University, Mass Eye and Ear, Stanford University, University of California, Los Angeles and the University of Minnesota; and 3) EarBase, a searchable database of temporal bone tissue with medical records and archived digital images, which is developed and coordinated by a resource awarded to the University of Southern California, cofunded with the National Institute on Dental and Craniofacial Research and the NIH Office of Data Science Strategy as part of the collaborative FaceBase endeavor. NIDCD is dedicated to encouraging the scientific community to continue to build and maintain national human temporal bone resources for scientific researchers and clinicians and this presentation will describe the three-part synergistic resource and the current status of each part. These overall resources are critical to advance human auditory and vestibular research to understand the underlying pathophysiology of disorders and the discovery of treatments.

Presidential Symposium: The Power of Collaboration - Part 2

Chair: Ronna Hertzano, *National Institutes of Health*

10:00 a.m. - 12:00 p.m.

Ballroom B, Floor 3

Session Overview: This year's Presidential Symposium celebrates the transformative impact of collaboration, how breaking boundaries, sharing expertise, and building trust create a synergy in which the whole becomes greater than the sum of its parts. Inspired by breakthroughs in single-cell analysis and accelerated progress in clinical trials across our field, the symposium, *The Power of Collaboration*, is organized into two thematic parts. Each segment opens with an inspiring plenary lecture, followed by a panel of concise, high-impact presentations that exemplify collaborative science in action.

Preparing for Precision Medicine: The PD GENERation Experience

James Beck*¹

¹*Parkinson's Foundation*

Individual Abstract: Parkinson's disease (PD) is a progressive neurologic disease affecting nearly 1 million in people in the US alone and is without a disease modifying therapy. The cause of PD is unknown for the majority of those affected, but in 1997 the first genetic forms of PD were identified and now dozens of genes are linked directly or indirectly to the disease. Though many of these genes are exceedingly rare, 10-15% of PD patients carry variants in one of seven well-known PD genes. Clinical trials targeting genetic-PD have been repeatedly attempted in the past decade but have failed because of considerable challenges in recruitment. Appreciably complicating the issue is that neither PD patients nor their clinicians know their genetic status. Physician surveys demonstrated that genetic testing was rarely offered to PD patients due to issues around insurance reimbursement, clinical utility, and a perceived lack of patient interest. Nevertheless, clinical development of gene-targeted therapies rapidly continues with nearly a dozen about to enter or in early phase clinical trials for PD.

To overcome this challenge and to accelerate precision trials for PD, the Parkinson's Foundation created the PD GENERation study (NCT04994015), which offers no-cost genetic testing and counseling to almost all diagnosed with PD. In parallel to patient outreach, the Foundation also offered physician education around genetic testing and return of results to bolster clinician knowledge and involvement. PD GENERation started in late 2019 with 6 US sites and now has more than 70 sites in 9 countries across the Americas and in Israel plus the study offers remote enrollment. Patient interest has been robust from the outset with waiting lists forming at one point. Enrollment averages 917 per month and nearly 30,000 participants have been recruited. Recent physician surveys have shown an increased comfort in genetic testing and counseling and a concomitant increase in patient referral. The experience of the PD GENERation study represents a path forward for other disease areas where precision therapies are being developed yet genetic testing is not standard of care.

PD GENERation is sponsored by the Parkinson's Foundation with support from the Global Parkinson's Genetics Program (GP2), a program of the Aligning Science Across Parkinson's (ASAP) initiative.

Lessons Learned From Genetic Testing for Hearing Loss in the USA

Richard Smith¹, Amanda Odell², Kevin T Booth³, Diana Kolbe², Thomas Casavant⁴, Brian Hong⁴, Michael J. Schnieders⁴, Terry Braun⁴, Hela Azaiez⁴, Hela Azaiez*⁵

¹*The University of Iowa Hospitals and Clinics*, ²*The University of Iowa Hospitals and Clinics, Molecular Otolaryngology and Renal Laboratories*, ³*Harvard Medical School*, ⁴*The University of Iowa*, ⁵*Indiana University*

Individual Abstract: Genetic testing has become an essential diagnostic tool in the USA in the evaluation of deaf and hard-of-hearing individuals. It delivers actionable information for prognosis, family counseling, and management, but it also exposes persistent technical and interpretive challenges. Disease-specific variant curation and multidisciplinary review substantially enhance diagnostic yield by prioritizing clinically relevant variants and recovering pathogenic or likely pathogenic variants that automated pipelines may filter out.

Systematic aggregation of deafness-associated variation through a large-scale genetic testing program involving more than 8000 individuals and resources like the Deafness Variation Database (DVD) reveal striking heterogeneity in mutational architectures across genes and protein domains rather than a uniform genome-wide pattern of constraint. Notably, genes such as GJB2 and SLC26A4 demonstrate high coding-region variant rates accompanied by a disproportionate fraction of pathogenic variants, a pattern that challenges the reliability of generic population constraint metrics and highlights the need for disease- and gene-specific variant interpretation frameworks.

Many hearing-related proteins have structurally and functionally distinct regions, and as such, domain-level analysis provides critical refinement for variant interpretation. Pathogenicity often depends on variant position, transcript context, and whether truncating alleles escape nonsense-mediated decay. Notable examples including DIAPH1 and COL11A1 illustrate how identical variant classes may produce distinct phenotypes or modes of inheritance depending on their location and functional impact. Furthermore, variant-type distribution differs substantially by gene. These gene-specific mutational signatures complicate automated pathogenicity prediction, inflate the proportion of variants of uncertain significance (VUS), and demand improved computational tools and targeted functional assays for accurate reclassification.

Integrating large-scale genomic data from patient cohorts into variant curation frameworks improves diagnostic accuracy, reduces VUSs, and refines genotype–phenotype correlations. Operational practices to improve outcomes include incorporation of deafness-specific databases like the DVD into annotation pipelines, routine multidisciplinary genomic case review to integrate phenotype with genotype, and retention of low-quality or ambiguously mapped variants for expert reassessment rather than automatic exclusion. Such practices reduce false negatives, clarify gene-phenotype relationships, and guide appropriate follow-up testing or referral for gene-targeted therapies.

Persistent gaps remain: the noncoding and regulatory landscape of deafness is under characterized, functional validation of many recurrent missense VUSs is lacking, and national harmonization of reporting standards and data-sharing infrastructures is limited. Addressing these gaps will require continued investment in curated databases, coordinated efforts to fund functional studies, standardized clinical reporting, expanded disease-based reference resources, and the development of domain- and transcript-aware pathogenicity models. Coupled with clinician education, accessible genetic counseling, and integration into newborn

hearing screening pathways, these strategies will greatly improve outcomes for individuals with hearing loss.

Genetic Architecture of Deafness in Mainland China Revealed From a Nationwide Genetic Cohort Study Involving 22,125 Cases

Huijun Yuan^{*1}, Jing Cheng², Yu Lu², Mingjun Zhong², Jia Geng², Fandi Ai², Gen Zhang², Fengxiao Bu²

¹*West China Hospital*, ²*Institute of Rare Diseases, West China Hospital of Sichuan University*

Individual Abstract: Over the past decade, the Chinese Deafness Genetics Consortium (CDGC) has conducted a nationwide genetic cohort study encompassing 22,125 individuals with hearing loss. In this cross-sectional study, participants were recruited from 91 special-education schools, 89 rehabilitation centers for deaf children, and 34 hospitals, covering 94.3 % of prefecture-level regions and 41 ethnic groups across mainland China. A three-stage genetic-testing strategy was implemented and enhanced by the Framework of Iterative Analysis (FIA) and the Recessive Genotype Network (RGnet) to improve variant interpretation. This nationwide effort linked detailed clinical phenotypes with comprehensive genomic data, enabling population-scale dissection of the genetic architecture of hereditary deafness.

Among the 22,125 individuals with complete analysis, most were affected by early-onset (96.0 %), severe/profound (94.7 %), and nonsyndromic (98.8 %) deafness. A molecular diagnosis was achieved in 50.1 %, implicating 110 deafness-associated genes. Notably, 96.6 % of diagnoses were attributable to 61 of 79 genes identified before 2005, whereas 49 of 122 genes discovered between 2005 and 2021 accounted for only 3.4 %. Among early-onset severe/profound cases (n = 19,062), the diagnostic yield reached 50.6 %, compared with 30.6 % in late-onset cases. GJB2 was the most frequently implicated gene (40.7 %) and, together with SLC26A4, accounted for 69.3 % of all diagnoses. The top ten genes (GJB2, SLC26A4, MYO15A, MT-RNR1, MYO7A, MITF, CDH23, TMC1, SOX10, and OTOF) represented 88.4 % of all genetic diagnoses, with marked regional variation (e.g., SLC26A4 in Guangxi, MYO15A in Fujian, MT-RNR1 in Qinghai).

Within the cohort, 111 individuals carried biallelic pathogenic or likely pathogenic variants in OTOF, corresponding to a 0.54 % positivity rate in the total cohort and 1.11 % among genetically diagnosed cases. The most recurrent variants were NM_001287489.1:c.5975A > G, c.2977_2978del, and c.2215-1G > C. The overall genetic contribution to early-onset severe/profound deafness was estimated at 67.7 %. Outcome data from cochlear-implant recipients linked to 80 deafness genes further informed genotype-based surgical counseling.

To refine interpretive accuracy, the RGnet and FIA frameworks together improved diagnostic yield by 7.6 % through cohort-informed variant interpretation. A distinct latitudinal gradient and a high population burden of GJB2 p.V37I were observed, showing quantitative association with severe/profound hearing loss. The prevalence of mitochondrial MT-RNR1 variants (m.1555A > G and m.1494C > T) declined markedly across successive birth cohorts, in parallel with national aminoglycoside-stewardship policies.

Collectively, this nationwide, data-driven effort delineates the comprehensive genetic landscape of deafness in China, establishes scalable analytic frameworks for variant interpretation, and illustrates how large-scale collaboration can transform Mendelian-disease research into a continuously learning healthcare system.

Advancing Genetic Testing for Hearing Loss in Puerto Rico: Addressing Systemic Barriers and Building a Path Toward Equitable Genomic-Based Care

Elinette Albino¹

¹Universidad De Puerto Rico

Individual Abstract: Genetic testing has transformed the diagnostic landscape for childhood hearing loss, enabling earlier identification of etiologies, more precise clinical management, and improved genetic counseling. However, despite the existence of a robust Newborn Hearing Screening Program, access to genetic testing in Puerto Rico remains limited, and the integration of genomic tools into routine clinical care is inconsistent. This presentation will describe the current state of genetic testing for hearing loss on the island, drawing on data from ongoing research initiatives and community partnerships, and will highlight the systemic barriers that hinder equitable access to testing and clinical genetics services.

Puerto Rico faces several entrenched obstacles that restrict the implementation of evidence-based genetic evaluations. These include scarcity of on-island clinical genetics providers, long wait times for evaluations (often exceeding 6–12 months), fragmented referral pathways, limited insurance coverage for molecular testing, and non-existing local clinical laboratory capacity for next-generation sequencing. Geographic disparities, socioeconomic constraints, and the lack of a centralized registry further contribute to unequal access across regions. Families frequently report diagnostic odysseys that span years, leading to delayed interventions and missed opportunities for targeted care. These challenges disproportionately affect Deaf and Hard of Hearing children from underserved communities, amplifying health inequities in a population already underrepresented in genomic research.

Our ongoing project, Genetics and Audiological Profiles of Hearing Loss in Puerto Rico, aims to bridge these gaps by integrating exome and genome sequencing with comprehensive audiological and vestibular assessments. Through partnerships with NIDCD, local audiology clinics, and community organizations, we are developing a population-specific genomic reference framework for Puerto Rican individuals. Preliminary findings highlight the presence of potentially novel or rare variants not well represented in existing databases, underscoring the importance of studying genetically admixed populations such as Puerto Ricans. Community engagement, particularly with Deaf and Hard of Hearing families, has also revealed pressing needs related to genetic literacy, culturally appropriate counseling, and clarity about the implications of genomic results.

Together, these efforts demonstrate the urgent need for systemic improvements in clinical genetics infrastructure, insurance coverage, provider training, and patient-centered communication strategies. Expanding access to molecular diagnostics in Puerto Rico will require multisector collaboration and sustained investment, but the potential impact on early detection, family planning, and targeted therapeutics is profound.

This presentation will situate Puerto Rico within global genomic initiatives and illustrate how population-specific data, community partnerships, and equitable implementation strategies can advance hearing-loss genomics in historically underserved populations.

Introducing HearGene Connect, a Nationwide Registry and Natural History Protocol to Correlate Genetic Variants With Phenotypic Outcomes and Therapeutic Eligibility

Isabelle Roux^{*1}, C. Brewer¹, K. Abbey¹, G.L. Poling¹, H. Azaiez¹, J. Sapp¹, R. Faridi¹, S. Haines¹, M. Hoa¹, W. Chien¹, N.M. Biassou¹, O. Shchelochkov¹, W. Zein¹, T.B. Friedman¹, A. Mahurkar¹, R. Hertzano¹

¹*NIDCD/NIH*

Individual Abstract: Genetic testing for hearing loss offers clear clinical benefits, including early identification of syndromic forms and eligibility for precision therapies. The recent success of OTOF gene therapy trials and the resultant indirect delay in cochlear implantation in some cases, underscores the importance of timely genetic diagnosis. However, access to genetic testing remains limited due to the need to travel to specialized centers, long wait times for geneticist appointments, and variable insurance coverage. Given the extreme genetic heterogeneity of hearing loss, there is a critical need for a large, nationwide natural history study to define genotype–phenotype correlations, enable collaborations worldwide to improve rare variant classification and genetic diagnosis, and leverage these insights to improve clinical outcomes. The HearGene Connect Registry and Natural History Protocol is designed to collect genetic and phenotypic data over many years from 10,000 individuals with hearing loss and their close family members from all over the United States and its territories. Individuals of any age are eligible to participate if they experienced hearing loss before the age of eight years. Participants will be asked to share health and audiological information via questionnaires, upload available audiograms and provide access to their temporal bone images. When a genetic diagnosis is available, variant pathogenicity will be confirmed based on current knowledge and integrated into the registry. If the etiology is unknown, biospecimens will be collected for genetic analysis. Genetic test results will be shared with participants through an educational session and written clinical reports. Certified genetic counselors will be available to answer questions. Participants will be re-contacted annually to update health and hearing information, enabling longitudinal analyses.

Collected data will be used to develop gene- and variant-specific phenotype profiles, that together with educational material will help participants better understand their hearing loss. Participants will also receive information on relevant FDA-approved interventions (e.g., cochlear implantation) and potential eligibility for emerging clinical trials, supporting their informed and timely choices on therapeutic interventions. Deidentified genotype–phenotype data will be made available in an open-access platform, enabling clinicians and genetic counselors to provide evidence-based prognostic guidance and care recommendations, and supporting researchers and industry partners in designing future clinical trials and therapies. HearGene Connect gnomAD will provide participant aggregated genomic data to facilitate global collaborations, variant classification, and reverse phenotyping. As HearGene Connect expands, summary statistics and gene- or variant-level information will be publicly shared to deepen understanding of hearing loss in the United States population. These resources will empower participants with greater knowledge of their diagnosis, prognosis, and therapeutic options; and offer them opportunities to engage in future research and treatment studies. They will also assist clinicians in counseling and management; and enable discovery of new gene–phenotype relationships.

Poster Session I With Coffee

1:00 p.m. - 2:30 p.m.

Ballroom A, Floor 3

Due to the policies of the Puerto Rico Convention Center, the Poster Hall will be available to attendees between the hours of 7AM – 11PM (local time), with a 1- hour break every day between 11AM and 12 PM (Noon) to facilitate setup for the next poster session. This is an appreciated extension of their normal permitted hours. ePosters are available on the conference website and the ARO MWM mobile app.

SA1. Immune Response in the Human Macula Utricle and Sacculle After Cochlear Implantation

Ji Eun Choi¹, Shinya Ohira², Ivan Lopez³, Gail Ishiyama³, Akira Ishiyama³

¹*Dankook University*, ²*St. Marianna University School of Medicine*, ³*David Geffen School of Medicine at UCLA*

Background: An inflammatory foreign body response has been proposed to mediate the development of fibrosis and new bone formation following cochlear implantation (CI). Prior human temporal bone studies have demonstrated an increase in macrophage presence in the cochlea following CI but few prior studies have evaluated these factors in the vestibular system. Fibrosis in the vestibular system following CI has been proposed to mediate hydrops formation associated with vertigo. This study investigates the immune response in human macula utricle and sacculle following CI in the human temporal bone.

Methods: Archival human temporal bones from six patients with a history of CI, and the non-implanted contralateral side (Age range 65-92), and 3 normal controls with normal hearing (Age 26, 38, 50 years old) were studied. Celloidin sections containing the macula utricle and sacculle underwent immunofluorescence (IF) using antibodies against the following macrophage markers: Iba1, CD68, CD163, and CD206. Colocalization of the macrophage markers was achieved using laser confocal microscopy.

Results: The maculae sacculle and utricle of the CI implanted side showed an abundant presence of Iba1-IF and CD163-IF cells. A less abundant presence of CD68-IF and CD206-IF macrophages was demonstrated. Iba1-IF cells and CD163-IF cells were present in the stromal tissue underneath the vestibular epithelium and in the basal sensory epithelium. CD68-IF and CD206-IF cells were present predominantly in the stromal tissue. In the contralateral non-CI cochlea and controls, there was a minimum presence of cells expressing any of the macrophage markers.

Conclusions: There was an abundance of macrophages in the human macula sacculle and utricle in the implanted side but not in the contralateral non-implanted side nor in the normal hearing controls. This supports the presence of inflammatory and anti-inflammatory processes in the vestibular system similar to the processes we have previously demonstrated in the cochlea following cochlear implantation.

SA2. The Mechanism Analysis on Cochlear Supporting Cell Activation in Response to Viral Infection Using RNA Sequencing

Yushi Hayashi*¹

¹*Nippon Medical School*

Background: Sudden sensorineural hearing loss (SSNHL) is a relatively frequent otologic disorder observed worldwide, characterized by acute unilateral sensorineural hearing loss. Viral infection has been proposed as one possible etiology; however, the underlying mechanisms remain unclear, and therefore no fundamental treatment has yet been established. We previously reported that cochlear supporting cells (SCs) are key components of immune responses to viral infection in the organ of Corti. In the early phase of infection, SCs protect cochlear hair cells (HCs) by secreting type I interferons (IFNs) via the retinoic acid-inducible gene I (RIG-I)-like receptor (RLR) signaling pathway. In the late phase, however, SCs promote HC necroptosis by secreting TNF-related apoptosis-inducing ligand (TRAIL). Intriguingly, SCs also express F4/80, a canonical macrophage marker, highlighting their unexpected immune-like properties. Given their role as glial-like cells, the response of SCs can be considered a form of glial activation; however, SCs are of ectodermal origin, unlike microglia, which are mesoderm-derived. In this project, we focus on elucidating the mechanisms that confer immune functions on these ectoderm-derived SCs.

Methods: 1. Organs of Corti were dissected from Ms4a3-Cre;tdTomato mice at postnatal day 2 (P2), in which monocyte-derived macrophages are labeled with tdTomato, for histological analysis.

2. Organs of Corti were dissected from CD1 mice at P2 for tissue culture. After overnight incubation, tissues were infected with Theiler's murine encephalomyelitis virus (TMEV) at 3.0×10^7 pfu/ml. At designated time points, virus-infected and mock-treated organs of Corti were dissociated, stained for F4/80, and subjected to FACS sorting. F4/80-positive cells were collected from each group for RNA sequencing.

Results: 1. No tdTomato-positive cells were detected among SCs or within the SC region, indicating that SCs are of ectodermal origin and do not include monocyte-derived macrophages.

2. Compared with mock-treated organs of Corti, TMEV-infected organs of Corti contained significantly more F4/80-positive cells. Because this experimental system is *ex vivo*—where systemic macrophages cannot infiltrate the organ of Corti as they would in *vivo*—this finding supports the notion that SCs themselves upregulate F4/80 expression in response to viral infection. RNA sequencing further revealed activation of signaling pathways potentially regulating this mechanism.

Conclusions: We previously demonstrated that SCs exerting immune functions express F4/80 in virus-infected organs of Corti, as shown by immunostaining. Experiments with Ms4a3-Cre;tdTomato mice confirmed that this cell population does not include monocyte-derived macrophages. In addition, FACS analysis revealed a significant increase in F4/80-positive cells, directly reflecting SC upregulation of F4/80 in response to viral infection. We are currently conducting inhibitor assays to pharmacologically disrupt the signaling pathways identified by RNA sequencing.

SA3. Age-Related Hearing Loss and Inflammatory Profile in the Human Aged Cochlea

Maria Luque*¹, Rudolf Glueckert¹, Marta Konopka¹, Pedram Ghaderi¹, Erich Brenner¹, Marko Kenschake¹, Elisabeth Pechriggl¹

¹*Medical University Innsbruck*

Background: Age-related hearing loss (ARHL) is among the most prevalent manifestations of ageing. According to the World Health Organization, hearing loss affects ~30% of individuals over 60 years, and by 2050 one in ten people is projected to suffer from disabling hearing loss. Beyond communication impairment, ARHL accelerates cognitive decline and imposes a substantial burden on healthcare systems. Chronic low-grade inflammation, commonly referred to as “inflammaging,” has emerged as a key contributor to sensorineural hearing loss alongside environmental insults such as noise exposure. A potential player in this process may be the nucleotide-binding domain, leucine-rich repeat, and pyrin domain-containing protein 3 (NLRP3) inflammasome, a cytosolic multiprotein complex that mediates the release of pro-inflammatory cytokines, including IL-1 β and IL-18. NLRP3 activation has been implicated in neurodegenerative and cardiovascular diseases, and recent evidence links it to auditory dysfunction.

This study investigates age-related inflammatory responses in rodent models of hearing loss and human cochlear tissue, with a focus on NLRP3 inflammasome activation and its correlation with auditory decline.

Methods: Immunohistochemistry was employed to examine immune activation and inflammatory markers in rodent cochleae of different ages. These findings were systematically compared with human cochlear specimens from elderly donors. Quantitative analyses assessed microglial activation, macrophage distribution, and their association with auditory brainstem response (ABR) thresholds in rodents and spiral ganglion neuron (SGN) integrity in humans.

Results: Inflammatory activity increased with age in both rodent and human cochleae. Microglial activation patterns showed a significant correlation with ABR thresholds in rodents, while in human samples macrophage distribution was closely associated with SGN degeneration. These findings indicate a conserved age-dependent inflammatory phenotype across species.

Conclusions: Characterizing the role of inflammation in cochlear ageing advances our understanding of ARHL pathophysiology. Elucidating NLRP3-mediated mechanisms may reveal novel therapeutic targets to mitigate auditory decline and its broader neurocognitive consequences in ageing populations.

SA4. Classical Complement Pathway Activation and C3 Opsonization of Inner Hair Cell Ribbon Synapses Following Noise-Induced Cochlear Synaptopathy

Shriti Thakur*¹, Dinesh Gawande¹, Emma Nicolaisen¹, Kanika Sharma², Vikas Kumar², Tejbeer Kaur¹

¹*Rutgers University*, ²*University of Nebraska Medical Center*

Background: Noise-induced cochlear synaptopathy (NICS) refers to the rapid and primary loss of inner hair cell (IHC) ribbon synapses following exposure to mild to moderate noise, which can occur without immediate hair cell loss or elevation on hearing thresholds. Such

synaptic loss contributes to deficits in auditory acuity, particularly in noisy environments, and may be associated with perceptual disorders like tinnitus and hyperacusis and cognitive decline. Our recent work suggested the critical role of macrophages, the innate immune cells, in facilitating the restoration of IHC ribbon synapses following NICS. To determine the factors that regulate macrophage-dependent synaptic repair, proteomics and functional enrichment analysis after NICS was performed, which revealed an upregulation of classical complement protein, C1q implicated in CNS synapse remodeling. The goal of this study was to validate the proteomics data and determine the expression, activation, source, and localization of complement proteins C1q and downstream C3 in the cochlea after noise-induced synaptopathy.

Methods: C57BL/6J mice at 5-6 weeks of age were exposed for 2 hours to a synaptopathic noise level of 93 dB SPL at an octave band of 8-16 kHz. Age-matched sham-exposed mice served as controls. C1q and C3 expression, activation, and localization in the cochlea were examined by immunoblotting, enzyme-linked immunosorbent assay (ELISA), and fluorescent immunohistochemistry, respectively, at 1-, 3-, 7-, and 15-days post-noise exposure (DPNE). The immunolabeled cochlear tissues were imaged using Zeiss LSM confocal laser and Airy scan microscopy.

Results: Complement protein C3 activity increased in the cochlea by 1 DPNE (9.9 %), peaked at 3 DPNE (60.3%) and started to decrease by 7 DPNE (33.5 %) and 15 DPNE (27.6 %) as measured by ELISA. Whereas immunoblotting for C1q and C3 showed no significant difference in their protein expression at any recovery period after noise exposure. At 1 DPNE, C3 immunolabeling showed increased fluorescent intensity (~2 fold) in the sensory epithelium of the middle region of the cochlea when compared to the sham-exposed ears. Super-resolution Airyscan imaging further demonstrated that accumulated C3 opsonizes the noise-damaged IHC ribbon synapses. In addition, macrophages displayed immunoreactivity for the complement receptor, CR3, and the phagocytic marker, CD68, in the synaptopathic noise-damaged cochlea. Lastly, in comparison to the presence of macrophages, the C3 protein levels were persistently elevated in the absence of macrophages in the sham- and noise-damaged cochlea.

Conclusions: These preliminary findings implicate classical complement pathway activation and C3 opsonization of IHC synapses in NICS, and that macrophages regulate C3 levels in the damaged cochlea. Future studies will determine the source of C3, macrophage engulfment of complement-tagged synapses, and the obligatory roles for C1q, C3, and CR3 in macrophage-dependent ribbon synaptic repair after NICS.

SA5. Glucocorticoid Receptor Beta Expression as a Marker of Steroid Resistance in Autoimmune Inner Ear Disease

Vijay Deopersaud*¹, Shresh Pathak², Andrea Vambutas²

¹Donald and Barbara Zucker School of Medicine at Hofstra/Northwell, ²Northwell Health

Background: Autoimmune inner ear disease (AIED) is a form of sensorineural hearing loss that is characterized by either fluctuation or worsening hearing loss in either one or both ears. The first line of treatment for AIED is high-dose corticosteroids. While 70% of initially respond, many lose responsiveness over time. Steroids are the mainstay of treatments as previous trials of other immunosuppressants, such as methotrexate and TNF-alpha inhibitors, have not shown significant benefit. Patients who fail to respond to corticosteroids express high levels of IL-1 β (Pathak et al 2011), and an early-stage clinical trial shows that anakinra, a recombinant IL-1 receptor antagonist, improves hearing capabilities in 46-70% of

corticosteroid-resistant AIED patients (Vambutas et al 2014, Vambutas et al, 2025). The mechanism(s) underlying this steroid resistance remain poorly understood. Evidence from other steroid-resistant inflammatory diseases such as asthma and ulcerative colitis suggests the involvement of glucocorticoid receptor beta (GR- β). Glucocorticoid receptor alpha (GR- α) is the active glucocorticoid receptor isoform that mediates anti-inflammatory effects, while GR- β is a splice variant that does not bind glucocorticoids and inhibits GR- α 's transcriptional activity, contributing to steroid resistance. The role of GR- β has not been studied in AIED.

Methods: We examined the relative mRNA expression and protein levels of GR- β and GR- α in peripheral blood mononuclear cells (PBMCs) of patients with AIED using qRT-PCR and Western blot, and investigated how these levels change following treatment with dexamethasone and anakinra under inflammatory conditions.

Results: In PBMCs from corticosteroid-resistant AIED patients, the relative expression of GR- β appears to increase with dexamethasone treatment when co-stimulated with LPS, while treating with anakinra and LPS reduces GR- β expression. Furthermore, this change was also reflected when assessing intracellular GR- β protein with Western blotting.

Conclusions: Characterizing the role of GR- β expression can deepen our understanding of steroid resistance in AIED patients and better predict who may respond to steroids. Further studies are underway to characterize the effect of interleukin-1 expression on GR- β .

SA6. Distinguishing Neurons in the Central Nucleus and Cortex of the Inferior Colliculus by Multiparametric Classification of Pure-Tone Responses

Jongwon Lee^{*1}, Maryanna Owoc¹, Adriana Johnson¹, Karl Kandler¹, Srivatsun Sadagopan¹

¹*University of Pittsburgh*

Background: The inferior colliculus (IC) is a central hub of auditory processing in the midbrain, integrating ascending and descending inputs arising from the auditory pathway as well as non-auditory information originating from other brain centers. These inputs target distinct subdivisions of the IC. Ascending inputs primarily innervate neurons in the central nucleus of IC (CNIC), whereas descending and multimodal inputs target the cortex of the IC (CtxIC). This differential innervation pattern suggests that the functions of these subdivisions will also be fundamentally distinct. However, the response properties of single neurons from these subdivisions to auditory stimuli are largely similar, and while some tuning differences have been reported, classifying IC subunits based on these differences has remained challenging. In this study, we examined whether neurons could be reliably localized to the CNIC and CtxIC using only response properties in both awake and isoflurane-anesthetized mice.

Methods: We used pure-tone responses to construct the frequency response areas of neurons localized to known IC subdivisions, and extracted tuning parameters (e.g., threshold, bandwidth, etc.) as well as response features (e.g., spontaneous rate and driven rate).

Results: Individual features failed to discriminate neurons from CNIC and CtxIC in awake or anesthetized states ($d' < 1$). However, a machine learning classifier (random forest) using a combination of the features could localize neurons to the CNIC or CtxIC at the highest accuracy ($d' > 1$).

Conclusions: These results demonstrate that CNIC and CtxIC responses differ subtly along multiple parameters, and combining these differences using appropriate multi-parametric

analytical techniques is necessary to effectively classify and localize single-neuron recordings to different IC subunits in awake or anesthetized in vivo studies.

SA7. The Influence of Ascending T-Stellate Projections on Sound Responses in the Auditory Midbrain

Yoani Herrera*¹, Michael Roberts¹

¹*University of Michigan*

Background: The inferior colliculus (IC) is a critical hub of computation in the central auditory pathway. Nearly all ascending projections from the auditory brainstem converge at the IC, and the IC is crucial for many aspects of sound processing. One major source of ascending input from the lower brainstem to the IC comes from T-stellate neurons in the ventral cochlear nucleus (VCN). T-stellate neurons encode information about sound frequency and intensity, including rapid fluctuations in sound intensity that are important for speech processing. T-stellates also represent the only class of neurons within the VCN that provide direct input to the IC, but how that input contributes to sound processing in the IC in vivo remains largely unknown. Recent work in our lab revealed that T-stellate input onto IC neurons undergoes short-term synaptic plasticity in vitro. Thus, we hypothesize that inhibiting T-stellate input to the IC reduces the frequency and amplitude modulation selectivity of many IC neurons, while also reducing the adaptation of IC neuron firing during ongoing sounds.

Methods: Using multi-channel silicon probe recordings and optogenetic techniques, we are investigating how silencing T-stellate input to the IC influences how IC neurons respond to sounds in awake, head-fixed mice. To specifically and reversibly inhibit T-stellate projections, we inject an adeno-associated virus encoding the inhibitory opsin eOPN3 into the VCN of mice. Two to six weeks later, we use a 32-channel probe with an integrated optical fiber to record neuronal spiking in the IC while locally delivering light on alternating trials to selectively activate eOPN3 in T-stellate synapses. During recordings, we are examining responses to tone bursts and sinusoidally amplitude modulated noise and tones to determine how the frequency tuning and amplitude modulation selectivity of IC units changes between control conditions and when local T-stellate input is inhibited. We are also comparing the spike-frequency adaptation that occurs during tone bursts between control and light-on conditions.

Results: We have optimized the surgical preparation and virus injections. We are now collecting data to determine how IC neuron responses change between control conditions and when T-stellate inputs are optogenetically inhibited.

Conclusions: The expected results of this study will provide insights on how T-stellate input contributes to frequency tuning, amplitude modulation selectivity, and adaptation in the IC.

SA8. Sex- And Etiology-Specific Effects on Predictive Processing in the Inferior Colliculus of Two Rat Models of Autism

S Cacciato-Salcedo*¹, AB Lao-Rodríguez¹, MS Malmierca¹

¹*Cognitive and Auditory Neuroscience Laboratory (CANELAB), Institute of Neuroscience of Castilla y León (INCYL), University of Salamanca, Spain*

Background: Atypical sensory processing is a core feature of autism, manifesting in a context-dependent manner that becomes more pronounced as environmental complexity increases. Predictive coding theory provides a unifying framework for these sensory differences and their heterogeneity across sex and etiology. According to this account, mental models of the environment, which typically anticipate incoming sensory stimuli and support efficient brain function, diverge in autism, resulting in less flexible models that struggle to accommodate changing and dynamic situations.

Predictive processes operate within the brain's hierarchical architecture, where higher- and lower-order regions interact in a feedback loop: top-down predictions are generated, and bottom-up prediction errors signal mismatches between mental models and the environment. The neural mechanisms underlying these divergences at the subcortical level, as well as their modulation by sex and etiological origin, remain poorly understood.

Methods: We investigated spontaneous activity and contextual auditory processing at the single-neuron level in the inferior colliculus, a midbrain hub that serves as an early site for contextual sound encoding. Using two rat models of autism—one carrying a heterozygous deletion of *GRIN2B* and another prenatally exposed to valproic acid, representing genetic and environmental etiologies—we recorded auditory responses from lemniscal and non-lemniscal subdivisions during oddball and cascade paradigms that dissociate adaptation from deviance detection.

From these responses, we derived three indices of predictive processing: repetition suppression, reflecting neural adaptation to repetitive stimulation; prediction error, the response to violations of established regularities that drive mental model updating; and neuronal mismatch, which integrates both adaptation and deviance detection to capture the overall mismatch response.

Results: Both autism-like models exhibited disrupted spontaneous firing and predictive processing in a sex- and region-specific manner, with the non-lemniscal inferior colliculus emerging as the primary locus of dysfunction. Males across autism-like models displayed reduced repetition suppression and attenuated mismatch responses, whereas females showed enhanced suppression and elevated mismatch signals relative to controls.

Conclusions: These findings identify convergent yet sex-dependent disruptions in subcortical predictive coding across distinct autism etiologies and establish a framework for exploring sensory heterogeneity in neurodevelopmental disorders.

This work was supported by MICIU/AEI (PID2023-148541OB-I00), the Junta de Castilla y León (SA218P23), the Regional Government of Castile and León/ERDF (CLU-2023-1-01) awarded to M.S.M., and a Spanish Ministry of Science and Universities fellowship (FPU2021/00124) to S.C.S. The funders had no role in the study.

SA9. Identifying Key Characteristics of Two New Neuron Types in the Inferior Colliculus

Elie Huez^{*1}, Lila Urogy¹, Michael Roberts¹

¹*University of Michigan, Kresge Hearing Research Institute*

Background: Uncovering how individual neurons contribute to circuit-level computations relies heavily on our ability to distinguish and selectively manipulate individual neuron types. The inferior colliculus (IC), the neuron-dense midbrain hub of the central auditory pathway, poses challenges in this regard, making it difficult to distinguish the roles of individual

neurons in auditory computations. However, recent advances have enabled the identification of subpopulations of IC neurons using molecular markers such as vasoactive intestinal peptide (VIP) and neuropeptide Y (NPY). Here, we report the discovery of two novel molecular markers, secreted phosphoprotein 1 (SPP1) and prodynorphin (PDYN). We have identified fundamental physiological, anatomical and morphological features of SPP1 and PDYN IC neuron types.

Methods: To characterize the intrinsic physiological properties of PDYN and SPP1 neurons, we used *Pdyn-IRES-Cre* and *Spp1-IRES-Cre* mice crossed with an *Ai14* reporter line to perform whole-cell patch clamp recordings in brain slices targeted to each neuron type. To determine the anatomical distributions of PDYN and SPP1 neurons in IC, we conducted fluorescent in situ hybridization (FISH) on IC sections from C57BL/6J and B6.CAST-Cdh23Ahl⁺ mice. To uncover morphological patterns in PDYN and SPP1 neurons, we crossed their respective Cre lines with MORF3 mice that sparsely label Cre-expressing cells with a multi-V5-epitope reporter protein. We extracted the IC and conducted whole tissue clearing, immunolabeling, light-sheet microscopy, and 3-D anatomical reconstructions of individual somas, dendrites, and axons.

Results: We find that *Pdyn* mRNA labels a population of excitatory neurons that are distinct from previously identified IC markers and that *Pdyn*⁺ neurons are present throughout the major subdivisions but are at higher densities in the IC dorsal cortex. Furthermore, our findings suggest that *Spp1* mRNA labels two populations of IC neurons: excitatory neurons that are distinct from previously identified excitatory neuron types, and inhibitory neurons. Using whole-cell patch clamp recordings we find that PDYN neurons have consistent intrinsic physiological properties, including sustained firing patterns in response to current steps while SPP1 neurons exhibit both sustained and adapting firing patterns in response to current steps, suggesting two subtypes that we hypothesize correlate with the excitatory and inhibitory subtypes of SPP1 neurons. Using sparse labeling and light-sheet microscopy, we are generating high-throughput 3-D reconstructions of SPP1 and PDYN neurons in the intact IC to identify patterns in their dendritic shape, soma location, and axonal projections.

Conclusions: Our findings suggest that SPP1 and PDYN are strong candidates for markers of novel IC neuron populations that do not overlap with previously identified markers for IC neurons. We also developed a high-throughput approach to investigate the 3-D morphology and axonal projections of molecularly defined IC neuron types utilizing whole IC tissue clearing and light-sheet microscopy. We are currently using quantitative methods to determine the axonal projection tendencies of each neuron type.

SA10. Pupil-Linked Modulation of Noise Correlations and Auditory Information Coding in the Inferior Colliculus

Kunpeng Yu^{*1}, Hemant Kumar Srivastava¹, Hong Jiang¹, Jay Alan Hennig¹, David Lipshutz¹, Matthew McGinley¹

¹*Baylor College of Medicine*

Background: Neuromodulatory brain state, indexed by pupil size, strongly shapes sound-evoked responses in the auditory thalamus and cortex (McGinley et al., 2015). In particular, response gain tends to exhibit an inverted-U relationship with pupil size on average. Yet it is still uncertain at which levels of the auditory pathway state-dependent modulatory signals shape sensory processing, and how they affect encoding of auditory information in earlier structures like the midbrain.

Methods: To address this, we assessed how brain state influences sensory processing in the inferior colliculus (IC) by simultaneously measuring pupil size and neural activity in head-fixed, awake mice. Using Neuropixels probes, we recorded central IC (ICC) responses to pure tones across 17 sessions in 10 animals. Computational analyses included pairwise noise correlations within and between neuronal subpopulations, stimulus decoding at both pairwise and population levels with decorrelation procedures to evaluate how noise correlations shape information coding. As a parallel control, we also implemented a pseudo-pupil size analysis to test whether the observed effects truly reflected state dependency.

Results: Our analyses revealed pronounced state dependence in ICC activity. At the population level, response gain exhibited an inverted-U pattern. In addition, we identified distinct neuronal subpopulations: while the largest group showed the inverted-U profile, others displayed either monotonically decreasing or monotonically increasing activity with arousal. Extending beyond response gain, we investigated how arousal-dependent modulation shapes population coding and influences auditory information represented in IC activity. We first measured decoding accuracy across pupil-defined states and observed systematic differences in discriminability that varied both with state and across neuronal subpopulations exhibiting distinct pupil-linked modulation patterns. Given these state-dependent changes in decoding, we further analyzed how brain state influences the magnitude and pattern of noise correlations, both within and across neuronal subpopulations. In addition, we examined the extent to which these correlations could enhance or limit the information available in the population, and how this impact is shaped by state-dependent modulation.

Conclusions: Our current results highlight the IC as an early auditory stage where brain state modulates response gain and population-level coding, and that noise correlation is state dependent. Ongoing analyses will determine how state-dependent noise correlations among IC neurons contribute to the representation of sensory information.

SA11. Expression of Mitochondrial Calcium-Regulatory Genes in Cochlear Aging

Mayakannan Manikandan¹, Ramkumar Katturajan², Mark Frilling¹, Niranj Kumar¹, Audrey Freedman¹, Ruben Stepanyan*¹

¹Case Western Reserve University, University Hospitals Cleveland Medical Center, ²Indiana University School of Medicine

Background: Age-related hearing loss (ARHL) contributes to social isolation, reduced independence, anxiety, depression, cognitive decline, and increasing healthcare costs. The condition is primarily associated with degeneration and death of mitochondria-rich cochlear cells, including hair cells, spiral ganglion neurons, and cells of the stria vascularis. Although extensively studied, the exact molecular mechanisms underlying cochlear aging and cell death remain poorly defined. Evidence suggests that programmed changes in gene expression, cumulative environmental insults, e.g., noise, ototoxins, as well as genetic predisposition all contribute to ARHL. Our previous findings indicate that dysregulated mitochondrial calcium homeostasis accelerates ARHL progression. We hypothesize that age-dependent alterations in the expression of mitochondrial calcium-regulatory genes impair energy metabolism, promoting cochlear cell loss and hearing decline. To test this hypothesis,

we examined age-related expression dynamics of genes involved in mitochondrial calcium and energy metabolism, such as *Mcu*, *Micu1*, *Micu2*, *Mcur1*, *Emre*, and *Mcub*, in cochlear tissue from FVB/NJ mice at multiple points across the aging timeline.

Methods: Gene expression was quantified using real-time quantitative PCR (RT-qPCR). Cochlear tissues were collected from FVB/NJ mice at 1, 6, 9, and 12 months of age. Total RNA was isolated with the Qiagen RNeasy kit and reverse-transcribed to cDNA using the qScript™ cDNA synthesis kit. Gene-specific primers and PowerUp™ SYBR™ Green Master Mix were used for amplification, and Ct values were analyzed. Data quality control was performed with DataAssist™, while fold changes were calculated using the $2^{-\Delta\Delta C_t}$ method in Microsoft Excel. Statistical analyses were conducted with GraphPad Prism 10. To validate differentially expressed candidates, results were compared with previously reported single-cell RNA sequencing (scRNA-seq) datasets exhibiting hair-cell degeneration.

Results: Of the 30 genes examined, several, including *Otof*, *Cav1*, *Gjb2*, *Mcub*, and *Serca2*, displayed significant expression changes associated with hair-cell degeneration in both mouse cochlear tissues and human utricle dataset. Interestingly, *Cdh23* expression was significantly elevated in RT-qPCR data but remained unchanged in the scRNA-seq dataset. *Micu1* and *Micu2* were upregulated in the supporting cell cluster in the scRNA-seq dataset but not in the hair-cell cluster or mouse RT-qPCR results.

Conclusions: Age-related alterations in cochlear gene expression may disrupt mitochondrial calcium homeostasis and energy metabolism leading to cochlear cell death and progression of ARHL. The next step will be to elucidate the key molecular mechanisms underlying ARHL and to identify potential therapeutic targets.

SA12. Aging and Noise Exposure Cause Differential Patterns of Cochlear Synaptopathy and Central Gain

Audrey Transue¹, Amanda Yagan¹, Claire Mitchell¹, Jennifer Klara¹, Luz Andrino², Megan Arnold³, Aravindakshan Parthasarathy*¹

¹University of Pittsburgh, ²Carnegie Mellon University, ³University of Pittsburgh School of Medicine

Background: Adults of all ages experience a wide variety of potentially damaging recreational and occupational acoustic exposures. These noise exposures may cause a loss of cochlear afferent synapses that remain “hidden” from audiometric assessments. Aging results in a progressive loss of cochlear synapses, while early noise exposures exacerbate cochlear synapse loss. However, the vulnerability to cochlear synapse loss, and subsequent effects on the central auditory pathway at later ages are still unclear. In this study, we investigate the interactions between aging and acoustic overexposures, focusing on cochlear deafferentation and subsequent central gain in a mouse model (CBA/CaJ). By systematically varying age of noise exposure, we aim to investigate vulnerabilities to noise-induced cochlear synapse loss and central gain as a function of age.

Methods: Male and female CBA/CaJ mice (N = 54) were exposed to a single synaptopathic noise exposure (100dB SPL, 2 hours, 8-16kHz) at various time points across their lifespan. Testing occurred two weeks post. Results were compared to unexposed age-matched litter-mate controls. Electrophysiological assessment of cochlear synapse loss and central gain were made using EEG-based envelope following responses (EFRs). Histological assessment of cochlear synapse loss was made using immunostaining of presynaptic ribbon terminals and post-synaptic glutamate receptors in the inner hair cells.

Results: Noise exposure produced significant synapse loss at the 30 kHz region while largely sparing the 12 kHz region across exposure ages, confirming the tonotopic vulnerability of noise-induced synaptopathy. Early noise exposure resulted in significant cochlear synapse loss and increased central gain compared to age-matched controls. The degree of synapse loss due to noise exposure was the same, regardless of age at noise exposure, suggesting a floor effect on the amount of cochlear deafferentation. However, noise exposure at later middle-ages resulted in lesser central gain, despite similar degrees of deafferentation.

Conclusions: Our results suggest that age at noise exposure can have a dramatic effect on the compensatory ability of the auditory system when faced with decreased peripheral inputs. These unique profiles of cochlear synapse loss and central gain likely have differing effects on speech perception in noisy conditions. Clinically, these results suggest that an individual's age when exposed to noise should be considered in determining potential damage to the auditory system and effects. The electrophysiology measures used here could potentially lead to objective clinical biomarkers for cochlear synapse loss and central gain assessments in the clinic.

SA13. Cortical Auditory Encoding Deficits in Mild Cognitive Impairment With and Without Alzheimer's Disease Biomarkers

Karli Nave*¹, Kelly Whiteford¹

¹*University of Michigan*

Background: Hearing loss is a leading potentially modifiable risk factor for dementias such as Alzheimer's disease (AD), yet auditory dysfunction in early AD can occur even in individuals with clinically normal audiometric thresholds. A recent meta-analysis concluded that auditory EEG may help identify individuals at risk for developing AD (Tarawneh et al., 2024). Specifically, AD is associated with longer latencies for N200 (sensory encoding) and P300 (cortical processing) compared to healthy controls. While no significant latency differences were observed between mild cognitive impairment (MCI) and AD groups, prior studies did not test for AD biomarkers, leaving it unclear whether auditory processing deficits in MCI reflect AD-specific pathology. Furthermore, some longitudinal work suggests that individuals with MCI who progressed to probable AD within five years showed significantly longer P300 latencies than those who did not (Golob, Irimajiri, and Starr, 2007).

Methods: In the present study, we recruited individuals with MCI who underwent AD biomarker testing, along with cognitively healthy controls. EEG data were recorded during a two-tone auditory oddball task. Each block consisted of 120 standard tones (500 Hz) and 30 deviants (1500 Hz) presented in a pseudo-randomized sequence at 85 dB SPL. Tones were 100 ms in duration and separated by 1500-1800 ms (jittered IOI). Each block began with at least five standards, and each deviant was followed by at least three standards before another deviant occurred. Participants were instructed to attend to the tones. Ten times per block (on five standards and five deviants), the tone stream paused and participants reported whether the last tone was "high" or "low", with a minimum of eight tones between prompts. Unlike traditional oddball tasks, this design minimized working memory demands ("count the deviants") and reduced motor artifacts from button presses ("press when you hear a deviant").

Results: We hypothesize that individuals with MCI and AD biomarkers (MCI+AD) will show delayed N200 and P300 responses relative to MCI without AD biomarkers (MCI-AD) and healthy controls, reflecting deficits in both sensory encoding and cortical attention/memory processes, respectively. Our target sample size is N = 60 (n = 20 per group), and preliminary data collection is underway.

Conclusions: This study aims to determine whether cortical auditory processing deficits in MCI are uniquely linked to AD-related neurodegeneration or reflect broader cognitive impairment. If confirmed, auditory ERPs measures could provide sensitive, scalable tools for early detection and monitoring of AD progression. Moreover, distinguishing MCI(+AD) from MCI(-AD) may improve diagnostic precision and inform earlier, targeted interventions. Preliminary results will be discussed. [Supported by NIH/NIA Michigan Alzheimer's Disease Research Center grant P30AG072931, the University of Michigan Alzheimer's Disease Center (Berger Endowment), and NIH grant R21DC019409.]

SA14. Microglia Interact With Gabaergic Interneurons and Myelin in the Central Auditory System of Aged Mice

Emily Fabrizio-Stover^{*1}, Tyreek Jenkins¹, Jamie L Barth¹, Hainan Lang¹

¹*Medical University of South Carolina*

Background: Aging is a complex disorder with multiple pathologies in the central auditory system, including chronic inflammation that leads to an increased number of pro-inflammatory microglia, the loss of GABAergic inhibition (often resulting in hyperexcitability), and reduced myelin integrity. Both decreased GABAergic inhibition and reduced myelin integrity are associated with age-related auditory deficits. There is increasing evidence that pro-inflammatory microglia play an important role in both the modulation and maintenance of GABAergic inhibition as well as myelin maintenance. However, the role of pro-inflammatory microglia in age-related central auditory system deficits is unknown. Here, we examine age-dependent alterations in the numbers of the of pro-inflammatory microglia and GABAergic interneurons, myelin state, and interactions of microglia with interneuron and myelin structures in the mouse auditory brainstem and cortex.

Methods: Quantitative immunohistochemistry was performed on sections of the auditory cortex (AC) and the central nucleus of the inferior colliculus (ICC) in young adult (4M) and aged (2+ Y) CBA/CaJ mice to characterize the relationship between activated microglia with loss of GABAergic interneurons and myelin integrity with age. GABAergic neurons were identified using GAD65/67 or GAD67 with NeuN co-expression. Activated, pro-inflammatory microglia were determined by morphological changes in IBA1+ cells. Myelin basic protein (MBP) was used to identify myelin structures. Analysis was performed using z-stack confocal images to quantify the number of GABAergic interneurons and microglia, and the interactions of microglia with GABAergic interneurons and MBP+ myelin structures. To identify expression-level changes in genes that occur with aging, we performed bulk RNA sequencing analysis of the AC and IC tissues.

Results: Aging mice exhibited fewer GAD65/67+ and GAD67+ neurons in both the ICC and AC compared to young mice, along with reduced MBP expression in both regions. Aged mice also exhibited a greater number of IBA1+ cells, with a greater proportion of ramified cells, in the ICC and AC compared to younger mice, although overall more IBA1+ cells were found in the AC. Interestingly, we found a subset of aged IBA1+ cells in only in the AC that exhibited engulfment of GAD67+ cell processes or debris. Enrichment analysis of RNA sequencing data revealed that aging resulted in more dysregulation of myelin in the aged AC compared to the aged IC.

Conclusions: These results show that aging results in increased numbers of activated microglial throughout the central auditory system and that this increase is coupled with a reduction in GABAergic interneurons and reduced myelination. These data suggest that aging, pro-inflammatory microglia may play a role in age-related structural changes in the

central auditory system, although further studies directly associating microglial activity with GABAergic interneuron activity and myelin are needed to investigate any causal relationships.

SA15. Aging Masks Auditory Dysfunction Associated With the Autism Spectrum Disorder Gene Mef2c

Tyreek Jenkins*¹, Jiaying Wu¹, Shelby Payne¹, Emily Fabrizio-Stover¹, Jeremy Barth¹, Dariusz Pytel¹, Rachel D. Penrod¹, Christopher Cowan¹, Hainan Lang¹

¹*Medical University of South Carolina*

Background: Autism spectrum disorders (ASDs) are associated with sensory deficits. Specifically, difficulties in hearing and sound processing are often reported in both children and adults with ASD. Mutations or deletions in the MEF2C gene results in a syndromic form of ASD known as MEF2C haploinsufficiency syndrome (MCHS). Global Mef2c heterozygosity is sufficient to elicit MCHS-like phenotypes in mice, including sensory deficits. Young-adult Mef2c-heterozygous mice exhibit auditory nerve functional impairment and a moderate reduction in hearing sensitivity. To date, most studies of auditory dysfunction in ASD preclinical models have focused on early development and young adulthood. The long-term trajectory of these deficits with advanced age is largely unknown, highlighting a critical gap in understanding the intersection of aging and auditory function in ASD.

Methods: Global Mef2c-heterozygous mice were backcrossed to B6.CAST mice to eliminate the Cdh23Ahl mutation present in the C57BL/6J background, which causes early-onset hearing loss, for auditory functional assessments. Auditory brainstem responses were used to assess hearing sensitivity and auditory nerve activity in aging Mef2c-heterozygous and wildtype mice. Bulk RNA-sequencing of cochlear tissue and Simoa (Quanterix) analysis of peripheral blood were performed to assess differential gene expression and circulating neurodegenerative biomarkers, respectively. Cognitive and behavioral phenotypes relevant to MCHS were evaluated using open field, vertical locomotor, social interaction, and acoustic startle tests.

Results: Aging Mef2c-heterozygous mice displayed similar auditory thresholds to wildtype controls, suggesting similar age-related hearing decline. Analysis of suprathreshold auditory brainstem responses revealed no significant differences in wave I amplitude or latency between groups, indicating that both genotypes experience similar age-related reductions in peripheral auditory nerve function. However, aging Mef2c-heterozygous mice exhibited a reduced acoustic startle response compared to wildtype controls, suggesting enhanced age-dependent declines in central auditory processing. Behavioral testing revealed increased hyperactivity in aging Mef2c-heterozygous mice compared to wildtype controls during the open field and locomotor activity assays, similar to changes reported in young-adult mice. Social interaction with social novelty test showed no significant differences between genotypes, indicating similar social behavior with aging. Bulk RNA-seq analysis of cochlear tissue identified a small number of differentially expressed genes between aging Mef2c-heterozygous and wildtype mice. Finally, biomarker analysis using Simoa (Quanterix) technology revealed evidence of increased age-related neurodegeneration in Mef2c-heterozygous mice compared to wildtype controls, including increased levels of neurofilament light chain (NFL).

Conclusions: While young-adult Mef2c-heterozygous mice exhibit auditory nerve impairment and mild hearing loss, age-related declines seem to mask auditory sensitivity,

peripheral auditory nerve activity, and cochlear gene expression changes between Mef2c-heterozygous mice and wildtype controls. Persistent hyperactivity and reduced acoustic startle responses, however, highlight central auditory processing effects and underscore the need to investigate how ASD risk genes influence cognitive behavioral outcomes across the lifespan.

SA16. Neurophysiological Functional Connectivity Changes During Difficult Listening in Older and Younger Adults

Vrishab Commuri^{*1}, I.M Dushyanthi Karunathilake², Stefanie Kuchinsky³, Behtash Babadi¹, Jonathan Z. Simon⁴

¹*University of Maryland*, ²*University of Maryland- College Park*, ³*Walter Reed National Military Medical Center*, ⁴*Institute for Systems Research, University of Maryland*

Background: Older adults often report increased difficulty understanding speech in noisy listening environments. These difficulties are thought to arise from neurophysiological changes associated with aging. Speech comprehension is believed to rely on coordinated activity across distributed cortical regions, mediated by the directional flow of electrical signals – their functional connectivity. This connectivity can be analyzed within specific frequency bands, e.g., delta and theta, each thought to play a distinct role in speech and language processing.

Methods: We utilize the Network Localized Granger Causality (NLGC) framework applied to magnetoencephalography (MEG) data to simultaneously estimate neural currents in cortex and the functional connectivity network that connects them. Whole-brain connectivity graphs were analyzed using graph-cluster enhancement and permutation testing, with additional analyses focused on language-related regions of interest.

Temporal Response Functions (TRFs) were obtained by relating NLGC-derived neural current estimates to the speech stimulus presented to listeners. These TRFs enabled localization of stimulus-driven responses within encompassing age-affected networks.

Results: We elucidate how cortical circuits change as listening conditions become increasingly adverse, and we reveal differences in regional connectivity between older and younger individuals. We provide evidence for distributed network changes with aging, particular to the delta and theta bands, and demonstrate the sensitivity of these network changes to listening conditions.

Conclusions: Our findings highlight age- and condition-dependent shifts in speech-related cortical connectivity across neurophysiological frequency bands. By integrating NLGC-derived networks with TRF analysis, we localize hierarchical speech processing within these circuits. Although demonstrated on a speech-listening dataset, the approach is broadly applicable to MEG studies of neural dynamics.

SA17. Relations of Auditory Temporal Processing Tests With Other Hearing Measures in Young Adult Mice

Claire Dorey^{*1}, Erol Ozmeral¹, Xiaoxia Zhu², Robert Frisina¹

¹*University of South Florida*, ²*Global Center for Hearing and Speech Research, University of South Florida*

Background: Neurophysiological assessment in animal models has traditionally focused on peripheral integrity of the auditory system. Yet, speech-in-noise difficulties are often cited as a primary patient complaint in outpatient audiologic practice, which may involve post-cochlear processing. Thus, there is utility in measurement of temporal processing in hearing loss animal models. The auditory brainstem response gaps-in-noise test (ABR-GIN) has previously shown efficacy in this area. Previous work has focused on showing a change in ABR-GIN responses in young versus older groups of mice, or in other studies, drug effects on auditory temporal coding. In this presentation we offer a relatively novel perspective with characterization of the neurophysiological profile of the 3-month-old CBA/CaJ hearing loss mouse model in reference to the ABR-GIN. These data were collected as the first timepoint in a 2-year ongoing longitudinal study of the aging auditory system.

Methods: Our analysis included N = 24, 3-month-old CBA/CaJ mice (12 male; 12 female). Animals were anesthetized using a ketamine/xylazine mixture of 120 and 10 mg/kg to the mouse's body weight. ABR-GIN recordings were obtained with presentation of a 25-ms noise burst followed by 0, 1, 2, 4, 8, 16, 32, and 64-ms durations of silence prior to a second wideband noise burst. Thresholds were determined by identifying the shortest gap duration with a replicable response after the silence. Latency and amplitude were measured for waves I and IV for each response. All physiology measurements were obtained using TDT BioSig software. Distortion product otoacoustic emissions were measured using L1 of 65-dB SPL and L2 of 50-dB SPL with a constant frequency ratio of 1.25 for F1 and F2. Auditory brainstem response recordings were obtained for 3, 6, 12, 26, 20, 24, 32, 36, and 48 kHz and using a wideband click. Latency, amplitude, and threshold were marked. Recordings were obtained twice for each frequency for replicability.

Results: Reliable ABR-GIN responses were recorded from all 24 mice, with thresholds recorded between 1 and 4 ms. Threshold ABR responses showed elevation in the very lowest frequencies compared to the mid and high frequency ranges. Emissions were most robust in the mid frequency range in the range of best hearing for the CBA mouse, but small responses in the lowest and highest frequencies. Relationships between the different test measures are being assessed to identify potential patterns of association, and how they change with age.

Conclusions: In conjunction with other traditional neurophysiological measures, the ABR-GIN can provide useful information related to temporal processing in an age-related hearing loss mouse model. The inclusion of this measure offers a broader characterization of auditory function with peripheral through central involvement. Ongoing longitudinal analyses will further clarify how these relationships evolve with age and contribute to understanding biomechanisms underlying speech-in-noise difficulties.

SA18. How Long Does the Capacity for Synapse Regeneration Persist Following Noise Exposure?

Kieran Coffey*¹, Catherine J. Kane¹, Steven H. Green¹

¹*The University of Iowa*

Background: Cochlear synapses between inner hair cells (IHCs) and spiral ganglion neurons (SGNs) are susceptible to damage caused by moderately loud noise, termed noise-induced cochlear synaptopathy (NICS), evident by histology as a loss of synapses and non-invasively by a permanent decline in auditory brainstem response (ABR) wave-I amplitude with no permanent elevation of hearing threshold. We have previously shown (Hemachandran et al. Front. Cell. Neurosci., 2024) that rolipram, a cyclic AMP PDE4 inhibitor, promotes synapse

regeneration and partial recovery of ABR wave 1 amplitude in vivo when administered one day after noise exposure. Here we ask how long the capacity for synapse regeneration persists following noise exposure. We systemically delivered rolipram either two or three days after noise exposure to determine whether rolipram retains its regenerative capacity. Establishing a therapeutic window for rolipram in recovery from NICS is critical to determining effectiveness of delayed treatment, which could enhance its potential for future clinical use in humans.

Methods: 12–14-week-old CBA/CaJ male mice were exposed to a 100 dB SPL, 8-16 kHz octave-band noise for 2 hours. ABR measures were made at 8, 16, and 32 kHz frequencies pre-noise and on post-noise day 1. Mice were subcutaneously implanted with osmotic minipumps delivering rolipram dissolved in DMSO or control DMSO on post noise day two (PND2) or three (PND3). Delivery of rolipram or vehicle control continued for two weeks (PND14), at which time ABR was measured again and the mice were euthanized. Cochleae were dissected and labeled with the following antibodies to visualize hair cells and their synapses: Myosin 6A/7 (hair cells), CtBP2 (presynaptic ribbons), and PSD-95 (postsynaptic densities, PSDs). Synapses (defined as adjacent CtBP2 and PSD puncta) were counted at 8, 16, and 32 kHz locations.

Results: Our noise exposure paradigm causes a temporary but not a permanent threshold shift, and a permanent reduction in wave-I amplitude, consistent with NICS. Rolipram itself has no effect on auditory threshold. Initiation of rolipram on PND2 partially restored ABR wave-I amplitude at 8 and 32 kHz, but not significantly at 16 kHz. Initiation of rolipram on PND3 did not restore wave-I amplitude at 16 or 32 kHz, but did partially restore wave-I amplitude at 8 kHz. Initiation of rolipram treatment on PND2 or PND3, unlike initiation on PND1, did not significantly increase synapse counts relative to vehicle control mice. Counts remained significantly lower than those of non-noise-exposed mice.

Conclusions: The capacity for rolipram to promote synapse regeneration declines rapidly after noise exposure. The therapeutic window for rolipram's effectiveness appears to be short, likely within 1-2 days post-noise exposure. Clinically, rapid intervention is critical for restoring hearing synapses after NICS.

SA19. Distinct Brain Connectivity Traits of Misophonia in Co-Existence With Hyperacusis and in Isolation

Shagun Ajmera¹, Rafay Khan¹, Gibbeum Kim¹, Namitha Jain¹, Ariana Castro¹, Howard Berenbaum¹, Fatima Husain¹

¹*University of Illinois at Urbana-Champaign*

Background: Misophonia and loudness hyperacusis are distinct sound tolerance disorders that share similar symptoms, which are involuntary and aversive responses to sounds. A comprehensive understanding of neural traits of these disorders is presently lacking. Our exploratory study aims to dissociate the intrinsic brain connectivity patterns underlying each condition which may help explain some of the variability in behavioral outcomes—such as autonomic versus emotional responses. Furthermore, we investigate neural alterations when both the disorders are endured (comorbid) so as to disentangle the unique cognitive burdens imposed by either or both conditions.

Methods: We examined resting-state functional MRI data acquired from three groups of young adults: having both misophonia and hyperacusis (MH; n=24), having misophonia only (MI; n=27), and control individuals with no complaints of decreased sound tolerance (CTR;

n=25). By training robust machine learning classification models, we processed brain-wide spontaneous functional connectivity and identified patterns that reliably differentiated either patient group from the control group.

Results: Compared to CTR, MI and MH showed atypical connectivity for the salience, somatomotor, and frontoparietal control networks. Additionally, subcortex-related connectivity patterns captured in MH classifier were also aligned with misophonia detection. Unique to MH were the connectivity trends for regions in dorsal attention network and default mode network. Interestingly, connectivity within subcortical basal ganglia was found disrupted in MI but not in MH. Taken together, distinct and overlapping resting-state neural markers of misophonia and hyperacusis warrant a more precise phenotyping and caution against conflating them in research or clinical settings.

Conclusions: Substantial alignment between the idiosyncratic network connectivity patterns of MH and MI groups indicates that core misophonia-related brain changes show dominant effects even in the presence of comorbid hyperacusis. While previous misophonia studies extensively report differences in the salience network, we identify additional connectivity dysregulations that suggest cognitive control impairments in misophonia; these likely manifest as issues with motor inhibition or attentional regulation, showcasing a previously underappreciated dimension of misophonia. Additionally, the results implicate reduced regulation of goal-directed attention, which may lead to emotional distress in presence of triggers, and psychiatric co-morbidities in the long-run. Altered subcortical connectivity trends observed in MI reflect common neural mechanisms with OCD, relating to obsessive behavioral symptoms. The impact of hyperacusis in MH is also evident through the disrupted interactions associated with higher-order visual processing and semantic integration. In summary, these connectivity traits advocate for a psychology-based therapeutic approach for misophonia. Future research should focus on translating these insights into clinical interventions such as cognitive behavioral therapy (CBT) that are grounded in the neurological and psychological characteristics of misophonia. Our results provide support for exercising CBT techniques in emotion regulation training, cognitive reappraisal, and attention-shifting strategies to positively modulate dysregulated connectivity in misophonia sufferers.

SA20. Cross-Validation of GPIAS Against an Operant Conditioning Model in the Assessment of Tinnitus in Mice

Fangyi Chen^{*1}, Yang Xu¹

¹*Southern University of Science and Technology*

Background: The investigation into mechanisms and pharmacological treatments of subjective tinnitus relies heavily on the development of reliable animal models. Currently, the most commonly used behavioral paradigms include operant conditioning and Gap Prepulse Inhibition of the Acoustic Startle (GPIAS). Operant models are considered to better reflect the perceptual experience of tinnitus in humans but require extensive and carefully designed training. In contrast, GPIAS allows more efficient and rapid screening of tinnitus-like behavior in animals, despite ongoing controversies regarding its theoretical foundation. Nevertheless, GPIAS remains widely applied across diverse animal models and tinnitus induction methods. Given the ongoing debate over whether GPIAS accurately detects tinnitus, this study employs a well-validated operant model to cross-validate the standard GPIAS procedure, and evaluates the sensitivity of GPIAS in detecting tinnitus induced by different etiologies.

Methods: Tinnitus was induced using either monaural noise exposure (100 dB SPL, 4–20 kHz, 2 hours) or via intraperitoneal injection of sodium salicylate (350 mg/kg). All mice underwent a two-week Sound Based Avoidance Detection (SBAD) training paradigm to establish a conditioned reflex. Those trained mice were subjected to both standardized GPIAS and SBAD tests before and after tinnitus induction. Auditory evoked potentials (AEPs) were recorded from the auditory cortex to evaluate gap detection ability. A comparative analysis of outcomes from the two behavioral assays was performed both within individual subjects and across induction methods.

Results: Both tinnitus induction methods led to significant tinnitus-like behaviors as detected in the SBAD test. The GPIAS paradigm yielded a similar proportion of tinnitus-positive animals as the SBAD test. Furthermore, cortical AEP recordings confirmed that the mice were capable of perceiving the silent gaps embedded in the GPIAS stimuli.

Conclusions: These findings support that GPIAS can serve as a sensitive screening tool for tinnitus in animal models, exhibiting comparable effectiveness to the operant conditioning paradigm. However, the validity of GPIAS does not depend on the presumed deficit in gap detection among tinnitus subjects. Tinnitus-related deficits may influence gap processing in more complex ways.

SA21. Calcium Signaling in the Organ of Corti Following Treatment of Novel $\alpha 9\alpha 10$ Nicotinic Receptor Small Molecules

Subramanya Hegde¹, Layla Azam¹, Kimberly Coffman¹, Alex Stark¹, J. Michael McIntosh¹, Holly Holman*¹

¹*University of Utah*

Background: Alpha9 and alpha10 subunits assemble into unique, highly Ca²⁺ permeable, nicotinic receptors (nAChRs) that are expressed in outer hair cells (OHCs) in adults and in inner hair cells (IHCs) during mouse development. Acetylcholine released from efferent terminals at the medial olivocochlear (MOC) efferents activates $\alpha 9\alpha 10$ nAChRs, creating an influx of Ca²⁺, which opens small-conductance (SK) Ca²⁺ activated K⁺ channels, hyperpolarizes hair cells, and reduces cochlear amplifier gain. Modulating $\alpha 9\alpha 10$ nAChRs can change efferent feedback and susceptibility to acoustic trauma, hearing loss, and tinnitus. In this study, we tested $\alpha 9\alpha 10$ nAChR antagonist and agonist small molecules in a cochlear explant model. We examined the specificity and mode of action of these small molecules using genetically encoded calcium indicators (GCaMP).

Methods: All procedures conformed to institutional and national animal welfare regulations and were approved by the Institutional Animal Care and Use Committee. Male and female mice of either sex were used in this study. For scale and kinetics, both GCaMP6s and GCaMP8m expressing lines were used and crossed with Gad2-IRES-Cre. Postnatal day (P) 6–30 cochlear ex vivo preparations (explants) were examined.

Cochlear Preparation

The cochlea was micro-dissected to access the sensory epithelium while preserving hair cells and supporting cells. Cochlear explants were placed in a perfusion chamber and stabilized with a harp.

Calcium Imaging, Drug Delivery, and Data Analysis

A Bruker swept-field confocal microscope was used for calcium imaging. Drug treatments included 100 μ M acetylcholine, 100 μ M muscarine, 5 μ M atropine, and 0.2–20 μ M UT-860

and UT-167. GCaMP fluorescence modulation was determined pixel-by-pixel. Statistical significance of differences was determined using Student's t-test.

Results: Quaternary salts of small molecules UT-167 (antagonist) and UT-860 (agonist) were synthesized to improve aqueous solubility. These derivatives displayed enhanced solubility for in vitro testing and pharmacological activity. Both UT-167 and UT-860 showed distinct micromolar responses in hair cells when administered via bath perfusion. In developing cochlea (P6-P8), treatment with 0.2 -6 μ M UT-860 produced large increases in Ca^{2+} in OHCs and IHCs. All three rows of OHCs responded to UT-860 with robust increases in Ca^{2+} signaling. A few distinct supporting cells also showed Ca^{2+} modulation during this developmental age. In adults (P14 and older), treatment with UT-167 showed both increases and decreases in Ca^{2+} modulation in OHCs.

Conclusions: $\alpha 9\alpha 10$ nAChRs are critical targets for continued small-molecule efforts. Detailed studies of their selectivity, kinetics, and signaling in OHCs, IHCs, and supporting cells are needed to advance this work. In parallel, in vivo bioavailability, efficacy, and safety studies are essential to determine their potential translational benefit for treating hearing loss and tinnitus.

SA22. Hyperacusis in Young Adults With Normal Hearing Does Not Differ by Autism Status

Sean Kashiwagura*¹, Kelly N. Jahn¹

¹*The University of Texas at Dallas*

Background: As many as 17% of the general population and 70% of autistic individuals experience some degree of hypersensitivity to sounds (i.e., hyperacusis). Compared to individuals without hyperacusis, these individuals perceive everyday sounds as abnormally loud, distressing, or even physically painful. Many sufferers adopt drastic behavioral changes to minimize exposure to sounds, often sacrificing social interactions and employment. Current tools for hyperacusis assessment lack diagnostic sensitivity and specificity, likely due, to insufficient pathophysiological understanding of the disordered processes underlying the condition in humans. Despite limited understanding of the neural underpinnings of hyperacusis, there is no evidence to suggest that hyperacusis is qualitatively or quantitatively different in neurotypical and neurodivergent populations. Thus, we propose that hyperacusis is a transdiagnostic condition that likely shares physiological mechanisms across people with and without ASD. Here, we sought to investigate the relationships between peripheral auditory function, central auditory activation, hyperacusis, and ASD. We hypothesized that individuals with hyperacusis would demonstrate signs of peripheral and central auditory dysfunction, but that their audiological profiles would not differ based on autism status.

Methods: Currently, fifty-eight adults (females = 37, mean age = 23.38, SD = 4.11) have participated; fifteen were autistic. Hearing thresholds were tested at standard- (250–8000 Hz) and extended high-frequencies (10000–16000 Hz), bilaterally. Loudness perception was characterized in all ears via loudness discomfort levels (LDLs). Ear-specific auditory brainstem responses (ABRs) were recorded using 95-, 100-, and 105 dB-SPL click stimuli and analyzed for amplitudes and latencies. Hyperacusis severity was estimated using the Hyperacusis Questionnaire (HQ). Hyperacusis status was qualified by HQ score (≥ 22) or by positive response to the question “Do you feel that you are more sensitive to sounds than other people?”.

Results: Though all participants had clinically normal hearing at standard audiometric frequencies, hyperacusis symptoms widely varied, with HQ scores ranging from 0 (no symptoms) to 37 (severe symptoms). Twenty-three participants (39.66%) met the criteria for having hyperacusis. Hyperacusis was found to be significantly correlated with lower (i.e., worse) LDLs at all frequencies ($p=0.011$). Furthermore, hyperacusis was associated with subclinical signs of peripheral auditory dysfunction; specifically, hearing thresholds were significantly poorer as a function of frequency in participants with hyperacusis ($p < 0.001$), irrespective of ASD status. ABR wave I amplitudes were significantly reduced at higher stimulus intensities only in participants with hyperacusis ($p=0.029$), irrespective of ASD. Wave latencies and wave III and V amplitudes did not differ based on hyperacusis or ASD status.

Conclusions: Hyperacusis is associated with subclinical peripheral auditory dysfunction in young adults with clinically normal hearing. These findings were consistent for neurotypical and autistic participants, suggesting that hyperacusis may be a transdiagnostic condition with shared mechanisms across multiple clinical populations. Subsequent analyses will identify central and autonomic markers of hyperacusis in individuals with and without ASD.

SA23. A Multimodal, Biomarker-Based Approach to Objectively Classify Tinnitus in Mice

Tom Naber*¹, Marc Thioux¹, Janine Doorduyn¹, Jürgen Sijbesma¹, Erik De Vries¹, Pim Van Dijk¹, Sonja Pyott²

¹University Medical Center Groningen, ²School of Medicine and Health Science, Carl von Ossietzky Universität Oldenburg

Background: Investigating tinnitus mechanisms in animal models requires an objective method to identify tinnitus while disentangling mechanisms underlying associated hearing loss. Based on preliminary findings, GABAA receptor binding potential may be elevated in tinnitus patients. We aim to assess viability of this biomarker for objectively classifying tinnitus in animals and compare it to existing methods for tinnitus classification.

Methods: Awake mice were bilaterally exposed to 10-16 kHz noise at 110, 115, or 120 dB for 1h, followed by a 12-week assessment. Tinnitus classification was evaluated using gap prepulse inhibition of the acoustic startle reflex (GPIAS), auditory brainstem response (ABR) wave V (inferior colliculus) to I (cochlear nerve) amplitude ratios to assess central gain, and PET imaging with [¹¹C]flumazenil to assess GABAA receptor binding. Inner ears and brains were collected for subsequent molecular analyses.

Results: At 12.5 kHz, the 110, 115, 120 dB noise-exposed groups had permanent threshold shifts of 20, 38, and 63 dB, respectively. GPIAS revealed behavioral evidence of tinnitus in the 115 dB group one week after noise exposure, persisting throughout the follow-up. In this group, ABR measurements also demonstrated increased central gain. In total, from the 115 dB-exposed mice, 4 out of 9 were classified as tinnitus-positive based on behavioral evidence of tinnitus via GPIAS and 3 out of 7 based on elevated ABR wave V/I ratios. Importantly, these two methods did not yield overlapping classifications.

Conclusions: This study establishes 115 dB bilateral noise exposure as an optimal stimulus for moderate chronic hearing loss. While GPIAS and ABR both detect evidence of tinnitus, their classifications differ, underscoring the need for a multimodal approach for robust and translatable tinnitus classification in preclinical research. Ongoing analysis of inner ear and brain tissues will reveal potential histological differences between classified groups. Ongoing

PET analysis and upcoming autoradiography experiments will determine whether GABAA receptor binding potential correlates with tinnitus classification based on GPIAS and/or ABR.

SA24. Triple Network Alteration in High β With Cochlear Implantation in Tinnitus: Source Level Resting State Functional Network Study

Jihoo Kim^{*1}, Nour Alsabbagh², Joel Berger², William Sedley³, Timothy Griffiths³, Heejung Yun⁴, Sungkean Kim¹, Il Joon Moon⁴, Phillip Gander², Inyong Choi²

¹*Hanyang University*, ²*University of Iowa*, ³*Newcastle University*, ⁴*Sungkyunkwan University*

Background: Cochlear implantation (CI) restores hearing and often alleviates subjective, non-pulsatile tinnitus. Meta-analyses shows clinically meaningful reductions in tinnitus questionnaire scores after CI despite substantial heterogeneity. However, the neural mechanisms by which reafferented input from the CI reorganizes large-scale cortical networks to alleviate tinnitus remain unclear. Guided by the framework of sensory reafferentation and the triple-network model of large-scale brain organization (salience network: SN, central executive network: CEN, and default mode network: DMN), we hypothesized that restored input from the CI (when it is turned on: CI ON) would reduce pathological engagement of attentional control networks, whereas transient removal of input (CI OFF) would increase their segregation. Thus, CI ON/OFF offers a within-subject probe of how sensory reafferentation reorganizes large-scale cortical networks at rest, particularly the interconnection between the DMN and attentional control circuits.

Objective: To test whether CI state (ON vs OFF) acutely reshapes functional network topology in tinnitus associated with sensorineural hearing loss and to localize any effects to large-scale networks.

Methods: Resting-state EEG was acquired during CI ON and CI OFF from 37 adult CI users with tinnitus (18 female; mean age 61.9 years). Mean deafness duration was 18.1 years; mean CI use 3.8 years; five were bilateral users. All completed the Tinnitus Handicap Inventory. EEG (64-channel BioSemi ActiveTwo) was preprocessed in EEGLAB/MATLAB. Cortical sources were reconstructed by minimum-norm imaging to estimate current source density. Weighted functional connectivity was quantified with the weighted phase-lag index, and graph-theoretic metrics were evaluated. Proportional thresholds (5–50% in 5% steps) were applied; paired statistics were corrected for multiple comparisons.

Results: High- β (18–30 Hz), global network strength was greater with CI OFF than CI ON across three consecutive proportional thresholds (20%, 25%, 30%), and the effect survived multiple-comparisons correction ($p = .001, .001, .002$ respectively). No other frequency band showed global differences. Nodal analysis in the high- β band showed higher local efficiency with CI OFF within CEN, dorsal attention network (DAN), and SN, indicating increased local segregation of attentional control circuits at rest. DMN topology did not differ by CI state. Effects were robust across thresholds from 5% to 50%; no consistent CI-state effects were observed outside high- β .

Conclusions: Acute deafferentation (CI OFF) selectively increases high- β segregation within executive-control and attentional networks, whereas reafferentation (CI ON) relaxes this configuration. This state-dependent pattern supports a network-specific account in which SN/CEN are preferentially engaged by salient internally generated auditory signals while the DMN remains comparatively stable. The results are consistent with CI ON/OFF modulation of cortical networks and complement meta-analytic evidence of tinnitus improvement after implantation despite interstudy heterogeneity. High- β local efficiency thus emerges as a

candidate systems-level biomarker to stratify tinnitus phenotypes and to guide adjunct neuromodulatory strategies targeting β -band control.

SA25. Neural Correlates of Decreased Sound Tolerance Disorders: Insights From Task-Based fMRI Study

Namitha Jain^{*1}, Shagun Ajmera¹, Somayeh Shahsavarani², Rafay Khan¹, Gibbeum Kim¹, Howard Berenbaum¹, Fatima Husain¹

¹*University of Illinois Urbana Champaign*, ²*San Jose State University*

Background: Sounds that do not bother most people—a neighbor chewing, a pen clicking, or the hum of machinery—can be intolerable for individuals with decreased sound tolerance (DST) disorders. DST includes clinically distinct but often co-occurring disorders, most notably hyperacusis and misophonia. Hyperacusis involves increased sensitivity to sounds above a certain loudness threshold, causing discomfort or pain. By contrast, misophonia is characterized by intense negative emotional reactions to specific “trigger” sounds (e.g., chewing or sniffing), regardless of their volume. Despite growing clinical recognition, the neural mechanisms underlying these disorders remain poorly understood. Prior neuroimaging studies have typically examined hyperacusis and misophonia in isolation and without accounting for comorbidity. To address these gaps, the present study aims to delineate the neural correlates of hyperacusis, misophonia, and their co-occurrence using task-based fMRI with emotionally valent sounds.

Methods: Ninety-two young adults were recruited and categorized into four groups: misophonia only (MISO; $n = 29$), hyperacusis only (HY; $n = 14$), comorbid misophonia and hyperacusis (MiHy; $n = 24$), and age- and sex-matched healthy controls (CTR; $n = 25$). Participants completed a task-based fMRI experiment during which they listened to 90 emotionally valent sounds (30 unpleasant, 30 neutral, and 30 pleasant) from the International Affective Digitized Sounds-2 database. Participants rated each sound as pleasant, neutral, or unpleasant using button presses. Whole-brain and region-of-interest functional activation, as well as seed-to-voxel functional connectivity analyses, were conducted with a primary threshold of $p < 0.001$ and cluster-level family-wise error correction at $p < 0.05$.

Results: Behaviorally, the comorbid group (MiHy) rated more sounds as unpleasant than both MISO and CTR groups, suggesting heightened aversive perception. fMRI analyses revealed both distinct and overlapping neural patterns. MISO and MiHy (relative to CTR) showed increased engagement of visual processing regions and altered salience–visual network connectivity during unpleasant (versus neutral) sound processing, suggesting atypical cross-modal sensory involvement. The HY and MiHy (relative to MISO and CTR) groups exhibited reduced connectivity between salience hubs and frontal control regions, indicating impaired top-down regulation. Notably, in MISO, this connectivity was preserved for non-trigger unpleasant sounds, suggesting intact regulation in that context. The comorbid group (MiHy) combined both neural signatures: altered visual engagement and reduced regulatory control. Finally, both MISO and HY (relative to CTR) groups showed increased dlPFC–SMA connectivity, pointing to a shared mechanism of motor readiness.

Conclusions: Misophonia was linked to atypical cross-modal visual processing, hyperacusis to reduced top-down control, and comorbidity combined features of both, revealing distinct and overlapping neural correlates of DST. Future research should integrate neural and behavioral measures to refine mechanistic models and guide targeted interventions.

SA26. Prolonged Cortical Auditory Latencies are Linked to Poorer Executive Function and Visuospatial Memory Independent of Age and Peripheral Hearing in Older Adults

Christopher Niemczak^{*1}, Samantha Leigh¹, Monika Adhikari¹, Robert Roth¹, Catherine Rieke¹, Shireen Geimer¹, Suwen Wu¹, Odile Clavier², Jay Buckey¹

¹Dartmouth-Hitchcock, Geisel School of Medicine, ²Creare LLC

Background: Central auditory timing reflects neural processing speed in aging and early cognitive decline, but its relation to traditional neurocognitive tests is unclear. We tested whether cortical auditory evoked potential (CAEP) latencies track executive function and visuospatial memory performance in adults with and without mild cognitive impairment.

Methods: In a cross-sectional study with 62 adults (age 57-85) at Dartmouth-Hitchcock Medical Center, we recorded the Acoustic Change Complex to an /u-i/ stimulus (primary site Cz) and derived N1 and P2 latencies from onset and change responses. Pure-tone thresholds and tympanometry assessed peripheral hearing status. Using principal component analysis a latency composite (LC1) was calculated that explained 64.1% of latency variance. This component was used as an predictor variable in the analysis to reduce dimensionality. Executive function tests were the Trail Making Test (TMT-A and B). The Rey Complex Figure Test (RCFT; copy/recall/recognition), and Brief Visuospatial Memory Test-Revised (BVM-T-R; total and T-score) were used for visuospatial memory. The associations between latency LC1 and cognitive outcomes were tested using linear regression adjusted for age, hearing thresholds (PTA), sex, and education. To assess how much the latency component added to the model, a change in R² (ΔR^2) was calculated between a model with only covariates and with covariates plus LC1. A false discovery rate (FDR) controlled multiple comparisons. Sensitivity analyses included bootstrap confidence intervals with replacement between latency LC1 and cognitive tests. A simple logistic regression explored diagnostic classification of mild cognitive impairment.

Results: Longer cortical latency was associated with worse executive performance and showed a trend toward worse visuospatial memory. Individual correlations of N1 and P2 components showed moderately-strong correlations to a variety of neurocognitive tests. For TMT-B, LC1 significantly predicted slower completion times ($\beta=0.125$, $p=0.0004$), with $\Delta R^2=0.144$ beyond covariates alone. The bootstrap 95% CI for $\beta=[0.046, 0.218]$ supported the strength of the finding. TMT-A showed a smaller effect ($\beta=0.049$, $p=0.033$; $\Delta R^2=0.034$); bootstrap 95% CI for $\beta=[0.004, 0.103]$. Associations with RCFT copy ($\beta=-0.717$, $p=0.069$) and BVM-T-R total ($\beta=-1.081$, $p=0.051$) trended in the expected direction. RCFT recall and BVM-T-R T-scores were not significant. A logistic regression using latency and covariates did not achieve useful discrimination among those adults with and without mild cognitive impairment ($p=0.079$, accuracy=66%, AUC=67).

Conclusions: Prolonged cortical auditory latencies were linked to poorer executive function and visuospatial memory, independent of age and peripheral hearing in older adults. Auditory cortical timing offers an objective and scalable neural index that could complement audiometry and speech-in-noise testing to flag cognitive vulnerability in otolaryngology and audiology settings. Future work will establish impairment cutoffs, assess longitudinal prognostic value versus PET/MRI biomarkers, and examine additional latency measures of cortical processing in background noise.

SA27. Human Auditory Cortex Encodes Multiscale Spectrotemporal Energy and Higher-Order Spectrotemporal Patterns Predictable From Deep Neural Network Models

Guoyang Liao^{*1}, Dana Boebinger², Christopher GARCIA³, Kirill Nourski³, Matthew Howard³, Thomas Wychowski², Webster Pilcher², Samuel Norman-Haignere¹

¹*University of Rochester*, ²*University of Rochester Medical Center*, ³*The University of Iowa*

Background: Much of the information in natural sounds is conveyed by complex patterns of spectrotemporal modulation in a time-frequency representation of sound. Yet, how these modulations are encoded in the human auditory cortex remains poorly understood, in part due to the coarse resolution of non-invasive neuroimaging methods.

Methods: We measured human intracranial responses from 35 neurosurgical patients listening to a diverse set of natural sounds, including speech, music, animal vocalizations, and other environmental sounds (each 2 seconds). We then compared the neural prediction accuracy of three encoding models: (1) a standard spectrotemporal receptive field (STRF) model (2) a multiscale spectrotemporal energy (MSTE) model (3) a deep neural network (DNN) model trained to recognize speech, music, and environmental sound categories from a spectrotemporal representation of sound.

Results: We show that multiscale spectrotemporal energy predicts spatiotemporally precise human intracranial responses to natural sounds with much higher accuracy than standard spectrotemporal receptive field models. The MSTE model showed higher prediction than the STRF baseline throughout primary and non-primary auditory cortex and nearly tripled the prediction accuracy of non-primary, category-selective regions. The MSTE model revealed large-scale spatial maps of modulation energy, spanning primary and non-primary auditory cortex, that helped to predict the anatomical location of speech- and music-selective regions. We also observed higher-order selectivity for speech and music structure that could not be predicted by our MSTE model but could be predicted using late layers of our DNN model.

Conclusions: Our findings reveal how the spectrotemporal structure of natural sounds is encoded, transformed, and organized across the human auditory cortex

SA28. Whole-Brain Connectome Changes Following Hearing Recovery

Timothy Edward Cole^{*1}, Junichi Hata², Daisuke Yoshimaru³, Yuji Komaki⁴, Naoki Oishi⁵, Hirotaka James Okano³, Masato Fujioka⁶

¹*Kitasato University School of Medicine*, ²*Graduate School of Human Health Sciences, Tokyo Metropolitan University*, ³*Jikei University*, ⁴*Central Institute for Experimental Medicine and Life Science*, ⁵*Keio University School of Medicine*, ⁶*Kitasato Institute Hospital*

Background: Hearing loss induces widespread neuroplastic changes, not only within auditory cortical regions but also across non-auditory networks. These alterations include cross-modal plasticity and reorganization of higher-order cognitive areas. Although auditory rehabilitation is known to partially reverse such changes, few studies have investigated the longitudinal structural connectome alterations following hearing recovery. Understanding these changes may provide valuable insights for optimizing postoperative treatment and rehabilitation strategies.

Methods: Seven patients with congenital hearing loss were recruited under the approval of the Keio University School of Medicine ethics committee. Diffusion-weighted imaging

(DWI) was acquired at three time points: preoperatively, 3 months postoperatively, and 6–12 months postoperatively. Data were analyzed using MRtrix3 software, applying constrained spherical deconvolution (CSD) tractography to overcome limitations of diffusion tensor models. Whole-brain regions of interest (ROI) were defined in two parcellation schemes (84 and 102 ROIs), and graph-theoretical network analyses were performed. Special focus was placed on Brodmann areas 7 (superior parietal lobe), 17 (primary visual cortex), 24 (anterior cingulate cortex), and 41 (primary auditory cortex). Connectivity changes were evaluated intra-hemispherically and inter-hemispherically across the three stages.

Results: Six patients were included in the final analysis (one excluded due to incomplete follow-up). Whole-brain analysis revealed a general increase in structural connectivity over time. Detailed data will be presented on site.

Conclusions: Our findings indicate that hearing recovery surgery promotes progressive neuroplastic reorganization within the auditory connectome. Detailed data will be presented on site.

SA29. Automated Word Timing From Continuous Speech Audio for Neural Signal Analysis

Stella Aluminah^{*1}, Vrishab Commuri¹, Charlie Fisher¹, Jonathan Simon¹

¹*University of Maryland - College Park*

Background: An important part of speech processing is the brain's identification and interpretation of words. The brain generates neural responses synchronously with (time-locked to) the presentation times of each word, and components of these responses are implicated in higher-level contextual processing, such as surprisal or prediction. To accurately derive such neural responses to words, the exact timing of the words in a speech stream must be known in order to align them with the neural responses they elicit. However, extant word alignment tools produce coarse timings with systematic biases that make them unsuitable for this task without manual intervention. We present and validate a new method to derive accurate, unbiased word timings from an ensemble of commonly used word aligners.

Methods: An initial pass at word timings was generated by several speech-to-text alignment tools. Incorrect timings produced by these models were corrected by hand – roughly 50% of all generated timings. The timings were then estimated from the ensemble of alignment tools using a linear regression framework. The regression enabled systematic biases of certain phoneme categories to be corrected, and optimally aligned with the hand-corrected times.

Time-locked neural responses to both model-predicted and by-hand times were estimated using the Temporal Response Function (TRF) framework.

Results: The results were model-predicted timings that closely matched those that were manually corrected. The model-predicted timings produced qualitatively similar time-locked neural responses (TRFs) to the by-hand times, but without the necessity of corrections made by hand.

Conclusions: The ability to generate precise word alignment efficiently in brain imaging studies, with minimal manual intervention, will allow researchers to more easily investigate brain activity at higher-level stages of speech processing.

SA30. Silencing Auditory Cortex After Sound Offset Impairs Tracking of a Learned Sound

Chengcheng Yang¹, William Liu¹, Kai Lu¹, Robert Liu*¹

¹*Emory University*

Background: How sounds acquire communicative meaning through learning is a central question in auditory neuroscience. Our previous work using an ethological sound learning paradigm, demonstrated that (1) auditory cortex (ACx) is necessary for learning sound cues predictive of a social reward (Dunlap et al, *Horm and Behav*, 2020); (2) female mice trained to use sound cues exhibit enhanced cortical firing at the communicative sound's offset (Chong et al, *J Neurosci*, 2020); and (3) auditory cortical activity is prognostically modulated by decision outcomes while performing the task (Lu et al, *bioRxiv*, 2024). We have hypothesized that a learned sound's meaning is reflected in the offset responses of auditory cortex, which enable the integration of sound sequences over time into holistic auditory objects. Here, we tested this hypothesis by optogenetically silencing ACx specifically during offset responses after learning.

Methods: Naïve female CBA/CaJ mice received bilateral injections of AAV-hSyn-eNpHR3.0-EYFP into ACx and were implanted with optic ferrules. After 3 weeks of viral expression, mice were trained to track the playback of an artificial sound to choose the T-maze arm where they would be given a pup to retrieve – a highly stereotyped and rewarding behavior normally elicited by pup ultrasonic vocalizations. We used a sequence of Gaussian noise bursts (60 ms duration, 140 ms gap), band passed between (30-50kHz). Eight mice were trained in the task (100 trials/day); one did not improve with training and was removed. Three mice have reached our learning criterion so far (binomial test, two consecutive days > 68%) within 8-20 days. Performance was then tested over four days under three trial conditions (randomly interleaved, 150 trials/day): (1) no inactivation (50% Control trials); (2) optogenetic silencing during the middle of each noise burst (~25% Middle trials, LED started 20 ms after the sound onset, lasting 20 ms and linearly decaying over 20 ms); and (3) silencing immediately after each noise offset (25% OFF trials, same LED pulse).

Results: Our preliminary results with the 12 test sessions from the three animals showed that silencing ACx in the OFF window significantly impaired task performance compared to Control trials without inactivation ($p < 0.001$, Wilcoxon signed rank test). Silencing ACx during Middle trials had no significant effect ($p = 0.380$).

Conclusions: These results suggest that ACx activity after sound offset may be crucial for retrieving newly learned sound associations and/or using them to guide decisions. Ongoing work will further test this effect to clarify the role of Off responses in auditory learning. Funding provided by NIH R01 DC008343 (RCL).

SA31. Contribution of Descending Auditory Corticofugal Projections to the Spectral and Spatial Response Properties of Neurons in the Inferior Colliculus

Fernando Nodal*¹, Inesh Sood¹, Josh Jankiewicz¹, Eren Akgun¹, Andrew J. King¹, Victoria Bajo¹

¹*University of Oxford*

Background: The descending projection from the auditory cortex to the inferior colliculus (IC) has been implicated in auditory spatial learning, the passive processing of speech-in-

noise, innate defensive fear behavior, and processing of behaviorally-salient stimuli. However, stimulation of auditory cortical inputs has both excitatory and inhibitory effects on the activity of IC neurons and some response properties, such as the spectrotemporal tuning properties of these neurons and their contrast gain control, seem to be independent of cortical inputs. Therefore, how auditory cortex influences the response properties of IC neurons is far from being understood.

Methods: We optogenetically activated corticocollicular neurons in anesthetized ferrets and recorded IC activity using Neuropixels probes to explore the effect of these descending inputs on the frequency selectivity and spatial sensitivity of IC neurons. Channelrhodopsin (ChR2) was expressed in corticocollicular neurons by injecting retrograde virus encoding Cre recombinase (Retro2 AAV.Cre.GFP) at multiple sites in the IC and a viral construct encoding ChR2 in reversed fashion under the FLEX cassette (AAV.Flex.ChR2.mCherry) at multiple locations in the primary auditory cortex (A1) 4-6 weeks before the recordings. Activation of ChR2 expressed in corticocollicular neurons was achieved by blue laser light illumination delivered by an optic fibre with an intensity of 10 mW at the tip, which was placed in the center of the middle ectosylvian gyrus, where A1 is located.

Results: Activation of corticocollicular inputs increased the magnitude of the driven responses to pure tones of most neurons recorded in the central nucleus (CNIC) and the dorsal (DCIC) and external cortex (ECIC) of the IC, while decreasing their frequency selectivity in DCIC and ECIC but not in the CNIC. However, some neurons (24%) showed the opposite effect. Activation of the corticocollicular pathway shifted the frequency tuning of IC neurons, increasing the representation of the most sensitive mid-frequency region (around 10 kHz) in the ferret audiogram. The responses of IC neurons to broadband noise presented diotically were reduced upon concomitant corticocollicular activation, whereas responses to sounds presented in virtual acoustic space became stronger and more broadly tuned, especially for the contralateral hemifield. Preliminary results with recordings under anesthesia, show reduced plasticity in the spatial response properties of IC neurons with a virtual unilateral earplug when the auditory cortex was optogenetically activated.

Conclusions: Our results demonstrate pronounced effects of cortical activation on both the spectral and spatial response properties of IC neurons, paving the way for future experiments in behaving animals to explore the role of this descending circuit in active listening.

SA32. Brain Plasticity Explains Why Deaf Adult Mice Receiving Cochlear Gene Therapy Rapidly Develop Normal Hearing

Kameron Clayton^{*1}, Joanne Li¹, Ethan Lawler¹, Evan Hale¹, Elizabeth Norris¹, Korey Sudana¹, Paul Gratias¹, Jennifer Zhu¹, Artur Indzhukulian¹, Daniel Polley¹

¹*Eaton-Peabody Laboratories, Massachusetts Eye and Ear*

Background: Clinical reports from otoferlin gene therapy trials suggest that the emergence of hearing defined behaviorally (e.g., pure tone detection thresholds) can outpace the degree and rate of auditory brainstem response maturation. This may reflect a progressive maturation of neural synchrony and responsiveness in the early auditory pathway. Alternatively, temporal integration and central gain at higher stages of auditory processing could amplify diminished inputs from the brainstem, producing normal cortical sound representations despite persistently reduced early auditory responses. We tested these two competing models by tracking the day-to-day maturation of sound-evoked activity at every stage of the auditory

neuroaxis in otoferlin-deficient Deaf5 mice that receive otoferlin gene therapy as young adults.

Methods: Deaf5 mice were treated at 6wks postnatal with a research grade hybrid dual-AAV encoding mouse *otof* in the left posterior semicircular canal. Day-to-day changes in sound-evoked ABRs and contralateral cortical auditory evoked potentials (CAEPs) were tracked with chronically implanted microwire arrays in awake, head-fixed mice. We also tracked day-to-day responses in hundreds of chronically tracked cortical pyramidal neuron responses via 2-photon calcium imaging in triple transgenic Deaf5 x VGlut1-cre x jRCaMP8s mice.

Results: Deaf5 mice have no ABR, CAEP, or single neuron calcium responses prior to AAV treatment. Sound-evoked CAEP responses emerged just 48 hrs after treatment and reached age-matched wild-type amplitudes and thresholds within one day (N = 4/4 treated/WT mice). In contrast, ABRs only emerged after a week, with potentials emerging in reverse chronological order, from Wave V to I. In contrast to the CAEP, early ABR wave amplitudes were persistently lower than wild-type controls throughout the first 4 weeks post-treatment, particularly when measured with standard stimulus presentation rates. We then captured the onset of adult sound processing at cellular-resolution with 2-photon calcium imaging (N = 4 treated mice, n = 3,318 neurons). Well-tuned, tonotopically organized cortical receptive fields were observed 48 hrs after treatment. The emergence of inhibitory receptive fields lagged excitatory receptive fields by several days. Cortical neural ensembles decoded pitch-shifted English phonemes at comparable accuracy to age-matched normal hearing controls < 5 days after treatment.

Conclusions: We find that sound-evoked cortical activity emerged within two days of AAV treatment, a week before early ABR waves were measurable, and was indistinguishable from age-matched controls with normal developmental hearing experience within several days. Our results suggest that unlike subcortical sound encoding, which bears indelible marks of developmental deprivation, cortical circuits for temporal integration and gain control support normal sound processing despite the absence of auditory experience throughout development.

SA33. Encoding Auditory Space in Marmoset Cortex

Yi Zhou*¹, Derel Nguyen¹

¹Arizona State University

Background: A century ago Jakob von Uexküll argued that every species inhabits its own Umwelt – a subjective perception of the physical world shaped by its sensory and motor capacities. For foveate primates such as the common marmoset, vision captures only the frontal space, leaving the vast rear hemisphere to be monitored acoustically. How does auditory cortex meet this ecological challenge, and how is its code influenced by visual events that compete for attention in the frontal field?

Methods: We recorded single units in the auditory cortex of awake marmosets in response to 200 ms broadband noises presented from loudspeakers spanning -180° to $+180^\circ$ in azimuth. In alternate sessions a wide field visual image ($\pm 40^\circ$ azimuth) was presented at 0° , providing a frontal visual stimulation. Eye position was continuously tracked with an infrared eye tracking system. Spatial tuning curves were analyzed with circular statistics to estimate best azimuth and tuning width.

Results: Three principles emerged. (1) Direction–sharpness coupling. Tuning sharpened progressively toward the contralateral pole, culminating in a dense cluster of narrowly tuned neurons at -90° . Fisher information analysis revealed that this non uniform distribution

maximizes directional precision at midline 0°— exactly where gaze can be rapidly deployed. (2) Vision dependent gain without remapping. The frontal wide field image multiplicatively scaled firing rates yet left best azimuth unchanged, revealing a cross modal gain field rather than a spatial realignment. (3) Rear space enhancement. Gain modulation of firing rates was strongest in the contra-rear field, suggesting that visual stimulation in front strengthens monitoring of the invisible rear hemifield.

Conclusions: These results outline a dual strategy for constructing a 360° auditory Umwelt: stable directional “anchors” anchored by contralateral sharp tuned neurons, and dynamic gain control that boosts regions left outside the visual fovea when frontal space becomes behaviorally loaded. Our findings bridge classic spatial hearing theory with Umwelt thinking and offer a neural explanation for how primates maintain situational awareness while looking forward.

SA34. Visual Stimulation Alters the Stability of Echo Perception

Yi Zhou*¹, Colton Clayton², Yihan Xue¹

¹Arizona State University, ²Mayo Clinic in Florida

Background: Echo suppression with the Precedence Effect is the brain's ability to minimize distracting reflections by localizing sounds according to the first-arriving wave (lead). This process is not purely auditory: Bishop et al. (2011) showed that visual cues coinciding with a lead increase one-event response, whereas cues with the lag increase two-event response. Whether visual capture of spatial localization occurs simultaneously at the echo threshold, and whether any bias favors the lead or lag, remains unclear. In this study, we investigated how visual stimulation influences both echo response and saccade localization to test the stability of echo perception.

Methods: Twelve normal-hearing adults participated in the experiment. Lead-lag pairs of 15 ms broadband noise bursts were presented from two loudspeakers positioned at $\pm 22^\circ$ in front. Lead-lag delays varied from 0 to 14 ms in 2 ms steps. A 50 ms LED was presented at either the lead or lag position, synchronous with the lead. After central fixation, participants made a saccade toward the perceived direction of the first sound, then pressed a button once to report hearing one event or twice for hearing two events. Eye position and button responses were continuously recorded with an infrared eye-tracking system. Echo response and eye movement were analyzed across delays and visual positions.

Results: Compared to auditory-only conditions, visual cues did not affect one-event response at short delays (0-4 ms) or two-event response at long delays (12-14 ms). At echo threshold (6-10 ms), echo responses varied widely across listeners, and no reliable group-level effect of visual cue position was found. All participants showed lead-dominant localization at 2–14 ms delays. However, visual cues produced two distinct patterns of saccade localization: eight participants exhibited visual capture toward the LED, while four showed repulsion toward the lag, creating a bimodal localization pattern and greater ambiguity between lead and lag directions.

Conclusions: Visual stimulation can flexibly modulate echo suppression - either reinforcing lead dominance or weakening it to allow lag cues to emerge. These dual effects reveal a dynamic perceptual regime in which echoes can be reinterpreted through cross-modal cues, informing models of multisensory spatial integration and echo processing.

SA35. Auditory Selective Attention is Impacted by the Temporal Coherence of a Task-Irrelevant Visual Stimulus in Ferrets

Rebecca Norris^{*1}, Zheyi Tang², Nadia Kordmahale², Jennifer Bizley²

¹*UCL*, ²*UCL Ear Institute*

Background: Multisensory integration is a fundamental property of mammalian sensory systems, allowing us to combine information about objects in the world across senses. Audio-visual integration is especially relevant for understanding auditory processing, as visual information impacts auditory scene analysis, multi-modal object formation and speech processing.

Methods: We trained ferrets on an auditory selective attention go/no-go task, requiring them to respond to the presence of a brief timbre deviant embedded in a target stream while ignoring those in a simultaneous non-target stream. Both streams were independently amplitude modulated artificial vowels, with the target stream cued by beginning 1s earlier than the non-target, and the non-target stream attenuated relative to the target stream by 6-8 dB, with levels determined by the ferrets' performance to avoid floor and ceiling effects. 25% of trials had no timbre deviants in either stream, requiring animals to hold for the full duration of the stimulus. Streams were 5 – 6.2s in duration, and target and non-target streams differed in both pitch and vowel identity (counterbalanced across trials). Each trial had a visual stimulus in which luminance modulation was temporally coherent with amplitude modulation in either the target, non-target or neither stream. Importantly, the auditory feature coherent with the visual stimulus (amplitude) was not informative about the feature used for the detection task (timbre). Properties of the visual stimulus were selected based on those that elicited the greatest impact on neural activity in auditory cortex recorded from ferrets presented with similar audio-visual stimuli in a passive context.

Results: Ferrets performed the task well, and response selectivity (d') was higher when the visual stimulus was coherent with the target stream compared to the non-target stream (0.94 – 1.52 vs 0.84 – 1.2, across 3 animals). The specific effects of visual coherence differed across animals, with d' changes in one animal driven by a higher hit rate in the target-coherent condition, while the two other animals additionally showed an increase in false alarms to non-target deviants when the visual stimulus was coherent with the non-target stream. Ongoing work involves recording neural activity from auditory cortex during task performance to explore how audio-visual integration and selective attention interact to shape the representation of sound in auditory cortical neurons.

Conclusions: Results are in line with previous findings in a human version of this task, suggesting that temporal coherence results in the integration of visual and auditory information to create a cross-modal object.

SA36. Enhancing Music Perception Through Auditory-Vibrotactile Training

Etienne Abassi^{*1}, Philippe Albouy², Emily Coffey³, Andreanne Sharp⁴, Robert Zatorre¹

¹*The Neuro, McGill University*, ²*Universite Laval Faculty of Psychology*, ³*Concordia University*, ⁴*Universite Laval Faculty of Medicine*

Background: Hearing loss can impair the ability to process complex auditory information, such as perceiving speech or music in noisy environments. Even with hearing aids or cochlear implants, limitations persist in encoding fine acoustic details. These deficits reduce

speech understanding and restrict access to music, an essential domain of cultural and emotional life. Auditory-tactile integration provides a promising strategy to address these challenges. Converging evidence indicates that vibrotactile feedback can complement auditory inputs by conveying rhythm, intensity, frequency, or other auditory information. Vibrotactile input engages the somatosensory system, and possibly the auditory system, and may offer a complementary channel for sound perception, that may support everyday listening.

Methods: Our research investigates whether vibrotactile information delivered through a novel technology, the Multichannel Vibrotactile Glove, can enhance auditory perception of short musical excerpts in noise. The glove enables high-fidelity conversion of complex acoustic signals (speech, music) into vibrotactile stimulation, either uniformly across fingers or tonotopically mapped to mimic the auditory system's frequency organization. Participants are randomly assigned to one of three groups: (1) control, auditory-only training; (2) auditory training with uniform vibrotactile feedback; or (3) auditory training with tonotopically mapped vibrotactile feedback. All groups complete a five-session protocol over two weeks, including baseline assessments, three days of training, and post-training evaluation. Auditory perception is measured with the Music-in-Noise Task (MINT), which requires participants to judge whether musical excerpts embedded in noise are the same or different upon repetition. In parallel, neural correlates of sound processing are assessed with EEG during the pre- and post-training sessions, focusing on reconstruction of the acoustic envelope of continuous music as a marker of neural encoding.

Results: Two pilot studies validated the feasibility of this approach. In the first, participants showed improved MINT performance in the auditory-tactile condition, when clean melodies were simultaneously presented through vibrotactile input. In the second, participants receiving combined auditory and vibrotactile stimulation demonstrated additional gains after repeated training, suggesting that vibrotactile feedback provides immediate benefits while also supporting learning over time. We expect EEG data to show enhanced envelope reconstruction for audio-tactile stimulation compared to auditory or tactile input alone. Together, these findings provide encouraging evidence that vibrotactile cues can enhance auditory perception and strengthen neural encoding of sound.

Conclusions: Our preliminary results highlight the potential of tactile feedback to improve auditory perception and engage mechanisms of multisensory plasticity, underscoring the value of multisensory approaches for auditory rehabilitation. If confirmed, these findings could inform the development of novel rehabilitative strategies to support individuals with hearing loss in everyday listening environments. The key take-away is that vibrotactile information delivered through wearable haptic devices has the potential to complement auditory input, promote neural plasticity, and ultimately improve communication outcomes for individuals with hearing loss.

SA37. Evaluating AMPA-Type Glutamate Receptor Saturation at Inner Hair Cell Ribbon Synapses With Glutamate Uncaging and Competitive Inhibition

Walen Gribaudo*¹, Mona Jawad², James Huettner², Mark A. Rutherford², Juan Goutman¹

¹INGEBI (CONICET), ²Washington University in St. Louis

Background: AMPA-type glutamate receptors in the mammalian brain mediate fast neurotransmission and are located in the postsynaptic densities (PSDs). Across synapse types,

the degree to which AMPA receptors are saturated with glutamate during synaptic transmission has been debated. In the mammalian inner ear, glutamatergic synapses are formed between inner hair cells (IHCs) and spiral ganglion neurons (SGNs). A key feature of the presynapse (IHCs) is the presence of a 'synaptic body' or 'ribbon' that organizes synaptic vesicles, modulating rates of glutamate exocytosis. Postsynaptic terminals of SGNs are characterized by large PSDs, 5 to 10 times bigger than those found in the brain. Responses to glutamate uncaging over the whole PSD have suggested that only a fraction of receptors are activated by even the largest events of synaptic transmission (ARO2024 poster, Goutman et al.). We speculate that spontaneous neurotransmission produces an overall low saturation, and therefore low desensitization, of the AMPA receptors in this PSD.

Methods: Explants of the organ of Corti from C57BL/6 mice aged 15-18 days were used. Responses to glutamate uncaging, or glutamate release by IHC evoked by high K⁺ were recorded by patch-clamp directly on SGNs terminals. Uncaging was produced by a 405 nm laser photolyzing the caged compound MNI-glutamate. Different laser intensities were used to produce glutamate transients of varying amplitudes. Competitive antagonism by 1 mM γ -DGG of responses to glutamate uncaging (uEPSCs) or high K⁺-evoked EPSCs (vEPSCs) was used to estimate the saturation level of AMPA receptors. Delivery of drugs was implemented locally through a theta-tube pipette.

Results: The low-affinity competitive antagonist γ -DGG was used to determine the level of saturation of AMPA receptors, as the percentage of block depends on the glutamate concentration. uEPSCs evoked on SGNs with high laser intensity averaged 1092 pA in amplitude and 34% block by γ -DGG, whereas uEPSCs produced by low intensity presented an amplitude of 131 pA and 60% block, with a linear relationship within a range of intermediate laser pulses. In recordings with approximately 1000 events each, vEPSCs had average amplitudes of 229 pA and block of 59%. Analysis of γ -DGG block of the 10% largest and 10% smallest vEPSCs showed differences in percentage of block that are consistent with concentrations of glutamate that are intermediate between those of uEPSCs evoked by low and high laser intensities.

Conclusions: The effect of γ -DGG on uEPSC evoked with varying laser intensities is consistent with AMPA receptors activated by different glutamate concentrations. This is also true for vEPSCs of different sizes. The overall percentage block of these synaptic currents suggests unsaturated receptors during neurotransmission between IHCs and SGNs.

SA38. Modulation of D-Serine Sensitive NMDAR Signaling as a Therapeutic Avenue for Excitotoxic Auditory Synaptopathy

Tong Yang^{*1}, Joseph Vecchi², Anissa Rym Saidia¹, Florence Francois¹, Jerome Ruel³, Jing Wang¹

¹INSERM, ²University of Iowa Hospitals and Clinics, ³C2VN, Aix-Marseille Université, INSERM

Background: Excessive glutamate release at the inner hair cell (IHC)–spiral ganglion neuron (SGN) synapse, triggered by noise, ototoxins, or aging, drives AMPAR-mediated excitotoxic synaptopathy. This pathology, marked by terminal swelling, ribbon synapse loss, and reduced auditory nerve output despite normal thresholds, underlies noise-induced “hidden hearing loss.” In contrast, cochlear NMDARs remain largely silent under physiological conditions but can be engaged under pathological stress. Since D-Serine, synthesized by serine racemase

(SR) in cochlear cells, acts as an NMDAR co-agonist, its modulation may rebalance NMDAR and AMPAR activity during excitotoxic insult.

Methods: We examined the role of D-Serine-induced NMDAR activation in cochlear synaptopathy and repair using two models: (i) a kainate-induced synaptopathy model in neonatal (P3) mouse cochlear explants, and (ii) an impulse noise exposure model (146 dB SPL, 1 pulse/s, 700 s) in vivo. Molecular assays, ultrastructural analysis, auditory brainstem response (ABR) recordings and acoustic startle reflex tests were combined to assess D-Serine's contribution to NMDAR function and excitotoxic pathophysiology.

Results: In the presence of NMDA, D-Serine significantly reduced kainate-induced acute synapse loss in cochlear explants and protected against impulse noise-induced threshold shifts in vivo. D-Serine-treated animals exhibited preserved ABR wave I amplitudes and higher synapse counts compared to noise-exposed controls. This protective effect was abolished by co-treatment with 5,7-dichloro-4-hydroxyquinoline-2-carboxylic acid (DCKA), a selective antagonist of the NMDAR glycine/D-Serine binding site.

Conclusions: These findings identify D-Serine-mediated activation of silent cochlear NMDARs as a protective mechanism against AMPAR-driven excitotoxic synaptopathy. Targeting D-Serine signaling may therefore represent a promising therapeutic strategy for auditory disorders associated with excitotoxic damage.

SA39. Modelling Auditory Nerve Demyelination upon Induction of Schwann Cell Loss in Mature Adult and Aging DTA Mice

Nicole Zoghby¹, Riya Patel¹, Jessica Cornberg¹, Ailee Snapko¹, Shreeya Sawant¹, Elizabeth Markuson¹, Hongji Zhang², Maria Traka², Michael Ebeid³, Riya Patel*²

¹Midwestern University Chicago College of Osteopathic Medicine, ²Midwestern University, ³Midwestern University College of Graduate Studies

Background: Demyelinating diseases of the PNS can be either inherited, such as Charcot-Marie-Tooth (CMT), or acquired from an autoimmune insult, trauma or nerve injury. In these diseases, a substantial damage to Schwann cells (SCs) lead to loss of the myelin sheath and subsequent impaired peripheral nerve conduction. Enhancing the endogenous remyelination potential of the PNS is a promising therapeutic approach for promoting functional recovery and axonal survival in these demyelinating diseases. PLP-CreERT;ROSA26-eGFP-DTA (DTA) mouse is an established model for studying the effects of the specific ablation of Plp1-expressing glial cells in the nervous system upon induction of expression of the diphtheria toxin A subunit. Previous work has shown that robust SC regeneration and axonal remyelination occur in the auditory nerve a few weeks after SC ablation in young DTA mice. The process of glial cell regeneration and ultimately remyelination in aging auditory system has not been investigated yet.

Methods: Three age groups (mature-adult; 4-month-old, middle-aged; 9-month-old and aged; 12 to 14-month-old) of PLP-CreERT;ROSA26-eGFP-DTA mice, both males and females, were treated with 4-hydroxytamoxifen (labelled as DTA mice) for three to four continuous days (Traka, 2019) to induce Cre-recombination and cell death in Plp1-expressing glial cells in the PNS. Uninduced PLP-CreERT;ROSA26-eGFP-DTA littermates were used as controls. Recovering DTA mice are collected at different time points post-induction (p.i. 1, 3 and 5 weeks). Inner ears are fixed, then spiral ganglion and auditory fibers are dissected and immunoassayed to label different types of glial cell and neuronal cell markers, node of Ranvier/paranode/juxtaparanode markers and macrophage cell markers. Proliferation in glial

cells is analyzed using 5-ethynyl-2'-deoxyuridine (EdU) cell proliferation marker injected 24 hours before collecting mice. Auditory brain stem responses (ABR) are used to assess hearing thresholds. Transmission electron microscopy is used to identify myelin and neuronal ultrastructure.

Results: In mature-adult DTA mice, SC density was 56%, 76% and 81% compared to controls at 1-, 3-, and 5-week p.i respectively, indicating a gradual recovery of SCs. SC proliferation showed 3.8-fold increase in DTA mice at 1-week p.i. compared to controls. ABR showed 10-20 dB shift at 4 and 8kHz at 5-week p.i. and 0.2-0.3 ms increase in peak I latency across most frequencies at both 3- and 5-week p.i compared to preinduction levels ($n = 6-10$ /age group, males only, Mixed-effects analysis with repeated measure and Tukey's multiple comparison tests, adjusted P Value < 0.05). TEM data showed generally intact myelin in both mature-adult and middle-aged DTA mouse groups, yet signs of active, ongoing myelin degradation and phagocytosis were noticed.

Conclusions: Robust SC regeneration occurs after cell ablation in mature-adult auditory system relying mainly on activated glial cell proliferation. Overall, despite the SC regeneration, persistent functional defects exist in auditory system of the aging DTA mice probably due to impaired PNS remyelination.

SA40. Objective Measures of Loudness in Cochlear-Implant Hearing

Charlotte Garcia¹, Dorothee Arzounian¹, Francois Guerit¹, Robert Carlyon^{*2}

¹University of Cambridge, ²Cambridge Hearing Group, University of Cambridge

Background: Objective measures provide a way to program cochlear implants (CIs) for patients, including infants, who cannot provide reliable reports. The Electrically Evoked Compound Action Potential (ECAP) can be measured quickly and does not require additional equipment, but the literature reveals only modest between-participant correlations with thresholds or most-comfortable-loudness levels (MCLs). In addition we (Garcia et al, JARO, 2021) showed that ECAPs can vary substantially across electrodes for a given participant even when all electrodes are stimulated at MCL. Experiment 1 tests two explanations for this discrepancy by measuring ECAPS in conditions that manipulate effects of neural synchrony and refractoriness. Experiment 2 combines and compares objective measures of the neural response of multiple stages of the auditory system to the same CI stimulus, to further probe this discrepancy and to obtain insights into the neural bases of loudness perception.

Methods: Many ECAP studies, including Garcia et al (2021), use the masker-probe (MP) method of artefact cancellation, whereby masker and probe pulses are presented separately and in quick succession. The resulting ECAPs depend on the masker in the combined stimulus reducing the neural response to the probe via refractory effects. Differences in refractoriness could therefore cause ECAP amplitudes to differ between equally-loud stimulation of different electrodes. Experiment 1 measured ECAPs on all electrodes for 11 users of Advanced Bionics CIs, using both the MP and the alternating-polarity (AP) artefact-cancellation paradigms, as the AP paradigm is immune to refractoriness. Both conditions used symmetric-biphasic pulses. Because of evidence that auditory-nerve (AN) response is more jittered to cathodic than to anodic stimulation, we additionally used the MP method with pseudomonophasic pulses consisting of a cathodic-leading long, low-amplitude phase followed by a short, high-amplitude anodic phase. We reasoned that the jittered response to the cathodic phase of symmetric pulses might contribute to loudness but not to ECAPs, and that this effect would be reduced by the low-amplitude cathodic phase in pseudomonophasic stimulation. Experiment 2 presents loudness-balanced ~40-pps pulse trains separately to six

electrodes spaced along the array, and simultaneously measures ECAPs, EABRs, and EASSRs using recently-developed methods and a hyper-rate EEG system (Arzounian et al, Hearing Research, 2025).

Results: Experiment 1 found no evidence that the across-electrode standard deviation (s.d.) of ECAP amplitudes differed significantly between conditions. Experiment 2 (underway) will compare the s.d. in each measure across the (equally-loud) stimulation of the 6 electrodes. To determine which measure most accurately reflects loudness these s.d. values will be compared to the effect of changing stimulus level for each measure.

Conclusions: Factors other than refractoriness or neural jitter are responsible for the discrepancy between ECAP amplitudes and loudness. Simultaneous measurements of the AN, brainstem, and thalamic/cortical response to the same CI stimulus may inform the neural stages determining loudness perception.

SA41. The UmboMic: Surgical Approach and Fixation

John Zhang*¹, Emma Wawrzynek¹, Julie Arenberg², D. Bradley Welling³, Ioannis Kymissis⁴, Elizabeth Olson⁴, Jeffrey Lang¹, Hideko Heidi Nakajima⁵

¹Massachusetts Institute of Technology, ²Massachusetts Eye and Ear Infirmary, Eaton Peabody Laboratory, ³Harvard U/ Mass Eye and Ear, ⁴Columbia University, ⁵Harvard Medical School, Mass. Eye and Ear Infirmary

Background: The cochlear implant of the future will be invisible to the naked eye. Currently, several totally implantable cochlear implants (TICIs) are in clinical trials. The core challenge remains delivering comparable audio quality to external microphones without excessive noise. An implantable microphone must have long-term robustness, simple surgery, low power consumption, and high margin of safety. Of the proposed TICIs, two use subdermal microphone and one uses middle ear microphones. The subdermal microphone is low risk, but sacrifices audio quality. Middle ear microphones would enable higher fidelity hearing. For the latter, without a well-engineered fixation system, even the best sensor is impractical.

Methods: We present a novel fixation system for our UmboMic sensor, which senses umbo motion. The design must offer adequate stiffness while permitting uncoupled motion in the key degrees of freedom to simplify surgery. We used kinematic analysis, stiffness calculations, and finite element simulation to validate performance. A 3D printed temporal bone provided preliminary sizing and positioning. Surgeon feedback and temporal bone experiments refined the geometry and size of the final design. The fixation system reaches through the facial recess and facilitates contact of the UmboMic to the umbo.

Results: A stainless-steel prototype was fabricated via wire EDM, waterjet, and machining. The prototype was tested in temporal bones to verify size, placement, and positioning. A bone plate is used to anchor to the mastoid cortex and sensors are glued to the distal end of an extensible arm for positioning. The low profile design provides visual access for the surgeon. Simulations show a fixation-to-sensor stiffness ratio ≥ 10 . The components of the fixation system can be locked in place using UV-curing glue. Techniques with applications to surgery such as the use of a viscous adhesive to form a foundation upon which to rest the fixation system in the mastoid bowl and an audio feedback mechanism for determining coupling to the umbo were explored.

Conclusions: We describe the design methodology, analysis, and initial validation of a fixation system. We find the stiffness ratio must be satisfied for good microphone performance. Thus, implant-grade stainless steel is preferred and the mastoid cortex is a

suitable anchor. The minimal design uses locking revolute and prismatic joints to achieve the desired motion and stiffness with flexural mechanisms as a possible enhancement. Further improvements pertain to the locking mechanism and custom tooling for facilitating surgery, eventually leading to experiments in cadaveric heads of the full implantable microphone (sensor, amplifier, fixation system) to evaluate system performance. This is a critical and anticipated step in the development of an implantable middle ear microphone for use with future TICIs.

SA42. Fiber-Specific Modeling of Electrically Stimulated Auditory Nerves

Rebecca Felsheim¹, David Sly², Stephen O'Leary³, Mathias Dietz^{*1}

¹*University of Oldenburg*, ²*Ear Science Institute Australia*, ³*University of Melbourne*

Background: A quantitative description of the functioning of electrically stimulated nerve fibers, as provided by a computational model, is of central importance to better leverage the potential of neuroprostheses, such as cochlear implants. However, there is virtually no openly available data of electrically stimulated auditory nerve (AN) fiber responses. Publications only offer graphic images of selective example neurons or in the form of population averages, posing severe limitations for follow-up studies, especially for modeling studies.

The goal of the present study is to demonstrate the added value of having access to a rich data set by fitting parameters of a computational model to individual fibers. As an exemplary application we compare chronic with acutely deafened fibers both with and without the model.

Methods: Spike times and voltage traces from 188 electrically stimulated auditory nerve fibers from guinea pigs, which were originally recorded by Heffer et al. (Journal of Neurophysiology 104, 2010), have been made publicly available (Heffer et al. Zenodo, 2025). 118 of these recordings were usable for this work – 74 of these fibers were from acutely deafened animals and 44 from deafening five weeks before the recordings. The stimuli were 100-ms long constant amplitude biphasic pulse trains, with multiple amplitudes and pulse rates.

We optimized the parameters of a leaky-integrator-based model of an electrically stimulated auditory nerve fiber (Felsheim and Dietz, Trends in Hearing, 2024) for the 118 fibers, to reproduce the response patterns as closely as possible. We then used the 118 fiber-specific models to extract established measures, such as refractory period or facilitation, and compared them to measures obtained directly from the recorded spike times.

Results: The response patterns of individual nerve fibers varied widely, generally in line with previous reports. When looking at the differences between the acutely deafened and the chronically deaf group, we saw that the longer deafened nerve fibers responded on average more than the acutely deafened ones. This was reflected in the model parameters, which showed a shorter refractory period for the chronically deaf fibers. For high-amplitude 1000 pps pulse trains, we found a significantly higher vector strength in the chronically deaf group and, correspondingly, a lower jitter was estimated using the model.

Conclusions: The model-based analysis of this large set of electrically stimulated auditory nerve fibers allows to analyze and explain fiber-specific response patterns as well as group differences between fibers from acute versus chronically deaf guinea pigs. In this way, more information can be extracted from existing data as with conventional analysis methods.

SA43. Effects of Phonological Working Memory and Speech Recognition in Quiet as Predictors of Speech-In-Speech Recognition in Adolescents and Young Adults With Early Cochlear Implantation

Josefin von Wachenfeldt¹, Johanna Eklind¹, Malin Dahlby Skoog², Ulrika Löfkvist³, Filip Asp^{*2}

¹Karolinska University Hospital, ²Karolinska Institute, ³Uppsala University

Background: Auditory neurocognitive models suggest that degraded auditory input affects the development of mental phonological representations, which are critical for phonological working memory -- a subcomponent of working memory responsible for the temporary storage and processing of information that specifically handles speech-related information. While children with cochlear implants show deficits in phonological working memory, it remains unclear whether these deficits are related to speech recognition under challenging listening conditions, as is the case for children with normal hearing. The aim of this study was to investigate the effects of phonological working memory and speech recognition in quiet on speech-in-speech recognition in adolescents and young adults with early cochlear implantation.

Methods: Thirty-four adolescents with bilateral cochlear implants participated (mean age = 16.5 years; range: 12.8 – 21.7 years). The mean age at first implantation was 1.3 years (range: 0.6 – 2.2 years). The participants completed three tasks: recognition of speech-in-quiet, recognition of speech-in-speech and repetition of nonwords. Speech-in-quiet (SIQ) was measured at 65 dB SPL in sound-field at frontal incidence using a Swedish clinical speech audiometry test, consisting of phonemically balanced lists of 50 monosyllabic words. The outcome was the proportion of correctly identified words. Speech recognition threshold (SRT) in competing speech was assessed using an adaptive psychoacoustic procedure. The target speech consisted of Swedish Hagerman sentences and was presented from a frontal speaker, whereas the competing speech – set at a fixed level of 63 dB SPL -- was spatially symmetrically separated from the target. The threshold was set to 40% correct speech recognition. Phonological working memory was assessed using the Repetition of Nonwords (RON) task from a computer-based test battery. Participants repeated nonwords of varying complexity presented as auditory-only stimuli through loudspeakers. Performance was scored using the percentage of correctly repeated consonants. A multiple linear regression analysis was performed with SRT as dependent variable and SIQ and RON as covariates.

Results: Multiple linear regression analysis revealed that the combination of phonological working memory and speech-in-quiet scores explained 47 % ($p < 0.001$) of the variability in speech-in-speech recognition. Phonological working memory explained 28 % ($SRT = 4.5 - 15.0 \times RON$, $p = 0.001$) and speech-in-quiet 39 % ($SRT = 11.9 - 0.2 \times SIQ$, $p < 0.001$) of the variability, respectively.

Conclusions: For adolescents with early implantation, phonological working memory is a factor in the ability to recognize speech masked by speech. By integrating cognitive and audiological factors into a unified model, the present findings contribute to the understanding of how speech recognition under adverse listening conditions may be improved. Further research on this association is warranted, as supporting phonological working memory in children with CI may benefit their speech recognition in challenging environments.

SA44. Electric Acoustic Interaction Across Auditory Pathway in Cochlear Implant Users With Ipsilateral Acoustic Hearing

Hanna Dolhopiatenko*¹, Waldo Nogueira²

¹*Hannover Medical School*, ²*Medical University Hannover and Cluster of Excellence, “Hearing4all”*

Background: Cochlear implant (CI) users with electric acoustic stimulation (EAS) combine electric stimulation (ES) through the CI and acoustic stimulation (AS) through the ipsilateral residual hearing. EAS typically improves speech perception, suggesting interaction between the two modalities. Psychoacoustic studies using acoustic masking of electric stimuli have provided evidence for such interactions, showing stronger masking with greater residual hearing. Moreover, acoustic masking has been observed at the base of the cochlea. The underlying mechanisms of this interaction remain insufficiently understood. Gaining deeper insight into the fundamental neural processes of electric-acoustic interaction through masking studies could facilitate the development of less invasive extracochlear implants and objective diagnostic tools for assessing low-frequency hearing. Such advances would be particularly valuable for newborn hearing screening, where current methods for accurately evaluating low-frequency residual hearing remain limited.

Methods: Eight EAS CI users with partial insertion participated in the current study. Three electrodes were tested: most apical active (A_El), most basal active (B_El) and a deactivated extracochlear electrode located at the round window niche (RW_El). Auditory brainstem responses (ABRs), middle-latency responses (MLRs) and cortical auditory evoked potentials (CAEPs) were measured to the electric pulses presented at the most comfortable level (MCL) across three electrodes. The same recordings were then obtained in the presence of a continuous acoustic noise at MCL, to assess electric-acoustic interactions. Evoked responses were measured using conventional averaging paradigms. In addition, a novel deconvolution method capable of capturing evoked responses across the entire auditory pathway within a single recording was validated in CI users for the first time.

Results: Deconvolution proved feasible for assessing evoked responses in CI users. ABRs, MLRs, and CAEPs were consistently measurable at A_El, while responses at B_El were observed only in a subset of participants. At RW_El, evoked responses were measurable in some participants, with MLRs being the most prominent. When continuous acoustic masking noise was introduced, preliminary analyses revealed the strongest suppression of evoked responses in the cortical region.

Conclusions: It was possible to measure evoked responses at RW_El in some participants demonstrating the potential of extracochlear stimulation. While reliable responses to electric stimulation were obtained at the A_El in all participants, responses at the B_El were less consistently observed. Analysis of acoustic masking on electric stimulation revealed that the most prominent suppression of neural responses occurs at cortical level. Moreover, these preliminary findings demonstrate the feasibility of using the deconvolution method to record evoked responses and analysis the interactions between acoustic and electric stimulation in CI users.

This project received funding from the European Research Council (ERC) under the European Union's Horizon-ERC programme (Grant agreement READIHEAR No. 101044753. PI: Waldo Nogueira) and from the ATRAE project NEUROHEAR from the Agencia Estatal de Investigación (Grant NEURO-HEAR: ATR2023-145064, PI: Waldo Nogueira).

SA45. Attentional Processing in CI-Users and Normal-Hearing Listeners Signified by Alpha Oscillatory Activity

Brilliant Brilliant*¹, Irina Schierholz², Pascale Sandmann³, Andrej Kral¹

¹*Institute of AudioNeuroTechnology, ENT Clinics, Hannover Medical School*, ²*Faculty of Medicine and University Hospital Cologne, University of Cologne*, ³*Carl von Ossietzky University Oldenburg*

Background: Cochlear implants (CIs) allow hearing-impaired individuals to gain access to speech, but the outcome variability remains high. The auditory input of a CI through electrical stimulation is in many respects different than acoustic stimulation of the normal hearing, yet the effect of this difference on cognitive processing of auditory input is not fully understood. Hearing with a CI requires more cognitive resources, involves more listening effort and requires more attentional resources. The objective in this study was to identify the oscillatory signature of attentional processing in CI users and to compare them with normal-hearing (NH) listeners.

Methods: Electroencephalographic (EEG) data (128 channels) were recorded from postlingually deafened CI users (n = 37) and NH controls (n = 37) during performance of a three-stimulus auditory oddball experiment. The paradigm consisted of frequent standard tones (Standard), infrequent deviant tones (Target) and infrequent unique complex sounds (Novel), all lasting for 400 ms. The participants performed the experiment once in an active and once in a passive condition, where in the active condition, they were instructed to respond via button press to the Target. The analysis of the EEG data included a time-frequency analysis, a reconstruction of the neural sources via beamforming and the estimation of neural activity in the transverse temporal gyrus (TTG), dorsolateral prefrontal cortex (DLPFC) and inferior parietal lobules (IPL).

Results: The most prominent oscillatory activities were found when involving attention towards the auditory stimulus (active condition, particularly in response to the Target). Attention-related oscillations were analyzed by subtracting the response to the Standard stimulus from the response to the Target stimulus. These included delta-theta synchronization, alpha desynchronization and beta desynchronization. The alpha desynchronization, observed in previous EEG studies in attention-related tasks, was prominent in both groups. Interestingly, CI users exhibited additional alpha signature also during Novel processing, suggesting that CI users elicit additional attention to the task-irrelevant stimuli. Furthermore, during Novel processing, the source reconstruction revealed an additional alpha source in CI users in the left parietal cortex. Combined with the distinct local neural activities in TTG, DLPFC and IPL, these data suggest that CI users recruit a different attentional network than NH listeners.

Conclusions: The present study revealed oscillatory markers of auditory attentional processing in CI users. CI users direct more attention towards task-irrelevant stimuli and utilize different attentional networks compared to NH listeners. In summary, the results in this study align with previous literature identifying alpha desynchronization as a reliable objective marker of attentional processing.

SA46. AC102 Hydrogel Combined With a Dexamethasone-Eluting Cochlear Implant Electrode Protects Residual Hearing and Reduces Electrode Impedances

Anselm Gadenstaetter*¹, Matthias Gerlitz¹, Till Buschhorn¹, Erdem Yildiz¹, Lisa Ashmawy¹, Marva Hamidi¹, Caroline Sesztak¹, Michael Nieratschker¹, Clemens Honeder¹, Christoph Arnoldner¹

¹*Vienna General Hospital, Medical University of Vienna*

Background: Cochlear implantation (CI) remains the most effective and widely accessible therapeutic intervention for individuals with severe-to-profound sensorineural hearing loss. Despite its well-established clinical benefits, CI can be associated with several limitations, such as electrode insertion trauma resulting in damage to the sensory and neural cells of the inner ear, as well as foreign body reactions leading to fibrotic tissue formation around the electrode carrier. The aim of this project was to evaluate the therapeutic potential of the promising compound, AC102, in combination with dexamethasone (DEX)-eluting CI-electrodes.

Methods: In Mongolian gerbils, AC102 formulated in a thermoreversible hydrogel was applied intratympanically either 1 or 24 hours prior to CI. Alternatively, control (CTRL)-hydrogel was injected 24 hours before intervention. Subsequently, either DEX-loaded or unloaded CI-electrodes were implanted via the round window. Thus, 5 different study groups (CTRL-/24h-AC102/1h-AC102 hydrogel and unloaded-electrode, CTRL-/24h-AC102 hydrogel and DEX-electrode; n = 10-16 per group) were followed up to 90 days with regular audiometric testing including cochlear compound action potential (CAP), and CI-electrode impedance measurements. After the study endpoint, animals were euthanized and cochleae harvested for histological analysis, including assessment of spiral ganglion neuron density and cochlear fibrosis formation, as well as quantification of hair cell and synapse survival.

Results: At the 90-day follow-up, AC102 treated animals had significantly lower CAP-threshold shifts in low frequencies (1 and 2 kHz) compared to untreated animals. This protective effect was less pronounced and insignificant in frequencies corresponding to the anatomical cochlear region surrounding the electrode tip (4 and 8 kHz). In high frequencies (16 and 32 kHz), AC102 treatment again led to lower CAP threshold shifts. Notably, CAP thresholds in these frequencies were higher in animals implanted with a DEX-electrode. Furthermore, impedances were significantly lower in animals implanted with DEX-eluting electrodes compared to animals implanted with unloaded-electrodes. Histological analysis is ongoing and will provide further insights into the cellular and structural mechanisms underlying the effects AC102 and DEX treatment.

Conclusions: This study confirms the otoprotective properties of AC102 in CI. Furthermore, it builds upon previous findings by demonstrating a synergistic effect when combined with DEX-eluting electrodes, evident in both the preservation of residual hearing and the attenuation of cochlear fibrosis. Notably, the timing of AC102 administration did not significantly influence outcomes, a factor that could support the development of flexible pre-treatment CI protocols in a clinical setting. Elevated CAP-threshold shifts at high frequencies following implantation of DEX-eluting electrodes may be attributed due to an increased rigidity of the electrode carrier, an effect likely to be less pronounced in the larger, human cochlea. Altogether, these findings underscore the promising therapeutic potential of AC102 in CI – particularly in combination with a DEX-eluting CI-electrode.

SA47. A Single-Center Study of Pupillary Dilation During Post-Auricular Vagal Nerve Stimulation in Cochlear Implantation

Maya Hatley*¹, Arianna Winchester¹, Sophie Jabban¹, Michael Bartellas¹, Justin Cottrell², Mario Svirsky¹, J. Thomas Roland Jr.¹

¹New York University Grossman School of Medicine, ²Yale School of Medicine

Background: Rehabilitation after cochlear implantation (CI) may require neuroplasticity as patients adapt to novel electrical sound signals.¹ Vagus nerve stimulation (VNS) has been shown to enhance neurocognitive function and knowledge acquisition, with recent studies showing that concurrent auditory input and VNS drive auditory cortex neuromodulation.² Animal studies have also shown VNS to improve performance on auditory learning tasks.³ VNS may therefore have applications in post-CI rehabilitation. As Arnold's nerve, a vagus nerve branch, can be visualized during the post-auricular CI approach, this study examined whether intraoperative stimulation of Arnold's nerve affects vagal activity, indexed by pupil dilation.

Methods: This IRB-approved, prospective study included 18 CI patients. An anesthesia protocol was developed to minimize confounding effects on vagal tone. A standard post-auricular CI incision was made, followed by a modified PALVA flap to preserve Arnold's nerve branches. Stimulation occurred prior to mastoidectomy completion. Baseline pupil size was obtained with the Neurolight pupillometer. Negative-leading biphasic stimulation (via the Medtronic NIM-Response 3 system) was applied at 0.5, 1.0, and 1.5 mA across three external auditory canal sites. Stimulation was applied for 10–30 seconds with continuous pupillometry measurements. Patients were classified as “responders” or “non-responders” using a threshold of $\geq 5\%$ average change in pupil diameter. We also assessed whether current amplitude or location of stimulation affected change in pupil size among responders.

Results: Of the 18 patients included in this study, pupillometry data from 14 patients were available for analysis. Among these 14 patients, 10 (71%) were classified as responders with a mean percent change in pupil size of 9.30% (SD: 8.0%). On linear regression, the percent change in pupil size was not significantly associated with current amplitude ($p > 0.05$). All sites of stimulation resulted in similar pupil dilation ($p > 0.05$). Only one patient exhibited a significant within-subject effect of location on change in pupil diameter ($p = 0.013$). No adverse events were noted during stimulation, including facial nerve stimulation, hemodynamic instability, or laryngeal stimulation.

Conclusions: In this preliminary study, intraoperative Arnold's nerve stimulation produced significant pupillary dilation in most patients. Pupil change was not significantly influenced by current amplitude or site of stimulation. If Arnold's nerve stimulation can safely and reliably generate VNS, it may offer an accessible post-auricular target for implantable VNS devices to enhance learning during post-CI aural rehabilitation.

SA48. Developing Optimization Strategies to Compensate for Losses Due to Auditory Nerve Synaptopathy

Ahsan Cheema*¹, Sunil Puria²

¹Harvard Medical School, Massachusetts General Hospital, ²Harvard Medical School

Background: Difficulty understanding speech in noise is the most common complaint of patients with sensorineural hearing loss. Cochlear neural degeneration (CND)—the loss of peripheral auditory nerve fibers (ANF)—has been hypothesized as a major contributor to

these deficits, yet it remains sub clinical in audiometry measurements. In the absence of noninvasive methods to probe for neural deficits, current hearing-aid (HA) fitting algorithms, such as NAL/NL2, which are based solely on audiometric thresholds, ignore the neural component of hearing loss. The first question we address in this study is how to effectively design speech stimuli that can probe deficits resulting from CND. The second question that we address in this study is how to explore the Hearing Aids parameter space to specifically address neural deficits.

Methods: We used a phenomenological model of auditory periphery (Bruce et. al 2018), to simulate the auditory nerve fiber responses to input sound stimulus. (1) To address the 1st question i.e. the effectiveness of speech materials to detect CND, we developed a Mutual information based framework that uses loss of information between inner hair cells receptor potential and ANFs to quantify the loss of encoding and reduction in information carrying capacity of ANF due to CND. (2) For the second question i.e. Hearing aids fitting, we developed a Simulation-Based Inference (SBI) pipeline to optimize HA level compression algorithms with a focus on compensating for CND. We simulated speech processing under varying degrees of sensory loss and CND. The HA parameter space, including compression threshold, slope, and attack/release times, were systematically explored within the SBI framework to identify parameter sets that minimize neural deficits. Our approach aims to identify alternative parameter combinations that could, in theory, provide better neural compensation and improve speech-in-noise performance.

Results: (1) Our mutual information framework suggests that time-compressed speech (40% and 65% dilatation) produces the greatest sensitivity to CND-related information loss, making it an effective speech probe for evaluating neural deficits. (2) Preliminary results indicate that hearing aid parameters can be explored using SBI to address CND deficits as a framework to reveal parameter-space not captured by the standard NAL/NL2 prescription, particularly for challenging listening conditions.

Conclusions: This project establishes an SBI-based approach to systematically evaluate and optimize HA parameter settings in the context of CND. By highlighting where current gain prescriptions fail, we will re-evaluate compensation strategies to better address the hidden neural deficits underlying speech-in-noise difficulties. Moreover, by exploring the larger parameter space of HA algorithms, this work could uncover fitting strategies that provide more effective compensation for CND-related deficits. [Work supported by MEE SharkTank award and grant R01 DC07910 from the NIDCD of NIH.]

SA49. Electrical and Biological Investigation of Electrospun PvdF-TrFE Fiber Mats to Reduce Fibroblast Growth After Cochlear Implantation

Vinzent Braemer^{*1}, Jan Drexler², Tom Bode², Thomas Lenarz¹, Gerrit Paasche¹

¹Hannover Medical School, ²Leibniz University Hannover

Background: Cochlear implants (CI) are implanted to restore hearing in patients with severe to profound sensorineural hearing loss. Due to the foreign body response and insertion trauma, connective tissue is formed around the electrode array, which electrically insulates the implant, hampering electrical stimulation of the auditory nerve. Modification of the electrode surfaces might be a way to reduce the adhesion of connective tissue. In the current study, fiber mats consisting of the hydrophobic material poly(vinylidene fluoride-trifluoroethylene) (PVDF-TrFE) were investigated in vitro regarding electric conductivity, biocompatibility, and growth of fibroblasts on their surfaces.

Methods: Fiber mats of three different thicknesses (15, 30 and 45 min spinning time) were cut into 2x6 cm rectangular samples. Using an in-house manufactured chamber with four measuring cells, the increase of impedance and the wetting process over time was measured on conventional SEM holders. In a second step, fibers were spun directly on platinum electrode contacts of a similar size as in CI electrode arrays, which were embedded in silicone. In addition, biocompatibility tests were performed as eluate tests on primary spiral ganglion cells and NIH/3T3 fibroblasts to investigate cytotoxicity. Furthermore, the growth of eGFP NIH/3T3 fibroblasts was examined on Ø 6 mm circular samples for seven days by means of confocal laser scanning microscopy and compared to the growth on cell culture material.

Results: The increase in impedance was dependent on the thickness of the fiber mats (thinnest: $1169.63 \pm 248.32 \Omega$, thickest: $3209.64 \pm 556.72 \Omega$). Immersion in physiologic saline decreases impedance in a time dependent manner. Wetting of the mats can be accelerated by the additional use of EtOH. The only constraint in biocompatibility was found with 100% extraction solution ($66 \pm 7 \%$ cell viability for 4h drying time, $57 \pm 10 \%$ for 24h drying time). The growth of fi-broblasts is reduced on the electrospun fiber mats compared to the surrounding cell culture material (fiber mat 70.8 ± 10.9 average fluorescence intensity, $82 \pm 2.9 \%$ cell covering after 7 days), (surroundings 79.5 ± 5.7 average fluorescence intensity, $92.2 \pm 0.7 \%$ cell covering after 7 days).

Conclusions: A thin film of electrospun PVDF-TrFE seems to have the potential to reduce fibroblast growth on stimulating contacts of CI electrodes without increasing the electrode impedance too much. An appropriate strategy for wetting the mesh appears mandatory.

SA50. Comparing Psychophysical Tuning Curves (PTCs) and Spread of Excitation (SOEs) in Children and Adults With Cochlear Implants

Scott C. Aker^{*1}, Dietmar Wohlbauer¹, Charles Hem², Caylin McCallick³, Julie Arenberg¹

¹Harvard Medical School, Massachusetts Eye and Ear, ²Harvard University, ³Massachusetts Eye and Ear

Background: Cochlear implants (CIs) can restore a sense of sound to people with severe hearing loss. However, while CIs are generally effective at providing speech understanding in quiet, noisy situations can still be a challenge. One possible reason is poor frequency selectivity, in which certain frequencies are more easily masked by sounds in nearby frequencies. The exact cause of this is not known, however one strong candidate is channel interaction, in which neighboring electrode channels stimulate overlapping regions of auditory nerve fibers. It has been shown that pediatric CI users perform better in vowel identification in noise than adult CI users (Arjmandi, 2025), signifying improved frequency selectivity. One reason could be that the central processing of pediatric CI users has better adapted to the CI and is less dependent on the periphery. In this pilot study, we test the hypothesis that pediatric CI users will have similar measures of channel interaction (spread of excitation or SOEs) to adult CI users but better behavioral measures of frequency selectivity (psychophysical tuning curves or PTCs) compared to adults.

Methods: Five pediatric CI users (ages 11–17, M = 14 years) with Advanced Bionics processors were compared with nine previously tested adults (ages 23–75, M = 52 years). Pediatric users were tested on electrode 8, adults on two electrodes with high and low thresholds. Three-point PTCs were obtained by measuring probe thresholds on electrode 8 in a 25 dB SPL-equivalent on-frequency masker, then raising the masker 12 dB and sweeping from basal and apical sides until detection failed. The probe was 20 ms, the masker 200 ms

with a 5 ms gap. Basal and apical slopes were then calculated. SOEs were measured with panoramic ECAPs (biphasic, cathodic-leading pulses) and fit with Gaussian curves to derive slopes. Linear regression tested whether age group predicted SOE or PTC slopes.

Results: PTC slopes ranged from 3.18–17.75 dB/electrode ($M = 8.08$) in pediatric users and 1.68–23.37 dB/electrode ($M = 8.75$) in adults. SOE slopes ranged from 0.06–0.23 ($M = 0.11$) for pediatric users and 0.004–0.25 ($M = 0.11$) for adults in proportion of max amplitude/electrode. Age group did not show a significant effect on PTC slopes ($p = 0.47$) or SOE slopes ($p = 0.94$).

Conclusions: We hypothesized that age group would not predict differences in SOE slopes but would predict sharper PTCs for the pediatric group. According to the present data, age group did not predict PTCs. Alternative measures may better account for differences in vowel performance for pediatric CI users, such as years of listening experience.

SA51. Evaluating Stimulation Strategies for Selective Activation of Auditory Nerve Fibers in a Guinea Pig Model

Inderbir Sondh^{*1}, Hubert Lim¹, Lei Feng¹

¹*University of Minnesota*

Background: Selective activation of distinct neural populations is essential for high-resolution neural prosthetic systems. In cochlear implants (CIs), current spread through cochlear fluids and current shunting along the cochlear bony anatomy limit spatial precision. In contrast, the auditory nerve implant (ANI) interfaces directly with the central axons of spiral ganglion neurons (SGNs), enabling more localized depolarization and hyperpolarization of relevant neural populations. This direct interface provides a unique opportunity to enhance spatial and temporal selectivity by optimizing stimulation waveform shape and timing, an approach shown to be effective in other neuroprosthetic systems, such as motor, somatosensory, and retinal implants. In this study, we systematically evaluate strategies for improving selective activation of auditory nerve fibers by varying stimulation configurations, pulse waveform parameters, and interleaved pulse timing. We assess how these factors influence spatial activation patterns and temporal response profiles through electrophysiological recordings in the auditory midbrain.

Methods: A 2-shank, 32-site electrode array (NeuroNexus) was positioned along the tonotopic axis of the central nucleus of the inferior colliculus (ICC) in ketamine-anesthetized guinea pigs to record multi-unit activity. Acoustic responses to pure tones (1–40 kHz) across eight intensity levels (0–70 dB SPL) were recorded to validate electrode placement and generate a frequency response map for reference during electrical stimulation. A transcochlear surgical approach was used to expose the modiolar portion of the auditory nerve. A 16-site single-shank edge electrode array (NeuroNexus) was inserted into the auditory nerve bundle for electrical stimulation. Charge-balanced biphasic pulses with a 40 μ s inter-phase gap were delivered using either cathodic- or anodic-leading waveforms. Pulse durations ranged from 40 to 120 μ s. Return electrodes were configured for either monopolar or bipolar stimulation. Additionally, interleaved stimulation across neighboring sites was tested to assess spatial interaction effects.

Results: On average, bipolar stimulation resulted in higher activation thresholds but more spatially confined responses in the ICC compared to monopolar stimulation. Thresholds decreased with increasing pulse width; however, spatial variability in threshold across the 16 stimulation sites increased with shorter pulse durations. This variability was more

pronounced in the bipolar configuration. No consistent threshold difference was observed between cathodic- and anodic-leading pulses within our limited sample. Interleaved stimulation across neighboring electrodes reduced cross-channel interference and preserved spatial selectivity.

Conclusions: Our results show that stimulation configuration (e.g., monopolar vs. bipolar), waveform characteristics (e.g., pulse width), and temporal strategies (e.g., interleaving) have a significant impact on activation thresholds, dynamic range, and spatial activation patterns in the auditory midbrain. These effects are likely driven by underlying physiological factors such as electrode-to-fiber distance, axon diameter, and the distribution of the electric field. Understanding how these neural response differences relate to perceptual outcomes, such as spectral resolution and loudness growth, is essential for guiding the development of next-generation auditory prostheses.

SA52. Development and Translation of a Novel Auditory Nerve Implant to Restore Hearing in Deaf Patients

Hubert Lim¹, Inderbir Sondh^{*1}, Lei Feng¹, Abigail P. Heiller¹, Karl-Heinz Dyballa², Moritz Leber³, Joseph Crew³, Keno Hubner⁴, Waldo Nogueira⁵, Luke Johnson¹, Geoffrey Ghose¹, William Thomas⁶, Holly Holman⁷, David J. Warren⁷, Richard Gurgel⁷, Steven A. Zuniga⁸, Aaron Loveland¹, Lisa Larson¹, Robert Franklin³, Stefan Strahl⁹, Amir Samii¹⁰, Andrew Oxenham¹, Loren Reith¹¹, Florian Solzbacher¹², Meredith Adams¹³, Thomas Lenarz¹⁴

¹University of Minnesota, ²Hannover Medical School (MHH), ³Blackrock Neurotech, ⁴MED-EL, ⁵Hannover Medical School and Cluster of Excellence Hearing4all; Universitat Autònoma de Barcelona, ⁶Johns Hopkins University, ⁷University of Utah, ⁸Shohet Ear Associates, ⁹MED-EL GmbH, ¹⁰International Neuroscience Institute, ¹¹West Virginia University, ¹²University of Utah, Blackrock Neurotech, ¹³University of Michigan, ¹⁴Hannover Medical School, Cluster of Excellence Hearing4all

Background: The cochlear implant is one of the most successful neural prostheses, with more than one million devices implanted into patients worldwide. However, advancing the performance of cochlear implants by better stimulating the auditory nerve has plateaued, largely due to the difficulty in directly stimulating the auditory nerve through the bony wall of the cochlea. This has limited progress in improving outcomes for real-world tasks such as understanding speech in noise and for music appreciation. Our project has developed a novel auditory nerve implant (ANI) that combines a Blackrock Neurotech ANI electrode array coupled to a MED-EL Synchrony 2 cochlear implant stimulator. The goal is to evaluate the benefits of more direct and focal microstimulation of the auditory nerve compared to a cochlear implant, which will be assessed through perceptual testing in an upcoming pilot clinical study. Extensive technology development, along with multiple pre-clinical and intraoperative clinical evaluations have been performed to pave the way for the pilot study of the ANI device, which is expected to initiate in Fall 2025.

Methods: Our pre-clinical studies included over 40 human cadaver head experiments to develop the proper surgical approach for the ANI. Additionally, a chronic cat ANI study was successfully performed with 3-month endpoints after device implantation. More recently, a first-in-human intraoperative study with nine volunteers was performed under Ethics Committee approval at the Hannover Medical School in Hannover, Germany. The electrical stimulation regimen for both the cat and intraoperative studies was evaluated through

electrically evoked auditory brainstem responses (eABRs) and electrode impedance measurements. Intraoperative experiments were performed with volunteers receiving tumor resection surgeries by a translabyrinthine approach, which is the same surgical approach planned for the upcoming ANI clinical study (future surgical approaches that do not compromise the labyrinth are also being investigated for broader patient adoption). The surgical approach, device handling, and electrode placement, as well as eABRs and electrode impedances were evaluated in the intraoperative study using a wired version of the ANI system.

Results: We found that the ANI could be safely and successfully positioned into the auditory nerve while exhibiting low stimulation thresholds between 20 and 40 μA , which are an order of magnitude lower than that observed with cochlear implant stimulation. eABR measurements showed robust activation of downstream auditory brainstem structures. Our chronic experiments in the cat model supported the sustained health of the nerve and performance of the device over clinically relevant periods.

Conclusions: Overall, our results have justified our upcoming ANI pilot clinical study, which has obtained Ethics Committee approval at the Hannover Medical School. In that study, we aim to collect first-in-human data showcasing surgical implantation of the ANI into the auditory nerve, stability and safety of the implant, and preliminary perceptual outcomes of ANI stimulation.

SA53. A Deep Learning Framework for Understanding Cochlear Implants

Annesya Banerjee^{*1}, Mark Saddler², Julie G. Arenberg³, Josh McDermott⁴

¹Harvard University, ²Technical University of Denmark, ³Massachusetts Eye and Ear, Harvard Medical School, ⁴MIT

Background: Cochlear implants (CIs) aim to replace dysfunctional cochlea in people with severe hearing loss by electrically stimulating the auditory nerve. Although highly successful, CIs fail to restore normal perception in many listening situations. Performance outcomes may be limited by stimulation strategies, neural degeneration, or suboptimal decoding by the brain. We propose a deep learning framework to evaluate these issues by estimating best-case outcomes with task-optimized decoders operating on simulated auditory nerve input from CI stimulation.

Methods: We optimized deep artificial neural networks to recognize words and localize sounds using simulated CI-stimulated auditory nerve representations, on the assumption that the performance of such models should approach the best that is possible given the simulated CI. Once trained we compared the models to humans as well as to models optimized for normal hearing input (all tested on the same tasks). To investigate outcomes for different device manufacturers (Cochlear, MedEl, Advanced Bionics), we separately trained models on simulated nerve activity evoked by their respective sound-coding strategy. To gain insight into other factors that might limit outcomes, we also manipulated the dynamic range and spatial spread of current, the extent of simulated neuronal loss, and the number of neural network stages optimized for CI input (simulating limits on plasticity).

Results: Best-case CI models exhibited impaired speech recognition and sound localization relative to the normal hearing model. Human CI users tested on the same task exhibited a range of behavior, with the best-performing users approaching the behavior of the best-case models. Performance was similar across the different sound coding strategies. Model performance was influenced to varying degrees by the dynamic range and spread of current,

neural survival, and the extent of neural network optimization, potentially explaining gaps between some CI users and the best-case models.

Conclusions: Our results clarify the factors limiting prosthetically mediated hearing and illustrate a framework for predicting real-world behavioral outcomes from candidate prostheses, opening the door to large-scale screening of new device strategies.

SA54. High-Resolution Computer Models Show Neural Degeneration is the Primary Obstacle for Multipolar Cochlear Implant Stimulation

Albert Croner¹, Jonas Geissdoerfer¹, Siwei Bai¹, Werner Hemmert*¹

¹*Technical University of Munich*

Background: Cochlear implants electrically stimulate the auditory nerve and restore hearing to otherwise deaf individuals. Electrical stimulation, however, is broad, resulting in a small number of available independent channels. An attempt to deliver a more "focused" stimulation was the introduction of multipolar stimulation, e.g., bipolar and tripolar stimulation. In multipolar stimulation, all active and return electrodes are intracochlear, theoretically resulting in narrower, more focused electric fields. Nevertheless, multipolar stimulation has not led to advantages in speech understanding compared to the classic monopolar stimulation.

In this study, we used computer models of the human cochlea and auditory nerve to investigate why multipolar stimulation did not outperform monopolar stimulation, clarifying key constraints for future stimulation strategies.

Methods: We simulated a volume conduction model of the cochlea using the finite element analysis to obtain current spread through the inner ear, for monopolar (MP), bipolar (BP), and tripolar (TP) stimulation. The volume model was based on a high-resolution μ CT scan of a human cochlea (6 μ m voxel size). Based on the calculated current spread, we simulated the excitation of 400 spiral ganglion neuron fibers distributed along the tonotopic axis of the cochlea. Neuron models were biophysical multi-compartment models, simulated in an intact and a degenerated state. We obtained excitation patterns of the auditory nerve, and analyzed their focality and excited regions.

Results: Multipolar stimulation of intact neurons exhibited excitation not only close to the active, but also close to the return electrodes. Excitation close to return electrodes is commonly described as "side lobes". Notably, pronounced excitation gaps were found between active and return electrodes, i.e., multipolar excitation happens primarily at the electrode locations, not in between.

Regarding focality, with intact neurons, TP was generally more focal than BP and MP, despite the observed side lobes. With degenerated neurons, MP, BP, and TP were similarly focal, except that MP was comparatively more focal at high loudness levels.

Excited regions were interpreted as "place pitch". Pitch analysis was focused on cases of pitch confusion and pitch reversals. With intact neurons, pitch confusions were observed in MP and BP, while TP pitch progression was almost perfect. With degenerated neurons, MP displayed increased pitch confusions, while with BP and TP multiple pitch reversals were observed.

Conclusions: Spiral ganglion neuron degeneration is likely the main reason multipolar stimulation does not perform better than monopolar stimulation. In a perfectly intact auditory

nerve, we observed advantages of TP stimulation, which were unfortunately lost with degenerated neurons.

SA55. Assessing Spatial Hearing in Pediatric Unilateral Conductive Hearing Loss With Head-Tracking and Bone Conduction Devices

Hillary Snapp^{*1}, Sebastian Ausili¹, Sandra Prentiss², Jean LaGuerre¹, Chrisanda Sanchez²

¹*University of Miami*, ²*University of Miami Miller School of Medicine*

Background: Unilateral conductive hearing loss (UHL) disrupts integration of binaural cues that underlie spatial hearing, leading to deficits in sound localization and spatial release from masking (SRM). Early auditory deprivation may result in persistent impairments in spatial processing, limiting the extent to which later amplification restores accurate binaural cue use. While implanted osseointegrated bone-conduction devices (BCDs) provide direct-drive stimulation with stable high-frequency transmission, transcutaneous non-surgical BCDs are often used in early childhood but deliver intermittent, attenuated stimulation. The impact of these differences on spatial hearing outcomes in children with UHL, remains unclear

Methods: We studied 8 children with implanted BCDs, 8 with transcutaneous non-surgical BCDs, and 8 age-matched normal-hearing (NH) peers. Participants completed a spatial speech perception task in four-talker babble with target sentences from 0° and ±60° azimuth across progressively poorer signal-to-noise ratios (SNRs). Continuous head-orienting behavior was recorded using a custom tracker. Primary outcomes included speech reception thresholds (SRTs) and reaction time to initiate head orientation toward targets. Secondary measures captured orienting dynamics, including number of head turns, corrective responses, cumulative orientation, and trial-to-trial variability.

Results: All participants showed performance decrements when signals were delivered to the impaired ear compared to the open ear or frontal targets. Implanted BCD users generally achieved better SRTs than transcutaneous users for targets on the impaired side ($p < 0.05$), though performance remained poorer than NH controls at low SNRs. Head-tracking analyses indicated NH children executed single, efficient turns with short latencies and low variability. BCD users, regardless of device type, exhibited longer reaction times, more corrective turns ($p < 0.05$), and larger cumulative head movements ($p < 0.05$), compared to NH controls. Transcutaneous users tended toward delayed initiation, increased orienting attempts, and greater overall excursion, particularly at poorer SNRs; however, the range of orienting behaviors was variable and overlapped with implanted BCD users.

Conclusions: Implanted BCDs provide more consistent stimulation and support measurable improvements in speech perception for targets on the impaired side compared with transcutaneous systems. Results also suggest that implantable BCDs support more efficient orienting behaviors compared to transcutaneous. Continuous head-tracking metrics offer ecologically valid, objective measures of spatial hearing that complement traditional audiologic outcomes. These findings highlight the role of device transmission characteristics in shaping access to binaural cues and provide insight into how different BCD approaches support spatial hearing development.

SA56. Frequency-Space Relationships in Barn Owl Auditory Pathways: Comparing Identity and Spatial Processing Streams

Roland Ferger*¹, Mohammad Rashid¹, Andrea Bae¹, Yoram Gutfreund², Brian Fischer³, Jose Luis Pena¹

¹*Albert Einstein College of Medicine*, ²*The Technion*, ³*Seattle University*

Background: Previous work in barn owl midbrain has revealed a systematic relationship between frequency tuning and spatial representation in the space map: neurons representing frontal space preferentially respond to higher frequencies than neurons representing peripheral space (Shadron and Peña, 2023; Cazettes et al., 2014). This frequency-space correlation emerges within the topographic space map of ICx, where precise spatial representations are first established. However, the barn owl auditory system employs two parallel forebrain pathways: an identity pathway (ICCore, Ov, Field L) that bypasses spatial maps entirely, and a precise localization pathway (ICCore, ICCls, ICx, OT, nRt, Entopallium). Understanding whether frequency-space relationships are pathway-specific has direct implications for comprehending the functional organization of auditory processing.

Methods: We record from Field L in the identity pathway of anesthetized barn owls using multi-electrode arrays while presenting broadband and narrowband dichotic stimuli corresponding to multiple azimuthal locations by varying the interaural time difference (ITD). For each recorded unit, we quantify frequency tuning (0.5-12 kHz) and spatial receptive fields, then analyze correlations between best frequency and preferred azimuth. Population-level analyses will examine whether alternative organizational principles emerge in this identity-processing stream. Future experiments may extend recordings to the spatial processing pathway (nRt/Entopallium) to directly compare how frequency-space relationships manifest across parallel auditory streams.

Results: Since Field L receives auditory information that branches off before spatial map formation in ICx, we predict it will exhibit robust frequency tuning but lack the systematic frequency-space correlations observed in midbrain space maps. This absence would support the hypothesis that frequency-space relationships emerge specifically within topographic spatial representations rather than being a fundamental property of all auditory processing. The identity pathway's organization may reveal alternative principles for integrating frequency and spatial information that serve stimulus recognition rather than precise localization. These findings will provide insights into how different auditory pathways solve distinct computational problems and inform our understanding of how frequency-specific spatial processing deficits might arise from pathway-specific damage.

Conclusions: This research addresses a fundamental question about the functional organization of parallel auditory processing streams. By testing whether frequency-space relationships are specific to spatial map pathways or represent a general organizational principle, we will reveal how the auditory system partitions computational resources between identity and spatial processing. The predicted absence of frequency-space correlations in Field L would demonstrate that this organizational principle emerges specifically within spatial maps and serves precise localization rather than general auditory processing.

SA57. Cue Weighting in Auditory Source-Width Judgments: Implications for Binaural Cue Extraction

G. Christopher Stecker*¹, Sara Momtaz¹, Selena G. Hopkins-Morand², Margaret K. Miller¹, Brittany T. Williams¹

¹*Boys Town National Research Hospital*, ²*University of Arizona*

Background: The spatial extent of a perceived sound, i.e., its apparent auditory source width (ASW) is known to vary with interaural coherence (IAC), or the similarity of waveforms arriving at each ear. Generally, greater IAC is associated with compact images whereas low IAC results in greater ASW, consistent with impacts of diffuse or reverberant sound. Lower IAC is also associated with greater (and more rapid) fluctuations in interaural differences of time (ITD) and level (ILD). It is not known whether the impacts of IAC on ASW relate to these fluctuations (and, if so, which ones) or to some other aspects of IAC per se. Past research suggests the importance of low-frequency IAC cues, implicating fluctuations of interaural phase difference. Here, we consider the relative weighting of ASW cues across the frequency spectrum and temporal extent of brief partially correlated noises.

Methods: Pairs of reproducible noise bursts of 100-ms duration and 0.3 octave bandwidth were presented stereophonically in the free field while manipulating the coherence of left and right audio channels. Noise bands were centered on 500, 1000, 2000, or 4000 Hz presented singly or in combination. Listeners used a graphical interface to report ASW and position judgments for each presentation. Spectral, temporal, and cross-cue weighting functions were estimated using multiple regression of judgments onto trial-by-trial variation in binaural features of each noise token extracted using simple peripheral models. Targeted features included envelope and fine-structure IAC, and dynamic ITD and ILD computed at multiple time scales.

Results: Significant variation in ASW was noted across tokens despite close matching of IAC. Token-level analyses suggest that ASW judgments reflect specific spectrotemporal dynamics of binaural cues, rather than the long-term or nominal IAC. Spectral weighting functions generally favored 500 and 1000 Hz components, consistent with a dominant role for low-frequency fine-structure cues.

Conclusions: Sensitivity of ASW judgments to temporal fluctuations of ILD and ITD, rather than IAC per se, appears consistent with known mechanisms of binaural-cue extraction supporting localization and binaural discrimination. The spectrotemporal characteristics of this process appear consistent with a dominant role of low-frequency ITD cues (as in localization), although quantitative differences in the range of frequencies and epochs involved may be noted.

SA58. Toward the Realistic VR Sound Localization Test: From Generic Audio to Personalized Recordings

Seungik Jeon^{*1}, Sun-Jeong Kim², Hyo-Jeong Lee³

¹*Laboratory of Hearing, Balance and Integrated Neuroscience (HBIN), Hallym University College of Medicine, ,* ²*Hallym University,* ³*Hallym University College of Medicine*

Background: Sound localization is a core component of auditory spatial perception, relying on cues such as interaural time difference (ITD), interaural level difference (ILD), and spectral cues. However, hearing-impaired individuals such as single-sided deafness (SSD) struggle to utilize these cues effectively, leading to impaired directional hearing and challenges in daily life. Nevertheless, clinical evaluation of sound localization is rare, as it requires specialized facilities and costly equipment. This study aims to develop an optimal auditory stimulus to establish a sound localization test system based on virtual reality (VR) technology, which not only overcomes the cost and spatial limitations of traditional sound

localization evaluations but also ensures a precise assessment of hearing-impaired individuals.

Methods: 20 participants with normal hearing (NH) and 14 with SSD (7 right, 7 left) underwent sound localization tests in sound field (SF) and a VR environment. All sound localization tests used seven speakers at frontal hemifield with 30-degree intervals. Three types of noise stimuli were used: broadband (BB), low-pass with a 1,500-Hz cutoff (LP), and high-pass with a 3,000-Hz cutoff (HP). Each 500 ms stimulus (5-ms rise/fall) was presented in two spectral profiles at 55-, 60-, and 65-dB HL. In total, 126 randomized trials (18 stimuli, 7 speakers) were delivered per condition. In VR, three types of stimuli were compared: (1) Unity-based directional audio (VR audio, VRA), (2) KEMAR-recorded audio (KR), and (3) personal recorded audio (PR). Root mean squared error were compared across conditions, and the level of deficit was categorized following the ICF framework.

Results: When compared the contained spatial cues across the VR audio stimuli, PR/KR offered similar spatial cues, while VRA oversimplified and exaggerated them. In the NH group, localization error in the SF was significantly smaller than that in all three virtual conditions. Among the three virtual conditions, errors were smallest in the PR and largest in the VRA, while the KR did not differ significantly from the PR condition. SSD participants showed no significant difference between SF and VRs, with wide interindividual variability. When applying the ICF framework across 3 VR conditions, PR condition yield the most consistent result (70.58%) with the lowest error (SD: ± 0.55) comparing to the SF, demonstrating its superior reliability as a sound localization test.

Conclusions: The result of the study underscores the potential of VR tests to enhance reliability and utility in clinical and research contexts. In particular, the PR condition yielded results most comparable to those obtained from traditional sound-field localization tests, highlighting its clinical relevance and the importance of individualized auditory spatial stimuli in virtual environment.

SA59. From Innate Bias to Learned Cues: The Role of Spatial Localizability and Perceptual Learning in the Auditory Looming Bias

Robert Baumgartner^{*1}, Tobias Greif¹, Karolina Ignatiadis², Diane Baier¹, Roberto Barumerli³, Brigitta Tóth⁴

¹*Acoustics Research Institute, Austrian Academy of Sciences*, ²*Acoustics Research Institute, Austrian Academy of Sciences*; ³*MED-EL Medical Electronics*, ⁴*Acoustics Research Institute, Austrian Academy of Sciences*; *University of Verona*, ⁴*Institute of Cognitive Neuroscience and Psychology, HUN-REN Research Centre for Natural Sciences*

Background: The auditory looming bias (ALB) describes the prioritized processing of approaching over receding sounds, supporting automatic hazard detection in dynamic environments. We previously showed that ALB is present from birth in Heschl's gyrus and persists even during inattentive listening. These findings suggest both innate and attention-independent components while leaving room for cue-specific flexibility. To probe this flexibility, we examined whether ALB depends on sound localizability and whether it can incorporate attentively learned spatial information.

Methods: In a completed study, we disrupted spectrospatial associations on the perceptual level while preserving acoustic complexity, and assessed behavioral discrimination, distance ratings, and EEG responses in comparison between native and those novel spectral cues. In an ongoing study, listeners were trained to consciously localize sounds using the novel

spectral cues, and ALB-related neural markers were collected during passive listening before and after training.

Results: Disrupting spectrospatial associations impaired localization in direction and distance and significantly altered ALB manifestation. N1 latency closely resembled distance ratings, and integrating this neural marker into a hierarchical perceptual decision-making model improved explanatory power, demonstrating a strong link between spatial localizability and ALB-related processing. For the ongoing study, we hypothesize that training will enhance ALB for novel spectral cues, such that attentively acquired localization knowledge will generalize to the sub-conscious hazard detection mechanism.

Conclusions: ALB comprises innate and attention-independent components but also relies on spatial localizability. Current work will test whether attentively learned localization cues can be integrated into this early hazard detection mechanism. Together, these studies shed light on the adaptive interplay between inborn mechanisms, automatic processing, and the flexible incorporation of learned spatial information in looming perception.

SA60. Long-Term Outcomes and Usage Patterns in Pediatric Sequential Bilateral Cochlear Implantation

Yi-Lu Li^{*1}, Chia-Szu Chen¹, Hui-Mei Yang¹, Jiunn-Liang Wu¹

¹*National Cheng Kung University Hospital*

Background: Bilateral cochlear implantation (CI) has emerged as a standard approach for auditory rehabilitation in children with severe-to-profound hearing loss. However, disparities in the timing of second-side implantation (CI2) and its long-term usage patterns remain key determinants of auditory outcomes.

Methods: This retrospective cohort study analyzed 14 pediatric cases (8 female, 6 male) who underwent sequential bilateral cochlear implantation. Audiological assessments included Categories of Auditory Performance (CAP), Pure Tone Audiometry (PTA), Lexical Neighborhood Test (LNT), and Word Discrimination Scores (WDS) at 3, 6, 12, 24, 36, 48, and 60 months post-CI2. Usage duration of CI2 was categorized as: stable use (≥ 8 hrs/day), moderate use (2–8 hrs/day), or minimal use (< 2 hrs/day).

Results: The mean age at CI1 and CI2 activation was 6.0 and 13.1 years, respectively, with an average inter-implant interval of 7.1 years. Nine patients maintained stable CI2 use, while three had minimal or no usage. Patients with consistent CI2 usage demonstrated significantly higher bilateral LNT scores at 12 months (mean: 82) compared to non-users (mean: 52). Bilateral WDS at 24 and 60 months remained above 80% in stable users but declined markedly in minimal users. Longitudinal data showed improved bilateral performance over time, though CI1 consistently outperformed CI2, particularly in early months post-activation. Refusal to use CI2 was often attributed to poor subjective auditory experience or psychological resistance.

Conclusions: In conclusion, long-term bilateral cochlear implant benefit is closely associated with consistent CI2 usage. Delayed implantation and poor adherence substantially impair CI2 performance and reduce overall binaural gain. Early intervention and post-implantation counseling are crucial to maximize CI2 utility and long-term auditory outcomes in sequential bilateral CI users.

SA61. Circulating Cell-Free Mitochondrial DNA as a Predictive Biomarker for Treatment Outcomes in Sudden Sensorineural Hearing Loss

Chao-Hui Yang¹, Yi-Lu Li^{*2}, I-Ya Chen¹, Ming-Yu Yang¹

¹*Chang Gung University*, ²*National Cheng Kung University Hospital*

Background: Sudden sensorineural hearing loss (SSNHL) is a common otologic emergency with variable outcomes following steroid therapy. Identification of biomarkers that can predict prognosis remains a critical unmet need. Circulating cell-free mitochondrial DNA (ccf-mtDNA) has been implicated in inflammation and tissue injury, but its role in SSNHL has not been well established. This study aimed to evaluate the association between plasma ccf-mtDNA levels, disease severity, and treatment outcomes in patients with SSNHL.

Methods: We enrolled 50 patients diagnosed with SSNHL prior to initiation of steroid therapy, along with 30 age- and sex-matched healthy controls. Plasma samples were collected on the morning before treatment. Quantitative polymerase chain reaction was used to measure ccf-mtDNA levels, expressed as log copy numbers per milliliter. Audiometric outcomes were assessed by hearing gain, percentage of recovery, and Siegel's criteria at follow-up. Multivariate logistic regression was applied to identify independent predictors of recovery.

Results: Baseline plasma ccf-mtDNA levels were significantly elevated in SSNHL patients compared to controls (mean $\pm$ SD: 8.10 ± 0.35 vs. 7.78 ± 0.65 log copies/mL; $p < 0.01$). Among patients, those with good recovery demonstrated higher pretreatment ccf-mtDNA levels than those with poor recovery (8.29 ± 0.34 vs. 8.02 ± 0.33 ; $p < 0.05$). Ccf-mtDNA levels were positively correlated with hearing gain ($r = 0.486$, 95% CI: 0.227–0.663) and percentage of recovery ($r = 0.361$, 95% CI: 0.103–0.574). Logistic regression showed that shorter duration from onset to treatment (< 7 days; OR: 7.389, 95% CI: 1.324–41.239) and higher ccf-mtDNA levels (OR: 24.634, 95% CI: 1.878–323.163) were independent predictors of favorable outcome.

Conclusions: Elevated pretreatment ccf-mtDNA levels were strongly associated with improved hearing recovery after steroid therapy in SSNHL. These findings suggest that ccf-mtDNA represents a promising prognostic biomarker that could guide clinical decision-making, allowing earlier identification of patients likely to benefit from steroid treatment. Future studies should investigate the mechanistic role of ccf-mtDNA in cochlear pathophysiology and explore its utility in tailoring individualized treatment strategies for SSNHL.

SA62. Open Board

SA63. Human Temporal Bone Histopathology in DFNB8: Findings From Two Brothers With TMPRSS3 Variants

Diana M. Correa^{*1}, Jennifer T. O'Malley¹, Sami Amr², Alicia M. Quesnel¹

¹*Massachusetts Eye and Ear, Harvard Medical School*, ²*Laboratory for Molecular Medicine, Mass General Brigham*

Background: Genetic hearing loss accounts for nearly 60% of sensorineural hearing loss cases worldwide. Mutations in the transmembrane protease serine 3 (TMPRSS3) gene cause autosomal recessive non-syndromic hearing loss, with either prelingual (DFNB10) or

postlingual (DFNB8) onset, and represent the eighth most common cause of genetic hearing loss. To date, no human histopathological data have been reported for TMPRSS3-related hearing loss. This study presents the temporal bone histopathological findings from two brothers with DFNB8.

Methods: Sixty-nine temporal bone donors with suspected genetic hearing loss, based on clinical history and with available frozen muscle (n = 40) or buccal swabs (n = 29), underwent whole-exome sequencing. Temporal bones from identified candidates were processed using standard histological techniques, followed by comprehensive histopathological analysis. Fractional hair cell survival was quantified using differential interference contrast (DIC) microscopy at 100x magnification. Supporting cell survival was evaluated using a semi-quantitative scale, and spiral ganglion neuron (SGN) counts, and three-dimensional distribution were obtained using a customized MATLAB analysis pipeline. Immunohistochemistry for TMPRSS3 protein was performed in normal control specimens to characterize its expression pattern in the human temporal bone.

Results: Two brothers were identified as compound heterozygotes for TMPRSS3 mutations, carrying the missense variants c.1276G > A (p.Ala426Thr) and c.413C > A (p.Ala138Glu). Clinically, both developed progressive hearing loss in their late twenties, which progressed to profound loss and led to unilateral cochlear implantation.

Histopathological analysis in the three available ears demonstrated poor survival of both inner and outer hair cells throughout the cochlear duct. Supporting cell survival was greater toward the apical turns but transitioned to a completely flat epithelium in the basal region above approximately 2 kHz. SGN survival differed markedly between the brothers: one exhibited reductions of 50.3% (right ear) and 56.5% (left ear) compared with age-matched controls, whereas the other demonstrated SGN counts exceeding 100% of age-matched controls.

Immunohistochemistry for TMPRSS3 performed in normal controls (n=11) showed specific labeling of Deiters' and Hensen's cells, as well as inner and outer hair cells, with particularly strong signal in the stereocilia. The outer and inner sulcus as well as the stria vascularis also exhibited specific staining. SGNs demonstrated a differential staining pattern suggesting distinct SGN populations.

Conclusions: This study provides the first human temporal bone histopathological description of TMPRSS3-related hearing loss. The findings reveal widespread hair cell loss, variable SGN survival between individuals with the same genotype, and distinct TMPRSS3 protein localization within cochlear supporting cells, hair cells, and SGNs. These results expand the understanding of the cellular pathology associated with DFNB8 and may inform future therapeutic strategies.

SA64. Automatic Scoring of Speech in Noise Tests

Malcolm Slaney*¹, Varsha M Athreya¹, Linnea Munro¹, Emily Saletan¹, Jwala Rejimon¹, Matthew Fitzgerald¹

¹*Stanford University*

Background: Measurement of speech recognition abilities is crucial given that the top complaint of individuals with hearing difficulties is understanding speech in noise. However, there are several limitations to the standard approach used in clinical and research settings. First, testing patients in a non-native language is problematic. Second, human scorers may be biased towards the expected words. Finally, audiologist-driven scoring limits the number of

individuals we can test. These issues can be addressed using automatic speech recognition (ASR); and are now feasible given advances in AI and speech-recognition systems.

Methods: We implemented 6 tests of speech recognition (CNC, QuickSIN, WIN, and AzBio in varying signal-to-noise ratios (SNR)). A tester played the sounds and scored the tests in real time. Spoken utterances were stored for later analysis. We tested 28 native English subjects, half of whom had normal hearing thresholds. The remaining individuals all had bilateral sensorineural hearing loss. We scored 4310 participant responses. Each response was converted to text using the Whisper AI Large Recognizer (v20250625). We scored each answer by looking for exact textual matches, regardless of their position or grammatical issues.

Results: We found that human and machine recognition agreed ~93% of the time for the multi-word tests (QuickSIN, AzBio) and ~81% of the time for the single word tests (CNC, WIN). This correspondence was similar across varying degrees of hearing loss and SNR values. In a random sample of 100 discrepancies, we found that 9 times the tester was incorrect, and 37 times the ASR system transcribed the answer incorrectly. There were three other types of errors, which we now realize were due to our experimental setup and thus correctable. These include 10 times when the ASR engine switched languages, 32 times when the recognizer produced a homonym or a variant of the word we were not expecting (5 vs. five). And 12 times when there was a recording issue and we should have asked the subject to respond again.

Conclusions: These results demonstrate that Automatic Speech Recognition is a feasible approach for scoring audiologic tests of speech recognition in quiet and noise in patients with normal hearing or hearing loss. This approach can enable open-set speech recognition tests measured online or remotely, and may therefore have many clinical or research applications. Going forward we want to 1) better characterize the discrepancies between machine and human scoring, 2) investigate the recognizer's biases, and 3) develop open-source testing material across a range of languages that we see in our clinic. In this way we can ensure that online testing of open-set speech materials is both robust and repeatable.

We appreciate funding from the Stanford Center for Digital Health.

SA65. Specialty-Specific Symptom Profiles for Vestibular Schwannomas: Insights From NLP Analysis of Otolaryngology and Neurosurgery Clinical Notes

Connie Chang-Chien*¹, Kevin Xin², Nicole Jiam¹

¹University of California - San Francisco, ²University of California - Irvine

Background: Vestibular schwannomas (VS) patients commonly present with hearing loss, tinnitus, dizziness, and imbalance. Both ENT and neurosurgery (NSG) evaluate VS, and documentation emphasis may differ in ways that reflect specialty-specific evaluation and management. This study seeks to compare specialty-specific documentation patterns using Natural Language Processing (NLP).

Methods: We compiled 982 de-identified clinical notes for 739 patients with first-time clinic visits to ENT (n=412) or NSG (n=570) at a tertiary academic medical center between 2014-2024. Notes were cleaned and pre-processed using stop words and Regex rules to filter out non-first-time clinic visits and templated history and physical exam findings. Note text was embedded with a Clinical BERT transformer model to obtain fixed-length semantic vectors, and a low-dimensional structure was visualized with t-Distributed Stochastic Neighbor

Embedding (t-SNE). Discriminability of specialties in the original embedding space was evaluated with logistic regression (AUC). Vocabulary divergence was quantified with bootstrap Jensen-Shannon distance (JSD). Clinically relevant bi-grams and tri-grams were extracted, and specialty frequency differences were tested with a two-proportion Z-test.

Results: Embedding revealed strong specialty-specific documentation patterns. In 2-D t-SNE, notes exhibited partial provider clustering with overlap; global separation was modest (silhouette score 0.05, centroid Euclidean distance 1.10; $p < 0.001$). In contrast, a logistic regression on all embeddings distinguished ENT vs NSG with near-perfect discriminability (AUC=0.998). Vocabulary distributions differed substantially (bootstrap JSD 0.62, 95% CI 0.59-0.65, $p < 0.001$). Shared high-frequency symptoms included hearing loss (ENT:2.88 mentions/note, NSG:1.12), sensorineural hearing loss (ENT:0.16, NSG:0.13), vertigo/dizziness (ENT:0.20, NSG:0.12), facial nerve weakness (ENT:0.14, NSG:0.17), facial numbness (ENT:0.35, NSG:0.26), tumor growth (ENT:0.44, NSG:0.05), and family history (ENT:0.38, NSG:0.18). After FDR correction, mentions of tumor growth, family history, likely/symptomatic hearing loss, vertigo/dizziness, and facial numbness differed significantly between specialties ($p < 0.005$). Additional phrases more unique in ENT notes include history of ear infections (0.29); hearing aid (0.28); diplopia (0.13). Phrases more frequently documented in NSG notes included tinnitus (0.32), ability/inability to use phone (0.29), balance issues (0.23), and facial pain (0.11).

Conclusions: Despite modest low-dimensional clustering, high-dimensional NLP features and phrase distributions reveal reproducible specialty-specific documentation differences between ENT and NSG VS notes. ENT documentation more often emphasizes hearing-related concerns, multi-systemic symptoms, and tumor growth, whereas NSG notes more frequently refer to facial nerve-related symptoms, tinnitus, and functional/quality of life issues. These results characterize documentation patterns and may reflect referral pathways, patient presentation, and specialty emphasis. Future studies should evaluate NLP-based tools to support referral routing and terminology that may better facilitate multidisciplinary care coordination for VS patients.

SA66. Chronic Rhinosinusitis in Non-Solid Transplant Recipients

Isaac Elijah¹, Estephania Candelo Gomez², Jorge Abello-Vaamonde³, Angela Donaldson⁴

¹Charles E. Schmidt College of Medicine, Florida Atlantic University, ²University of Washington, ³Universidad Anáhuac México, ⁴Mayo Clinic Jacksonville

Background: Non-solid transplants, which includes bone marrow transplants (BMT) and hematopoietic stem cell transplants (HSCT), are becoming increasingly used to treat hematological and autoimmune conditions. Several characteristics of this population make them more susceptible to developing chronic rhinosinusitis (CRS) after transplantation, most notably the use of immunosuppressive medications. However, there is a lack of robust studies evaluating the incidence of CRS in non-solid transplant populations and other related characteristics. Therefore, our aim is to understand the extent and type of evidence available in relation to the incidence, clinical characteristics, and management of CRS in non-solid transplant recipients.

Methods: A systematic review was conducted to identify studies describing CRS in non-solid organ transplant recipients. Databases searched included Ovid Medline, Ovid Embase, Pubmed, Scopus, Web of Science, Cochrane, and Google Scholar. Keywords and medical subject headings that were searched included chronic rhinosinusitis, rhinosinusitis, sinusitis, bone marrow transplant, and stem cell transplantation. The primary objective was to analyze

the current literature regarding the prevalence of CRS in this population. The secondary objective was to characterize the clinical presentation of CRS among these patients.

Results: A total of 2735 studies were identified and 1970 studies were screened. From these, 44 studies full-text studies were assessed for eligibility. From these, 14 studies met the inclusion criteria. Of the 14 manuscripts, there was 1 case-control and 13 cohort studies. A total of 1356 transplant recipients were identified, with 312 of the recipients developing CRS, resulting in a pooled prevalence of 23.0%. The most common underlying hematological malignancies included acute myelogenous leukemia (AML, 19.02%), acute lymphocytic leukemia (ALL, 9.66%), and chronic myelogenous leukemia (CML, 7.08%).

Conclusions: Individuals receiving non-solid transplants are at a significantly greater risk of developing CRS than the general population, with an incidence of 23.0%. Individuals with underlying AML seem to represent a particularly susceptible subtype of hematological malignancy. Further investigation is warranted to identify predictive factors and high risk subgroups related to CRS development in this population.

SA67. A Study on Food Intake Level Scale and Rehabilitation Interventions Following Aspiration Prevention Surgery at Our Hospital Evaluation of the Food Intake Level Scale and Rehabilitation Interventions Following Aspiration Prevention Surgery at Our Institution

Shuhei Shinohara^{*1}, Junko Tsuda², Makoto Hashimoto², Kazuma Sugahara²

¹*Yamaguchi University*, ²*Yamaguchi University Graduate School of Medicine*

Background: Surgery for preventing aspiration is a reliable method for preventing aspiration in patients with severe dysphagia. It can improve patient quality of life (QOL) by offering the possibility of resuming oral intake postoperatively. At our institution, we actively implement swallowing rehabilitation by speech-language pathologists (SLPs), nutritional support by registered dietitians, and multidisciplinary interventions by the swallowing team to promote postoperative swallowing function recovery. However, there are few reports on the relationship between specific intervention methods and improved feeding status following anti-aspiration surgery.

Methods: This study included 44 patients aged 18 years or older who underwent aspiration prevention surgery in our department between January 2014 and December 2023. Pediatric cases were excluded due to underlying conditions and difficulties in intervention. Eating status was assessed using the FILS (Food Intake Level Scale) at admission for preoperative status and at discharge for postoperative status. Factors associated with FILS improvement pre- and postoperatively were analyzed univariately. For factors with $p < 0.01$, multivariate logistic regression analysis was performed adjusting for age and gender. Additionally, ROC curve analysis was performed for the number of ST interventions to calculate a cut-off value.

Results: FILS improvement was observed in 29 cases (65.9%) between pre- and postoperative periods. Additionally, 29 cases (65.9%) achieved a postoperative FILS of 4 or higher, enabling oral intake. Cases with lower preoperative FILS showed significantly greater improvement ($p < 0.05$). The group receiving ST intervention showed significantly improved postoperative FILS, with the improvement rate increasing with the number of interventions. ROC analysis indicated a cut-off value of 0.5 interventions (≥ 1 intervention) for the number of ST interventions. OT intervention and the number of postoperative rehabilitation sessions were also suggested to be associated with improvement.

Conclusions: The presence and number of ST interventions were the most important factors for improving feeding status after dysphagia prevention surgery. Improvement is possible even in cases with low preoperative FILS scores, making proactive multidisciplinary intervention desirable. Further investigation is needed on the effectiveness of comprehensive team interventions, including OT intervention.

SA68. Establishing an in Vivo Model for Stem Cell Based Treatment of Laryngotracheal Stenosis

Claire Victoria Ong^{*1}, Grace Randall¹, David Gonzalez¹, Benjamin Laitman¹, Ya-Wen Chen¹

¹*Icahn School of Medicine At Mount Sinai*

Background: Laryngotracheal stenosis is a common complication of prolonged mechanical ventilation with devastating consequences on a patient's quality of life. Despite this, there remain no effective treatments to prevent or reverse it. The advent of stem cell-based therapeutics presents a promising treatment option for airway injury. We have developed a novel strategy to produce lung epithelium basal cells in vitro (iv-BCs) from human pluripotent stem cell derived lung organoids (hPSC-LPs). Furthermore, we have demonstrated in previous experiments the survival, proliferation and differentiation of hPSC-LPs into various airway epithelial cell types when seeded onto de-epithelialized mouse and human tracheas cultured ex vivo. We believe that stenosis forms when the injured airway epithelium fails to repair in time, allowing underlying fibroblasts to react to the injury and secrete excess extracellular matrix, ultimately leading to scarring and narrowing of the airway. We hypothesize that if iv-BC or hPSC-LPs are applied to the site of injury, they will function like a "biologic band-aid," promoting rapid epithelial repair and thereby preventing or reducing the degree of stenosis. As a critical next step towards establishing translational clinical trials, we aim to demonstrate the same successful engraftment, proliferation and differentiation of hPSC-LPs in vivo using a medium-sized animal model, a proof of concept study.

Methods: We obtained 10 male New Zealand white rabbits to undergo surgery to induce short segment laryngotracheal stenosis. The surgery consists of a 3 cm longitudinal incision at the neck and blunt dissection through the neck fascia to access the trachea, followed by an incision cutting approximately two-thirds of the tracheal circumference in order to access the lumen. A 5.5 mm steel brush is then inserted into the tracheal lumen and brushed back and forth five times across the luminal mucosa to damage the epithelial layer and induce stenosis. The trachea is closed, the rabbits allowed to recover until 21 days post-operation. The rabbits are then sacrificed and their tracheas are dissected. The trachea is paraffin embedded and later stained via hematoxylin and eosin (H and E) to determine the extent of stenosis and whether this is standardized across rabbits.

Results: We observed successful laryngeal stenosis in all of our rabbit models. This is denoted by an enlarged lamina to cartilage ratio measured in all of our surgically injured rabbit tracheas as compared to our control, uninjured tracheas.

Conclusions: The success of our medium animal stenosis model is an essential first step in achieving our ultimate goal of demonstrating the successful engraftment and proliferation of hPSC-LPs in vivo in rabbit models. Future directions are aimed at producing the same injury in immunodeficient rabbits with the added engraftment of hPSC-LPs at time of injury. This will be followed by similar histological analysis.

SA69. Potassium Channels Underlying Serotonergic Excitation of Medial Olivocochlear Efferent Neurons

Kirupa Suthakar*¹, Catherine Weisz²

¹The University of Texas at Dallas, ²National Institutes of Health

Background: Activation of auditory efferent neurons directly modulates cochlear sensitivity to sound. Axons of cholinergic medial olivocochlear neurons (MOCs) located in the ventral brainstem directly target outer hair cells (OHC), hyperpolarizing them to reduce the effect of cochlear gain. We have previously shown that exogenously applied serotonin (5-hydroxytryptamine or 5-HT) affects intrinsic response properties of MOC neurons, increasing their excitability, consistent with the idea that serotonin may be implicated in protection from acoustic trauma. Here, we explore the role of different potassium channels expressed in MOC neurons mined from previously published nucSeq data (Frank et al., 2023) to investigate the contribution of potassium currents to this serotonin mediated excitation of MOC neurons.

Methods: In vitro patch clamp recordings were made from cholinergic MOC neurons from ventral brainstem slices of ChAT-IRES-Cre;Ai14 mice (n = 56) in current clamp configuration. Pharmacological experiments were designed to block specific potassium channels before and during bath application of 100uM serotonin. Specific channel targets were: apamin to block small conductance calcium-activated potassium (SK) channels (100nM), iberiotoxin to block big conductance calcium-activated potassium (BK) channels, XE-991 to block Kv7 channels (1μM), guangxitoxin-1E to block Kv2 channels (100nM), phrixotoxin-2 to block Kv4 channels (200nM), and tertiapin-Q to block g-protein coupled inwardly rectifying (GIRK) channels (100nM).

Results: Pharmacology experiments confirmed the presence of multiple functional potassium channels in MOC neurons. The excitatory effects of serotonin on MOC neurons—measured using firing rate in response to 100pA of injected current—persisted in the presence of all potassium channel blockers tested, apart from apamin (SK channels) and XE-991 (Kv7 channels). The serotonin mediated increase in MOC neuron input resistance was occluded in the presence of apamin, iberiotoxin and phrixotoxin-2, implicating both calcium-activated (SK and BK), and Kv4 channels. Together, these results suggest that the mechanism underlying serotonergic excitation of MOC neurons may be tied to calcium ions: SK and BK channels are calcium gated, and the Kv4.2 subunits and Kv7.1 subunits (both enriched in MOCs), are reported to interact with multiple calcium channels and calcium-binding proteins, respectively.

Conclusions: In conclusion, we found that potassium conductance through SK, BK, Kv4 and Kv7 channels contribute to serotonin mediated increases in MOC neuron excitation in vitro. Because increasing MOC activation attenuates cochlear responses to loud sounds, it is tempting to speculate that serotonin mediated excitation could be a mechanism of providing context dependent efferent control of the cochlea. Further in vivo experiments are necessary to understand the functional significance and circumstances under which this neuromodulation of MOC neurons contributes to auditory processing.

SA70. A Population of Monaural Brainstem Neurons Projecting Into the Lateral Lemniscus Shows Enhanced Temporal Synchronization to Stimulus Fine-Structure

Philip Joris*¹, Philip Smith¹

¹*Katholieke Universiteit Leuven*

Background: Enhanced synchronization to the temporal components of sound, relative to the auditory nerve, is well documented for several cell types in the cochlear nucleus. Prominent examples are bushy cells (for encoding the temporal fine-structure of low-frequency sounds) and octopus cells (for encoding onsets and envelopes). Similar but less well documented behaviors are found in the subcollicular targets of these neurons.

Methods: We used a new dorsal surgical approach close to the DNLL to record from axons in the lateral lemniscus (LL). Binaural and monaural stimuli were presented through speakers directly coupled to the bulla. Each axon was studied with stimuli traditionally used to classify monaural and binaural responses. Axonal penetration and injection of biocytin was then attempted to morphologically identify single neurons that generated responses of interest.

Results: Although the cell types projecting into the LL are reasonably well documented, there was a clear recording bias towards certain response types likely reflecting axonal bundling and axon size. Unexpectedly, we frequently encountered monaural neurons with “hi-sync” responses to contralateral low-frequency tones, whose degree of temporal enhancement surpassed that of bushy cells recorded in the same species. Neurons showed “entraining” (i.e. phase-locked entrainment) for tones up to ~ 600 Hz. Responses to broadband noise were enhanced as well, as assessed with autocorrelograms. In only one case was an axon successfully injected: while the parent cell body could not be found, the labeled axon had a large diameter.

Conclusions: Because bushy cells do not project as far dorsally in the LL as our recording site, we surmise that there is a source of monaural neurons somewhere in the superior olivary complex generating highly synchronized spiking which is relayed to rostral and dorsal levels in the midbrain. Cells or their axons showing such behaviors have been poorly sampled in previous (extracellular) studies of the superior olivary complex, but are important to consider and further study to help clarify the mechanisms underlying binaural temporal sensitivity and pitch.

SA71. Imaging Unipolar Brush Cells Using Fluorescently Tagged Fabs and Nanobody Probes

Tim Balmer¹, Larry Trussell*²

¹*Arizona State University, School of Life Sciences*, ²*Oregon Health and Science University, Oregon Hearing Research Center*

Background: Unipolar brush cells (UBCs) of the vestibular cerebellum and dorsal cochlear nucleus are excitatory interneurons that transform synaptic signals from mossy fiber terminals into a complex pattern of spikes and convey these signals to postsynaptic granule cells and to other UBCs. The contact between mossy fibers and the UBC brush dendrite is a complex structure that appears to retain glutamate for relatively long periods compared to conventional synapses, thus prolonging synaptic signals. These signals are mediated by ionotropic (AMPA) and metabotropic (mGluR) glutamate receptors. We sought to examine these contacts using confocal microscopy.

Methods: We used GRP-cre x Ai9 mice in which tdTomato was expressed in the ON subtype of UBC. Postsynaptic receptor clusters were labeled using a GFP-tagged antibody fragment (Fab) directed against an extracellular portion of the GluA2 subunit of the AMPA

receptor, the dominant subunit identified with RNAseq of UBCs. Efficient labeling required incubation of unpermeabilized, unfixed, living brain slices in the Fab. Following 30-min incubation, slices were rinsed, fixed, permeabilized and incubated overnight with an Atto643-tagged nanobody directed against Vglut1 to label presynaptic terminals. Slices were then rinsed, mounted in Fluoromount-G and imaged with a Zeiss 980 using Airyscan deconvolution.

Results: This approach revealed receptor clusters and presynaptic terminals with low background fluorescence. The absence of secondary antibodies enabled faster processing than with conventional immunohistochemistry and likely contributed to the low background. Most clusters were clearly positioned adjacent to presynaptic terminals. Some clusters were positioned on the surface of the brush dendrite while others were not; the latter were likely receptors at mossy fiber-granule cell synapses. These presumptive granule cell synapses (not associated with the UBC) were the majority of clusters in each image and appeared as puncta of ~ 0.2 micron diameter, at the limit of the PSF. Notably, clusters on the UBC dendrite were clearly different in shape and size from the puncta, with many appearing as extended, branched fingers over 1.5 micron long, in keeping with previous EM observations of synaptic densities.

Conclusions: Two striking take-home observations were 1) although UBC postsynaptic sites were large, there were not many of them. Most of the dendrite surface was apparently not devoted to fast transmission, suggesting additional functions to the brush dendrite. 2) The brush dendrite wrapped around mossy fiber synapses and receptors that appeared to be not synaptically associated with the brush, suggesting that the brush enshrouds granule cell claw dendrites. We speculate that there may be a functional difference between mossy-fiber/granule cells contacts confined by the UBC brush and those unconfined, perhaps differing in the retention of transmitter.

SA72. State-Dependence of Cell-Type Specific Circuit Interactions in the Dorsal Cochlear Nucleus

Hemant Kumar Srivastava^{*1}, Drew Jordon¹, Katharina Bochtler¹, Nikolas Scarcelli¹, Hong Jiang¹, Matthew McGinley¹

¹*Baylor College of Medicine*

Background: Activity in neuromodulatory systems fluctuates continuously during wakefulness, influencing neural processing broadly across the brain. While the effects of brain state in the auditory cortex and thalamus have been extensively characterized (e.g. McGinley et al., 2015), its effects on earlier stages of auditory processing remain poorly understood. For example, the dorsal cochlear nucleus (DCN) is an early brainstem structure that integrates auditory with non-auditory inputs to flexibly localize sounds, representing a critical site for investigating how internal brain state shapes sensory encoding.

Methods: Here, we recorded single-unit activity from the DCN of awake, head-fixed mice using high-density Neuropixels probes. We simultaneously tracked pupil diameter and locomotion as proxies for neuromodulatory brain state, as well as ear kinematics due to their importance in sound localization. DCN neurons were classified into putative cell types: putative principal cells and their response subtypes, or cartwheel or vertical cell (the two main classes of DCN inhibitory interneurons), based on their responses to tones and broadband noise and with optogenetic photo-tagging.

Results: We found that spontaneous firing rates exhibited robust, cell-type specific modulation by pupil-indexed arousal level. Principal neuron subtypes that were excited at their BF (type III) or exhibited complex tuning (type IV) showed monotonically increasing firing rates with pupil size, with much stronger modulation than the subtype inhibited at BF (type IIIi). Cartwheel cells also displayed robust state dependence, whereas vertical cells, due to their minimal spontaneous activity, showed no state dependent modulation. Moreover, neuronal synchrony in the DCN varied systematically with pupil size in a cell-pair type-specific manner: cartwheel cells exhibited a U-shaped relationship, whereas principal neuron subtypes showed a monotonic increase in synchrony with pupil size, suggesting that internal state not only modulates individual neuron excitability but also affects circuit-level interactions.

Conclusions: In contrast to downstream cortex and thalamus, the effects of pupil size on sound-evoked responses in DCN were comparatively small, suggesting fundamentally different principles govern state-dependence DCN compared to e.g. thalamo-cortical circuits. Furthermore, we find that the mice exhibit several types of ear movements, including orienting, twitch, perking, and wiggling, each with distinct relationships to pupil-indexed state. These ear movements have cell type-specific effects on DCN activity and sound location decodability. Together, these findings highlight the DCN as a critical node in auditory system state-dependent auditory processing.

SA73. Measuring Meaningful Outcome for Adult Hearing Health Interventions

Colleen Le Prell^{*1}, Kelly King²,

¹*University of Texas at Dallas*, ²*National Institutes of Health - National Institute on Deafness and Other Communication Disorders*

Background: The pure-tone audiogram is the clinical gold standard for adult hearing assessment. However, speech is a complex acoustic signal and the audiogram does not directly capture communication difficulties. Moreover, restoring audibility does not assure communication challenges resolve. When assessing functional benefits associated with use of a drug or device, researchers and clinicians have used a variety of different outcome measures to supplement the audiogram. However, even if outcomes beyond the audiogram are measured, the tools used to measure these outcomes vary across studies, clinicians, and patient encounters.

Methods: To work towards meaningful outcome measurements, the U.S. National Institutes of Health, Defense Health Agency, and Veteran's Administration commissioned a report from the National Academies of Science, Engineering, and Medicine (NASEM). An ad hoc committee was assembled by NASEM. The committee was tasked with identifying domains that are important across patients, settings (clinic, research), and interventions (hearing aids, pharmaceuticals, biologics, auditory training). The committee examined the state of the science in outcomes research for interventions in adult hearing healthcare (excluding surgically placed prosthetic devices), with an emphasis on measures that are meaningful to the individual and the clinician.

Results: The NASEM committee report, "Measuring Meaningful Outcomes for Adult Hearing Health Interventions," was released May 7, 2025. The report recommends a core set of outcome domains with corresponding measures. The committee came to consensus on two recommended outcome domains: understanding speech in complex listening environments and hearing-related psychosocial health. Recommended measurements include the Words-in-

Noise (WIN) test and Abbreviated Profile of Hearing Aid Benefit (APHAB) global score (speech understanding), and the Revised Hearing Handicap Inventory (RHHI) (hearing-related psychosocial health). These outcome measures are recommended across settings (clinic, research), indications (age-related hearing loss, noise-induced hearing loss, etc.), and interventions (hearing aids, pharmaceuticals, etc.). The report notes that supplemental measures may be needed; these are a minimum recommended standard data set for those measuring patient and participant outcomes.

Conclusions: The current lack of standardization limits direct comparisons across data sets and is an obstacle to the development of big data approaches within hearing health intervention research. Big data approaches require data repositories. Open data requirements increase the urgency of the need for data repositories to be both available and used. The authors invite meeting attendees to discuss the report from both the sponsor perspective and the committee perspective.

SA74. Using Click Interaural Time Difference Stimuli to Characterize Excitatory and Inhibitory Inputs to the Inferior Colliculus in Awake Rabbit

Johanna Fritzinger^{*1}, Laurel H. Carney²

¹*University of Michigan*, ²*University of Rochester*

Background: Responses to interaural time differences (ITDs) of click stimuli in the inferior colliculus (IC) of anesthetized cat were used to characterize the dynamics of excitation and inhibition from ipsilateral and contralateral sources (Carney and Yin, 1989, *J. Neurophysiol.*, 62:144-161). These results informed IC model parameters and contributed to our understanding of differences between responses to diotic and contralateral stimuli. However, IC responses differ between anesthetized and awake animals, and responses to click ITD have not been recorded in awake animals. Here we determined the timing and strength of inhibition and excitation of IC neurons by recording click-ITD responses in awake rabbit.

Methods: Single-neuron responses were recorded using tetrodes in the central nucleus of the IC in awake Dutch-belted rabbits. Click rate-level functions were created by presenting 100- μ s clicks to the ipsilateral or contralateral ear at sound levels 30-100 dB peak-equivalent sound pressure level (dB peSPL). Click ITD stimuli with 100- μ s duration were presented with interaural delays from 0 to $\pm$ 50 ms, in increments of 1 ms. Twenty repetitions of each stimulus were presented in random order. Sound levels were chosen to ensure suprathreshold responses, based on the rate-level function, and spanned 53-83 dB peSPL. Contralateral and ipsilateral contributions to the click-ITD response were determined using alpha functions to estimate post-synaptic potentials for excitation, inhibition, and facilitation.

Results: IC neurons had consistent and robust responses to clicks. Most often, the contralateral click elicited strong excitation, and the ipsilateral click elicited weak excitation followed by stronger inhibition. Facilitation, when a contralateral click increased the response of a following ipsilateral click, was also observed. However, neurons showed a wide variety of responses to stimuli depending on the timing and strength of these inputs. Most neural responses fell into four categories: 1) Reduction in rate near zero delay and increase in rate at other delays resulting from contralateral excitation and contra/ipsi inhibition, 2) reduction in rate near zero delay with an increase in rate at other delays resulting from additional facilitation components, 3) increase in rate at zero delay and suppression at other delays and 4) weak inhibition or excitation near zero delay. Additionally, the spontaneous rate of IC

neurons was often high enough to observe inhibition, which differed from the anesthetized cat study.

Conclusions: These results identified and characterized several different time courses of ipsilateral and contralateral excitatory and inhibitory inputs that influence binaural sound encoding in the awake IC. Results may improve computational IC models and explain differences in responses to complex stimuli presented diotically or contralaterally. Supported by: NIH R01-DC010813, NIH F31-DC020630

SA75. A Molecular Roadmap for Central Auditory Projections

Hung Sheng Shih¹, Shih-Hsin Chang¹, Yuvraj Joshi¹, Francois Lallemand*¹

¹*Karolinska Institute*

Background: All auditory signals from the cochlea are transmitted via the auditory nerve to the cochlear nucleus (CN), the first central hub for auditory processing. Within the CN, these signals are integrated and relayed to higher brain regions for auditory perception, sound localization, aversive responses, and integration with circuits mediating emotional salience and memory. However, the precise diversity of CN neuronal subtypes and the specificity of their long-range projections remain poorly understood.

Methods: We leveraged virus-based retrograde labeling and deep single-nucleus RNA sequencing to comprehensively map CN neuronal diversity and link transcriptomic cell types to their projection targets. In parallel, we are performing electrophysiological recordings to correlate CN molecular subtypes with their physiological properties and using rabies virus tracing from downstream brain circuits to test for selective “labeled line” pathways.

Results: Our approach uncovered substantial molecular and biological diversity among CN populations with distinct anatomical projections, even when they form a single genetic cluster. We established a unified transcriptomic and projectional taxonomy of CN neurons across functionally distinct auditory pathways, revealing organizational principles of the CN.

Conclusions: This work defines how molecularly diverse cochlear nucleus neurons contribute to distinct auditory pathways. It provides a framework to understand the organization and routing of auditory information in the brain, which will help dissecting the mechanisms of early auditory processing.

SA76. Vasopressin and Oxytocin Distribution in the Auditory Brainstem of Rodent With Diverse Social Structures

Luberson Joseph*¹, Elizabeth McCullagh¹

¹*Oklahoma State University*

Background: The nonapeptides vasopressin (AVP) and Oxytocin (OT) play critical roles in regulating social behavior across diverse taxa. Their distribution has been well documented in the forebrain and midbrain, revealing relatively strong evolutionary conservation. However, their distribution throughout the hindbrain remains poorly understood.

Methods: Here, we used immunohistochemical techniques to quantify AVP and OT cells' distribution in the superior olivary complex of the brainstem - specifically the lateral superior olive (LSO), the medial superior olive (MSO), and the medial nucleus of the trapezoid body (MNTB) across six wild rodent species with distinct social structures. The species examined represent solitary (*Chaetodipus hispidus* and *Dipodomys ordii*), monogamous (*Microtus*

ochrogaster and *Onychomys leucogaster*), and group-living (*Mus musculus* and *Rattus norvegicus*) social systems. We also measured overall size and structural differences in these auditory brainstem regions among species.

Results: We predicted that group-living species will exhibit higher distribution of AVP and OT cells in the LSO, MSO, and MNTB compared to monogamous or solitary species. We also predicted that group-living species will have larger LSO, MSO, and MNTB areas than other measured groups.

Conclusions: These findings will provide a comparative mapping of AVP and OT cells' distribution in the rodent brainstem and offer a foundation for understanding nonapeptide-mediated behavior in species with varying social structures.

SA77. Parallel Auditory Brainstem Response (pABR) Accurately Predicts Air- And Bone- Conduction Thresholds in Adults

Isabel Herb^{*1}, Ross Maddox², Melissa Polonenko¹

¹*University of Minnesota*, ²*University of Michigan*

Background: Frequency-specific auditory brainstem responses (ABRs) are essential for estimating hearing thresholds when behavioral testing is not feasible. The parallel ABR (pABR) has been shown to speed up testing by presenting multiple frequencies to both ears (Polonenko and Maddox, 2019), and an in-progress study suggests it provides accurate estimates of hearing thresholds in adults with sensorineural hearing loss. Up to now, work on the pABR has focused on air-conducted stimuli. However, validating bone-conducted stimuli is important as they allow clinicians to distinguish between types of hearing loss. Therefore, in this study, we extended the pABR to include both air- and bone-conduction and evaluated its accuracy in estimating thresholds and classifying both the type and degree of hearing loss.

Methods: Two-channel ABRs were recorded from 40 adults (11 men, 29 women; aged 30–70 years) with varying audiometric configurations: 20 with sensorineural hearing loss and 20 with conductive or mixed losses. Stimuli consisted of 0.5, 1, 2, 4, and 8 kHz tonebursts presented to both ears for air-conduction testing and 0.5, 1, 2, and 4 kHz tonebursts presented monaurally for bone-conduction testing, with contralateral masking (pABR stimuli presented at a faster rate) delivered to the non-test ear. ABR wave V responses were identified online during testing and compared with behavioral thresholds obtained after the pABR testing in the same session.

Results: pABR testing produced accurate threshold estimates for both air and bone conduction. For air conduction, 85% of pABR-estimated thresholds (without correction factors applied) were within 10 dB, and 96% within 15 dB of behavioral thresholds, with a very strong correlation between predicted and behavioral thresholds ($r = 0.92$, 95% CI: 0.90–0.93, $p < 0.001$). For bone conduction, 77% of pABR-estimated thresholds were within 10 dB and 91% within 15 dB of behavioral thresholds, also with a strong correlation between thresholds ($r = 0.75$, 95% CI: 0.69–0.80, $p < 0.001$). Testing was also efficient, requiring a median of 65 minutes to collect all 18 thresholds (~3.6 minutes per threshold), regardless if the loss was purely sensorineural or had a conductive component (median times of 64 and 68 minutes, respectively). These findings suggest that the pABR can efficiently test thresholds without sacrificing accuracy.

Conclusions: The pABR provides fast, accurate, and reliable threshold estimates across air and bone conduction testing, allowing accurate classification of both the type and degree of hearing loss. These findings highlight the clinical potential of pABR to improve diagnostic

efficiency and inform treatment decisions. Future work will evaluate its performance in infants and young children, where objective, rapid threshold estimation is most critical.

SA78. From Sound to Movement: The Neural Backbone of the Acoustic Startle Reflex

Jan Frederik Ahrend*¹, Jana Erlmoser¹, Kathrin Deborah Wicke², Felix Felmy², Christian Vogl¹

¹*Auditory Neuroscience Group, Institute of Physiology, Medical University Innsbruck,*

²*Institute of Zoology, University of Veterinary Medicine Hannover Foundation*

Background: The acoustic startle reflex (ASR) is a fast bodily reaction to a loud and unexpected auditory stimulus – a protective mechanism inherent to most mammalian species. On cellular level, large cochlear root neurons (CRNs), located between the auditory periphery and cochlear nucleus, have been identified as the first neural substrate of the underlying reflex circuitry. CRNs receive glutamatergic input from primary afferent spiral ganglion neuron (SGN) collaterals and were shown to be subject to various efferent modulatory pathways. Their large axons mainly target neurons of the contralateral pontine reticular nucleus (PnC) formation, which project onto cranial and spinal motor neurons and are in turn subject to extensive modulatory inputs from various brain areas. Despite their fundamental role in a survival reflex circuit, CRNs are still remarkably poorly characterized in regard to their cellular excitability and activity patterns as well as their molecular composition and morphology in situ. Despite behaviorally apparent acoustic startle reflexes in humans, the taxonomic equivalent of rodent CRNs has yet to be identified. However, ASR measurements are of major clinical relevance, as altered startle behavior is linked to neuropsychiatric or neurodevelopmental disorders – such as autism spectrum disorders.

Methods: Here, we prepared fixed vibratome-sectioned tissue slice preparations of the cochlear root nucleus as well as whole-mount preparations of the intact peripheral auditory pathway of mice (*Mus musculus*) for immunohistochemical stainings and ethyl cinnamate based tissue clearing. For fiber input tracing experiments, we utilized various genetic reporter mouse models alongside lipophilic tracer dyes. Data were acquired using confocal and lightsheet fluorescence microscopy and analyzed using Imaris software. To probe evolutionary conservation and the functional role of CRNs in various animal models with distinct hearing frequency ranges, we additionally analyzed Mongolian gerbils (*Meriones unguiculatus*), Etruscan shrews (*Suncus etruscus*) and common fruit bats (*Carollia perspicillata*).

Results: In this work, we were able to develop a novel tissue preparation technique that preserves the cochlear root nucleus within its native context in the intact peripheral auditory pathway. Lightsheet images of such chemically-cleared preparations allowed us to characterize the exact 3D localization, morphology, size and count of the CRN population. Furthermore, we analyzed the afferent and efferent synaptic connectome of CRNs to establish excitatory and inhibitory neurotransmitter identities as well as their respective innervation densities and further plan to probe their role on cellular excitability measures.

Conclusions: In this project, we aimed for a holistic in situ characterization of the CRN population by performing detailed anatomical, morphological and functional analyses regarding cellular location and neuronal connectivity. Our current findings yield strong evidence for distinct CRN subpopulations that may serve differential functions in the ASR

pathway – thereby highlighting the surprising complexity of a supposedly simple and rapid reflex circuit.

SA79. Evidence for a Vestibular Contribution to Auditory Processing via the LVN–IC Pathway

Sunghee Kang*¹, Youngraee Ji¹, Gunsoo Kim¹

¹*Korea Brain Research Institute*

Background: The vestibular nuclei (VN) are brainstem structures essential for balance and posture. They play a key role in natural behavior by broadcasting vestibular signals across the brain and interacting with other sensory systems. When this multisensory coordination is disrupted, neurological disorders may occur, often resulting in combined vestibular and auditory symptoms. However, the specific contribution of the VN to auditory processing remains unclear. Clarifying how the VN connects to the inferior colliculus (IC) and what functional influence this connection may provide insight into this question. Accordingly, this study aims to investigate whether the VN and IC are anatomically and functionally connected.

Methods: C57BL/6J mice (7–9 weeks old) were anesthetized and injected with CTB-Alexa568, anterograde AAV, or retrograde AAV into the IC or lateral vestibular nucleus (LVN). For electrophysiology, mice were implanted with a headpost before recording. Two small cranial windows were then made over the IC and LVN for neural recording and optogenetic stimulation. Neural signals were acquired using a 6-channel tungsten electrode array (~5 MΩ, FHC). To assess sound responses, animals were placed in a sound booth and exposed to 70 dB pure tones (8 and 32 kHz) for 2 hours following 90 minutes of silence. Brains were fixed, sectioned, and processed for c-Fos immunostaining to verify sound stimulation-evoked activity.

Results: To explore the connectivity between the LVN and IC, we used viral tracing. Retrograde virus injection into the IC resulted in labeled neurons in the LVN. Anterograde virus injection into the LVN revealed labeled fibers in the ventromedial region of the IC. Retrograde virus injection into the LVN led to labeling in the uvula and cochlear nucleus (CN). Double-labeled neurons expressing both retrograde labeling from the IC (mCherry) and anterograde labeling from the uvula (GFP) were identified in the LVN. We performed optogenetic stimulation of the LVN. Subsequent electrophysiological recordings from the IC revealed strong short-latency modulation of IC neuron firing rates. To test whether IC-projecting LVN neurons respond to auditory stimuli and vestibular input, we conducted a sound exposure experiment. After sound stimulation, c-Fos expression was detected in the LVN in response to 8 and 32 kHz sounds.

Conclusions: Our findings demonstrate both anatomical and functional connectivity between the LVN and the IC. These results suggest that the LVN, in addition to its role in balance control, also contributes to auditory processing, thus providing new evidence for how vestibular and auditory functions are integrated through the LVN–IC pathway.

SA80. Inhibition of Extracellular Vesicles Disrupts Nucleus Laminaris Development in the Chicken Auditory Brainstem

Jackson Blackman*¹, Joleen Wardeh¹, Karina S. Cramer¹

¹*University of California, Irvine*

Background: The pathway connecting nucleus magnocellularis (NM) to nucleus laminaris (NL) in the chicken auditory brainstem facilitates sound localization using interaural time differences. Projections from the cochlear (VIIIth) nerve innervate NM. Axons from NM neurons branch, projecting to the ventral contralateral dendrites of NL and the dorsal ipsilateral dendrites of NL. The cell bodies of NL form a thin monolayer of neurons surrounded by neuropil. We previously discovered that cleaved (active) caspase-3 is expressed in NM axons and NL dendrites prior to the period of programmed cell death. Caspase-3 is a proteolytic enzyme known for its roles in apoptosis. When caspase-3 is inhibited in ascending axon projections from NM, NL lamination is greatly impaired. To understand the mechanism through which caspase-3 regulates development, we first identified several hundred caspase-3 proteolytic substrates. GO term analysis revealed an abundance of substrates associated with exosomes/extracellular vesicles (EVs), suggesting a potential downstream modulator of caspase-3 activity during development.

Methods: If the primary substrates of caspase-3 modify EVs, then EVs may be necessary for circuit assembly downstream of caspase-3. If so, elimination of EVs would likely cause deficits in NL lamination, similar to those seen with caspase-3 inhibition. To test this possibility, we used DPTIP, a drug known to inhibit EV biogenesis. Fertilized chicken eggs were placed into ex-ovo culture on E2. We performed 2.5 μ M DPTIP and control injections at E8 and E9. After cryosectioning, Nissl-stained sections were imaged and NL cells were plotted. We used linear regression r-squared value of the plotted cell bodies to examine whether NL in DPTIP treated embryos was significantly less organized than control embryos.

Results: DPTIP treated animals showed irregular NL lamination compared to control animals (DPTIP $n = 8$, $r^2 = 0.797$; VCS $n = 9$, $r^2 = 0.955$; $p = 0.034$, Welch's Two Sample t-test). The cell bodies under normal conditions lie in a well-organized plane resulting in a linear array in sections. In contrast, DPTIP treated animals showed disrupted cell body ordering and significantly decreased linearity.

Conclusions: Our findings present the first evidence that extracellular vesicle inhibition disrupts NL lamination. This phenotypic similarity to caspase-3 inhibition is consistent with the idea that extracellular vesicles are required for proper development. This mechanism may represent a new model for the establishment of neural circuits.

SA81. Lineage Tracing of Repopulating Microglia in the Auditory Brainstem of Mice

Heidi Liang^{*1}, Sima M. Chokr¹, Giedre Milinkeviciute¹, Kim N. Green¹, Karina S. Cramer¹

¹*University of California, Irvine*

Background: Microglia, known for their immunological role in the central nervous system, have significant roles in central auditory circuit development. Auditory processing circuits, including those for computing sound source locations, require coordinated adaptations of precise developmental mechanisms. We previously showed that pharmacological depletion of microglia in mice from postnatal day P2 with a colony stimulating factor 1 receptor (CSF1R) inhibitor led to impaired synaptic pruning of the calyx of Held in the medial nucleus of the trapezoid body (MNTB), reduced ABR peak amplitudes, and increased ABR peak latencies. After withdrawal of the CSF1R inhibitor at P10, microglia returned gradually, beginning in lateral regions (including the ventral cochlear nucleus), later in middle regions (including the lateral superior olive), and beginning at about P22, the MNTB, which also mirrored the pattern seen during normal development. Significantly, this repopulation was associated with restored synaptic pruning and ABR measures, even at ages beyond the normal period of

circuit refinement. In contrast, long-term microglia depletion without repopulation led to retained polyinnervation and further decline in auditory function.

We hypothesized that repopulating microglia recapture developmental features of the original microglia during normal developmental stages. The goal of this project is to characterize the sources of these repopulating microglia and their developmental stages. Normally developing microglia arise from the yolk sac myeloid lineage and enter the brain early in development. Our preliminary differential gene expression results show that *Itgal*, a monocyte lineage gene, was upregulated in the repopulating microglia population of the CSF1R-inhibited mice relative to control mice. This observation suggests that, after microglia elimination, repopulating microglia could arise from peripheral monocytes.

Methods: We used a lineage tracing approach by injecting BLZ945, a CSF1R inhibitor, into mice every other day between P2 and P10, then observing microglia or monocyte markers to determine whether the new microglia have characteristics of peripheral monocytes. The *Ms4a3Cre-RosaTdT* reporter mouse shows recombination in granulocyte-monocyte progenitors (GMPs) and their progeny to express the TdTomato reporter. We immunolabeled repopulating microglia using the *Iba1* marker and evaluated the extent to which these repopulating microglia expressed the reporter, indicating a monocyte lineage.

Results: As expected, microglia were present throughout the auditory brainstem in control mice, but only in the lateral region in BLZ-treated mice at P21, consistent with our previous studies. In the selected area of the lateral auditory brainstem region of the *Ms4a3Cre-RosaTdT* mice, we found that up to 21% of *Iba1*-labeled repopulating microglia also expressed TdTomato, with up to 75% of the total monocytes overlapping with microglial *Iba1*. In contrast, we found almost no TdTomato-positive cells in the brainstems of control mice.

Conclusions: These findings suggest that a significant proportion of repopulating microglia arise from peripheral monocytes.

SA82. Muscarinic Modulation Activates Non-Selective Cation Channels and Increase the Excitability of Fusiform Cells of the Dorsal Cochlear Nucleus

Tomohiko Irie*¹, Rei Yamada¹

¹*Kitasato University School of Medicine*

Background: The dorsal cochlear nucleus (DCN) of mammals plays a crucial role in suppression of self-generated sounds and monaural sound localization by integrating auditory and somatosensory information. Auditory information is conveyed by auditory nerve fibers, whereas somatosensory information is mediated by parallel fibers from granule cells in the cochlear nuclear complex. These inputs converge in fusiform cells, the glutamatergic principal cells in the DCN, which send their axons to the inferior colliculus. Therefore, fusiform cells are considered to play a central role in the DCN function. In the mammalian central nervous system, cholinergic signaling is essential for brain functions. The DCN receives cholinergic inputs from some brainstem regions, suggesting that these inputs modulate the output of fusiform cells to inferior colliculus. However, the direct evidence and underlying mechanisms of the cholinergic modulation in fusiform cells are still lacking.

Methods: In order to investigate the cholinergic modulation in fusiform cells, whole-cell patch-clamp recordings in acute slice preparations from the mouse brainstem (age: postnatal

17-27 days) were conducted. Several cholinergic agonists (Acetylcholine, nicotine, oxotremorine-M) were applied by bath-perfusion.

Results: Application of acetylcholine (100 μ M) and oxotremorine-M (a selective muscarinic agonist, 20 μ M) induced a clear inward current, while nicotine (10 μ M) did not elicit any significant response. This current had linear current-voltage relationship and the reversal potential of the current was approximately 0 mV. Additionally, this current was blocked by two types of TRP channel inhibitors, flufenamic acid (100 μ M) or 2-APB (100 μ M), indicating that the current was induced by the activation of non-selective cation channels with weak voltage dependence. Consistent with these findings, oxotremorine-M depolarized the membrane potential with reduction of membrane resistance, and increased both spontaneous and evoked firing in fusiform cells. Acetylcholine (500 μ M) had no significant effect on either excitatory and inhibitory synaptic transmission onto fusiform cells.

Conclusions: The muscarinic modulation enhances the excitability of fusiform cells by activating the non-selective cation channels, and may affect the integration of multimodal sensory inputs.

SA83. Central Auditory Synapse Alterations in Mice With Modified Medial Olivocochlear Efferent Activity

Daniela Chequer Charan^{*1}, Fangfang Wang², María Eugenia Gómez-Casati³, Haoyu Wang⁴, Yumeng Qi⁴, Carolina Wedemeyer¹, Yunfeng Hua⁴, Ana Belén Elgoyhen¹, Mariano Nicolas Di Guilmi¹

¹*Instituto de Investigaciones en Ingeniería Genética y Biología Molecular, INGEBI-CONICET*, ²*Shanghai Ninth People's Hospital*, ³*Instituto de Farmacología, Facultad de Medicina, Universidad de Buenos Aires*, ⁴*Shanghai Institute of Precision Medicine, Shanghai Ninth People's Hospital, Shanghai Jiao Tong University School of Medicine*

Background: In many mammals, the auditory system is functionally immature at birth and undergoes postnatal refinement to achieve precise connectivity in adulthood. Spontaneous activity in the immature cochlea drives the organization of auditory brainstem circuits, a process modulated by the medial olivocochlear (MOC) efferent system. While the MOC pathway is known to protect against noise-induced hearing loss in adulthood, its developmental role remains less understood. We investigated how altered MOC activity during the critical period impacts the synaptic and morphological maturation of the calyx of Held (CH) synapse in the medial nucleus of the trapezoid body (MNTB)

Methods: We combined whole-cell patch-clamp recordings from MNTB principal neurons with 3D reconstructions from serial block-face electron microscopy (SBEM) at P12–14. Three mice genotypes were analyzed: wild type (WT), α 9KI (enhanced MOC activity), and α 9KO (absence of MOC activity). Morphological complexity of CH terminals was quantified using a custom Python pipeline based on graph theory, which enabled classification into distinct morphotypes.

Results: Electrophysiological recordings revealed that α 9KO mice showed electrophysiological responses comparable to WT. However α 9KI mice displayed reduced synaptic strength compared to WT, including smaller excitatory postsynaptic current (WT: 5.01 ± 1.58 nA, n=28; α 9KI: 3.61 ± 1.23 nA, n=25; α 9KO: 4.23 ± 1.34 nA, n=20; ANOVA: p=0.0013; Tukey WT- α 9KI, p=0.0008), stronger short-term depression during repetitive stimulation (100Hz: WT: $33.59 \pm 1.62\%$, n=12; α 9KI: $22.52 \pm 2.99\%$, n=10; α 9KO:

33.92±4.16%, n=11; ANOVA: p=0.0224; Tukey WT-α9KI: p=0.0403) and a decreased readily releasable pool size (WT: 374.02±29.11, n=10; α9KI: 253.01±21.78, n=12; α9KO: 323.21±21.39, n=9; ANOVA, p=0.0057, Tukey WT-α9KI, p=0.005). Morphological analysis indicated that α9KI animals exhibited a lower proportion of structurally complex CH terminals and evidence of loss in synaptic pruning, both in pre- and post-hearing stages. The α9KO mice displayed reduced morphological complexity but neither pruning nor electrophysiological performance were significantly altered (poly-innervation rate: WT/α9KO~10%; α9KI~30%).

Conclusions: Synaptic depression pattern in α9KI matches well with a higher proportion of simple CHs, according to literature linking structure and function at this synapse. Although previous studies in other auditory centers show both synaptic and morphological alterations when MOC efferent activity is lost, these results suggest that there may be some type of compensation at the level of the MNTB. Our findings demonstrate that enhanced MOC efferent activity during early development triggers profound modifications in both synaptic physiology and morphology at the CH–MNTB synapse. These results highlight the critical role of efferent pathways in shaping auditory brainstem maturation and suggest that altered efferent activity may contribute to long-term deficits in auditory processing.

SA84. The Function of NFI Transcription Factors in Cochlear Differentiation and Supporting Cell Plasticity

Angelika Doetzlhofer*¹, Charles Morgan¹

¹*Johns Hopkins University School of Medicine*

Background: The loss of cochlear hair cells is a leading cause of hearing loss in humans. Research in mice shows that supporting cells can regenerate hair cells at early postnatal stages. However, the limited regenerative potential is lost as supporting cells undergo maturation. Our recent findings indicate that reprogramming cochlear supporting cells into progenitor-like cells improves their mitotic and hair cell-forming potential at more mature stages. The reprogramming of supporting cells into progenitor-like cells is accompanied by the downregulation of NFI transcription factors. NFI transcription factors control the differentiation of glial and neuronal cells in the developing brain and were recently identified as the main repressors of damage-induced cell proliferation in the mouse retina. The function of NFI transcription factors in cochlear supporting cell differentiation and supporting cell plasticity has yet to be addressed.

Methods: Published single cell RNA-seq data and NFIB-immunostaining was used to characterize cochlear Nfia, Nfib and Nfix expression. The Nfia, Nfib and Nfix genes were conditionally deleted in cochlear progenitors and supporting cells using Sox2-CreER transgenic Nfia,b,x triple floxed mice. For developmental experiments, tamoxifen was administered at E12, followed by EdU at E13.5 and EdU incorporation and the phenotype of control and Nfia/b/x deficient hair cells and supporting cells was analyzed at E18.5. For regenerative experiments, tamoxifen was administered at P3 and the mitotic and hair cell-forming potential of control and Nfia,b,x deficient supporting cells was analyzed at P5 using an organoid culture model.

Results: We found that Nfia and Nfib are co-expressed in cochlear progenitor cells, whereas Nfia, Nfib and Nfix genes are co-expressed in differentiating and maturing supporting cells. We found that loss of NFIA, B, and X function delayed the cell cycle exit and the differentiation of cochlear progenitor cells into hair cells and supporting cells. Furthermore, we observed defects in the medial-lateral pattern of hair cells, with more inner hair cells and

fewer outer hair cells being formed in Nfia/b/x triple knockout mice (TKO). Using a Tecta-cre strategy, we are currently examining whether loss of NFIA, B, and X during cochlear differentiation impacts hearing. Furthermore, we found that acute deletion of Nfia, Nfib, and Nfix increased the mitotic and hair cell-forming capacity of maturing cochlear supporting cells. We found that Nfia/b/x-deficient supporting cells formed larger organoids and proliferated at a higher rate than control. Moreover, we found that Nfia,b,x-deficient organoids formed small clusters of hair cells, whereas control organoids failed to do so.

Conclusions: Our research indicates that the transcription factors NFIA, NFIB, and NFIX promote cell cycle withdrawal and differentiation of cochlear progenitor cells. Additionally, our findings indicate that high NFIA, B, and X expression prevents cochlear supporting cells undergoing maturation from re-entering the cell cycle and from regenerating hair cells.

SA85. Loss of Zbtb20 Disrupts Sensory Epithelial Patterning and Maturation and Extends the Postnatal Hair Cell Regenerative Window in Mice

Angelika Doetzlhofer*¹, Charles Morgan¹, ZIA UR REHMAN²

¹*Johns Hopkins University School of Medicine*, ²*Johns Hopkins University*

Background: The transcription factor ZBTB20 is mutated in Primrose syndrome, a rare developmental disorder that can cause progressive hearing loss. A recent study (Xie et al. 2023 PNAS), using an early otic conditional knockout (cKO) mouse model of Zbtb20, reported profound hearing loss and atypical maturation of the non-sensory lateral cochlear epithelium. Here, we used cochlear and sensory epithelial-specific Emx2-cre and Tecta-cre lines to determine to what extent defects in the maturation of the cochlear sensory epithelium contribute to the hearing loss in Zbtb20 cKO mice. Furthermore, we use the chronic Emx2-cre Zbtb20 deletion model to determine whether blocking maturation of cochlear SCs enhances their mitotic and HC regenerative potential.

Methods: To study the role of ZBTB20 during cochlear development, Zbtb20f/f; Emx2-cre mice and control littermates were generated, and cochlear tissue was analyzed at Postnatal Day 0 (P0) through P30 using immunolabeling and histological techniques. Auditory Brainstem Responses (ABRs) were recorded at P30 to evaluate hearing capacity. Additionally, RNA sequencing (RNA-seq) was performed at P5 on isolated cochlear sensory epithelia. To evaluate the contribution of sensory epithelium defects to the reported hearing phenotype, Zbtb20f/f; Tecta-cre mice were generated. To profile regenerative capacity following chronic loss of Zbtb20, the Zbtb20f/f; Emx2-cre mice and control littermates were used to generate cochlear organoid and explant cultures at P5, which were then evaluated using microscopy, immunolabeling, EdU-labeling of proliferating cells, and RT-qPCR. In a subset of experiments the Pou4f3-DTR transgene was used to ablate HCs using diphtheria toxin.

Results: Deletion of Zbtb20 in the developing cochlear duct using Emx2-cre caused severe hearing loss. Notably, severe hearing loss was also observed in the Tecta-cre mouse model, which restricts the cKO domain to the sensory epithelium and Greater Epithelial Ridge (GER). Emx2-cre; Zbtb20 cKO mice exhibited patterning defects in the cochlear sensory epithelium, showing an increase in outer HCs (OHCs) and Deiter's cells. Notably, the apical tip showed no tapering of OHC rows, instead producing a blunt end with 4 rows of OHCs. RNA-seq and immunolabeling at P5 showed downregulation of key SC subtype-specific genes, such as Fabp7 in Hensen's Cells, and an upregulation of the stemness-related genes

Hmga2 and Sox11. Profiling of the Emx2cre; Zbtb20 cKO using a P5 organoid culture model showed increased organoid size and formation efficiency, increased proliferation, and increased HC regeneration.

Conclusions: This study identifies ZBTB20 as a master regulator of cochlear sensory epithelial differentiation and maturation. Loss of Zbtb20 in developing HCs and SCs leads to profound hearing loss, SC and HC patterning defects, and a delay in SC maturation. Furthermore, our findings indicate that halting cochlear maturation greatly enhances the mitotic and HC regenerative potential of cochlear SCs.

SA86. Chd7 and Sox2 Regulate Regional Organization of the Mammalian Cochlea and Expression of Vestibular Patterning Genes

Jingxia Gao^{*1}, Derek Bukowski¹, Yehoash Raphael², Donna Martin¹

¹University of Michigan, ²University of Michigan, Medicine, Kresge Hearing Research Institute

Background: Hereditary hearing loss and balance disorders are important clinical problems that have become easier to diagnose but have not greatly benefitted from advances in molecular therapies. An important step in designing therapies for hereditary hearing loss and balance disorders is understanding their underlying mechanisms. Chd7 encodes the ATP-dependent chromatin remodeler CHD7, mutated in CHARGE syndrome. Sox2 encodes Sex determining Region Y-box 2 family transcription factor SOX2. Our previous study showed that the expression of Chd7 and Sox2 is tightly regulated during inner ear development, and perturbation of the balance between these two genes leads to complex inner ear malformations, including shortened cochlea and malformed semicircular canals. In this study, we explored possible roles of Chd7 and Sox2 in regional organization of the mouse cochlea and expression of vestibular patterning genes.

Methods: Chd7 germline and conditional mutant (Chd7Gt/+; Chd7flox/flox), Sox2 inducible Cre knockin (Sox2CreER/+), and Pax2-Cre transgenic mice were used to study Chd7 and Sox2 in cochlear and vestibular development. E11.5 or E14.5 embryos were processed for in-situ analysis. Regional cochlear markers Fst, Efnb2 and Msx1 in the apex, and Inhba, Aldh1a3, and A2m in the base, were used. Expression of vestibular patterning genes Bmp4, Dlx5, Lmo4, and Otx1 was analyzed.

Results: In E14.5 double heterozygous (Chd7Gt/+;Sox2CreER/+) embryos, Fst, Efnb2 and Msx1 were highly expressed in the apical cochlea, similar to wild type littermates, and expression of cochlear basal markers, Inhba and Aldh1a3, was preserved in the base. However, A2m was greatly downregulated or absent in the basal cochleae of Chd7Gt/+;Sox2CreER/+ mutant embryos. Formation of the posterior vertical pouch, labeled by Dlx5 and Lmo4, was defective in E11.5 Chd7Gt/+;Sox2CreER/+ embryos. In contrast, formation of the anterior vertical pouch and the lateral wall (labeled by Lmo4 and Otx1) were normal in Chd7Gt/+;Sox2CreER/+ embryos.

Conclusions: These results demonstrate that the apical and basal cochlear identity was preserved in Chd7Gt/+;Sox2CreER/+ embryos. Downregulation of the basal marker, A2m, in Chd7Gt/+;Sox2CreER/+ embryos may reflect direct A2m expression regulation by Chd7. Chd7 and Sox2 cooperate to regulate expression of the vestibular patterning genes, which contributes to the semicircular canal defects in Chd7Gt/+;Sox2CreER/+ mice. These results will inform the design of novel molecular therapies to treat hearing and balance disorders associated with CHARGE syndrome.

SA87. Sox11 and Chd7 Act in the Same Gene Regulatory Network to Promote Inner Ear Development

Jelka Cimerman¹, Ethan Sperry¹, Hojjati Ronus², Jingxia Gao^{*1}, Jennifer Skidmore¹, Donald L. Swiderski³, Yehoash Raphael³, Ksenia Gnedeva⁵, Lei Lei⁶, Donna M. Martin³

¹*University of Michigan*, ²*University of California- San Francisco*, ³*Kresge Hearing Research Institute, University of Michigan*, ⁵*Keck School of Medicine University of Southern California, Los Angeles*, ⁶*University of New England*

Background: Inner ear development requires precise spatiotemporal regulation of gene expression. Research has shown that two SRY-related high-mobility group box (SOX) transcription factors, Sox4 and Sox11, act as key regulators in inner ear morphogenesis. In the brain, SOX11 and SOX4 are essential neurogenic fate regulators and are direct targets of CHD7 (Chromodomain Helicase DNA binding protein 7). In humans, haploinsufficiency of CHD7 causes CHARGE syndrome which presents with inner ear dysplasia, hearing loss and balance impairment. Pathogenic variants in SOX11 are associated with Coffin-Siris syndrome and inner ear malformations. The specific mechanisms by which loss of CHD7 or SOX11 affects ear development are not fully understood but likely involve changes in downstream gene expression due to transcriptional regulation and nucleosome remodeling. In this study, we utilized mouse models to investigate whether Chd7, Sox4, and Sox11 operate within a shared or separate genetic regulatory network during inner ear development.

Methods: Embryonic inner ears with germline or conditional (Pax2Cre) deletion of Sox4, Sox11, and/or Chd7 were examined for morphological abnormalities using paint-filling and histological analysis. Molecular markers expressed during early inner ear development (E10.5-12.5) were assessed via qRT-PCR, immunofluorescence, and in situ hybridization. Laminin staining was assessed to visualize basement membrane integrity at the fusion plate. Cell Proliferation and apoptosis were evaluated using EdU incorporation and anti-Caspase3 assays, respectively.

Results: Severe abnormalities in the posterior and lateral semicircular canals were observed with loss of Sox11 or Chd7. In contrast, Pax2Cre;Sox4flox/flox inner ears exhibited no semicircular canal defects but displayed mild anomalies with enlarged common crus and endolymphatic duct. Sox11^{-/-} mutants exhibited delayed formation of the canal fusion plate, normal basement membrane laminin, reduced cell proliferation in the surrounding mesenchyme, and no aberrant cell death. Expression of Sox11 was reduced in Chd7 null ears, while expression of other genes known to regulate semicircular canal development (Otx1, Lmo4, Dlx5, and Bmp4) were normal in Sox11^{-/-} mutant ears.

Conclusions: Proper dosage of Sox4, Sox11, and Chd7 is crucial for normal development of vestibular structures in the mammalian inner ear. Sox11 functions downstream of Chd7 to regulate semicircular canal fusion plate formation and promote proliferation of cells in the surrounding otic mesenchyme.

SA88. Developmental Maturation of the Cochlear Sensory Epithelium Through Local Erk Signaling

Kevin Yu^{*1}, Trinh Nguyen¹, Travis Babola¹, Patrick Parker¹, Sergi Regot¹, Jonathan Gale², Dwight Bergles¹

Background: Formation of the sensory epithelium in the cochlea is achieved through tight coordination of cell transformation and cell loss. The most conspicuous cellular changes in the developing cochlea occur medial to hair cells, as Kölliker's organ (greater epithelial ridge, GER) transforms into the inner sulcus. The columnar epithelial cells of the GER create the tectorial membrane and induce spontaneous activity of inner hair cells before hearing onset, functions that are essential for the normal development of the biomechanical properties of the cochlea and maturation of central auditory circuits. Previous studies have shown that changes in thyroid hormone cause the GER to regress prematurely or persist beyond the point of hearing onset, resulting in elevated ABR thresholds, morphological defects in the tectorial membrane, and changes in cochlear tuning. However, the cellular mechanisms that control the transformation of the GER are unknown. Here, we explored the contribution of ERK signaling to this process, a pathway that controls cellular patterning in epithelia throughout the body.

Methods: To visualize ERK signaling dynamics in the developing cochlea, we generated cochlear explants from CD1 mice expressing an ERK kinase translocation reporter (CAG-ERK-KTR-P2A-H2B-mRuby2 mice), and recorded changes in localization of mClover from the nucleus (unphosphorylated ERK) to the cytosol (phosphorylated ERK). To determine the functional role of ERK signaling we applied inhibitors of ERK and EGFR to cochlear explants and recorded changes in ERK signaling and cellular transformation.

Results: Longitudinal imaging in explants from pre-hearing mice revealed that ERK was activated sporadically in spatiotemporally restricted clusters of GER cells (abbreviated as Spatiotemporally Restricted ERK Signaling, "SpaRKS"). These events lasted for approximately 40 minutes, appeared throughout the GER, and were abolished following the addition of a MEK1 inhibitor. SpaRKS first appeared at the base of the cochlea at P5 and progressed from the base-to-apex, increasing in frequency along the length of the cochlear coil with age. Inhibition of EGFR and ERK caused apoptosis of GER cells, suggesting that SpaRKS regulate apoptosis of GER cells during development. Imaging cochlear explants in propidium iodide revealed that SpaRKS occurred around dying cells, suggesting that apoptosis leads to the release of EGFR ligands that temporarily promote the survival of surrounding cells within the GER. This mechanism provides a means to slow the rate of GER regression, allowing gradual cellular transformation to occur along the length of the cochlea.

Conclusions: Our studies indicate that local ERK signaling occurs within GER cells as it transforms into the inner sulcus. These clustered events are induced by the release of EGFR ligands from dying cells, promoting survival of neighboring cells. These SpaRKS allow the gradual formation of the inner sulcus, coordinating GER regression with the maturation of other aspects of the sensory epithelium at hearing onset.

SA89. PEA3 Transcription Factors Role in Cochlear Epithelial Development

Selena Tian^{*1}, Mathew Papiernik¹, Hongji Zhang², Michael Ebeid²

¹Midwestern University College of Osteopathic Medicine, ²Midwestern University College of Graduate Studies

Background: The PEA3 subfamily of ETS transcription factors (ETV1, ETV4 and ETV5) contribute to the development of various tissues including nervous tissue, kidneys and lungs. They function through their evolutionary-conserved ETS domain that mediates DNA binding

and thereby regulates gene expression. In the cochlea, mesenchymal ETV4 and ETV5 operate downstream FGF signaling to regulate cochlear lengthening during early development. While epithelial FGF signaling has been shown to regulate multiple processes during cochlear development including placode induction, progenitor proliferation and differentiation, the role of potentially downstream PEA3 transcription factors has not been studied. In this work, we study the impact of epithelial-specific ETV1/4/5 single and combined deletions on cochlear epithelial development.

Methods: We generated single, double and triple mutant mouse models for the PEA3 family members through a conventional deletion of ETV4 and conditional deletions of ETV1 and ETV5 utilizing Sox2-driven inducible CreERT2. Mutant mouse embryos from pregnant females induced by tamoxifen at embryonic day (E) 12.5 and E13.5 were collected at E19.5 and analyzed using immunohistochemistry of whole mount tissues and cryosections. A One-Way ANOVA test followed by Tukey's multiple comparisons test were used to detect statistical significance and adjusted P value < 0.05 was considered significant. Single-cell RNA sequencing of cochlear duct cells from ETV1/4/5 triple mutant embryos and controls at E15.5 followed by 10x genomics cloud analysis were performed to analyze differentially expressed genes within the supporting cell cluster.

Results: ETV4/5 double and ETV1/4/5 triple mutants showed 22-35% increase in inner hair cell density throughout all cochlear turns with no change in outer hair cell density. TUJ1 staining showed disorganized innervation pattern to outer hair cells in both double and triple mutants. Hair cell densities and innervation in single mutant cochleae were comparable to controls. As for supporting cells, ETV4/5 double mutants showed 30-40% reduction in NGFR+ cell density and 5-33% increase in CD44+ cell density without any change in SOX2+ cell density. ETV1/4/5 triple mutants showed a more severe phenotype including 85-93% reduction in NGFR+ cell density and 64-78% increase in CD44+ cell density indicating a possible dose-dependent role of the PEA3 subfamily members in pillar cell development. Sox2-CRE positive control cochleae were comparable to Sox2-CRE negative cochleae and displayed no change in hair cell or supporting cell densities. Single-cell RNA sequencing of ETV1/4/5 triple mutant embryos at E15.5 showed 26 upregulated genes within the Fgfr3+ supporting cell cluster (Negative Binomial Exact Test, Log2 Fold change > 1, adjusted P value < 0.05) including 6 genes involved in glutamatergic synapses. Only 2 genes were downregulated when compared to triple heterozygote controls.

Conclusions: PEA3 family of transcription factors regulate epithelial development in mammalian cochlea. PEA3 deletion causes upregulation of glutamatergic synapse-specific genes within the supporting population. Pathways downstream PEA3 factors are currently under investigation.

SA90. Working Towards Human iPSC-Derived Vestibular-Cochlear Assembloids

Esther Fousert*¹, George Flamourakis¹, Winnie van den Boogaard¹, Peter Paul van Benthem², Wouter van der Valk¹, Heiko Locher¹

¹*OtoBiology Leiden, The Novo Nordisk Foundation Center for Stem Cell Medicine (reNEW), Leiden University Medical Center,* ²*OtoBiology Leiden, Leiden University Medical Center*

Background: The human inner ear comprises two interconnected systems: the cochlea and the vestibular system. While recent advances have enabled the generation of cochlear and vestibular organoids from human induced pluripotent stem cells (iPSCs), these systems are

typically developed in isolation, missing the anatomical unity seen in vivo. This separation poses limitations, especially when studying drug distribution or modeling diseases that affect the entire inner ear.

Methods: To address this, we propose a novel in vitro strategy to assemble a unified inner ear model by fusing separately differentiated vestibular and cochlear organoids. Organoids are initially directed toward vestibular or cochlear fate until day 22 (d22), corresponding to the stage when otic vesicle formation and lineage specification occur. At this point, we merge the organoids using different approaches, including direct co-culture in the same dish and a 3D-printed structure to push fusion of the two organoids.

Results: To distinguish and track the developmental contributions of each organoid, we used a combination of a wild-type iPSC line and a SOX2+ reporter iPSC line. After 4 days in the same well, the vestibular and cochlear organoid fused together. These "assembloids" are cultured until day 90 (d90), when the majority of vestibular and cochlear cell types have matured. The tissues are then fixed and analyzed via immunohistochemistry to assess cellular composition, organization, and potential interactions, and compared to individually cultured vestibular and cochlear organoids.

Conclusions: As a next step, we aim to apply this inner ear assembloid platform to model genetic hearing and balance disorders. Using iPSCs derived from a patient with a mutation causing USH2A disease, we generate disease-specific cochlear-vestibular assembloids. Furthermore, we test the therapeutic potential of previously established antisense oligonucleotides to counteract the disease phenotype within this integrated system.

SA91. ZMYM4 May Mediate Some Aspects of Spiral Ganglion Neuron Development and Specification

Karyn Jourdeuil^{*1}, Tessa Sanders², Matthew Kelley²

¹*The University of Iowa*, ²*National Institute on Deafness and Other Communication Disorders, National Institutes of Health*

Background: Zinc finger MYM-containing type 4 (ZMYM4) has recently been shown in *Xenopus laevis* to be expressed within the pre-placodal epithelium (PPE) and the neural crest cells (NCCs) during early embryogenesis. Loss of ZMYM4 results in a down regulation of NCC and PPE markers with a concomitant expansion of the neural ectoderm while overexpression had little to no effect. These data, combined with recent studies into other members of the ZMYM family, suggest that ZMYM4 may be acting as a pioneer factor during early specification of the PPE and NCCs. As the PPE gives rise to the otic placode and later, the sensorineural epithelium of the inner ear, we hypothesize that ZMYM4 may be involved in cell fate specification within the inner ear. More specifically, as it has been linked to neurodevelopment and the neural epithelium expands with loss of ZMYM4 at the expense of the NCCs and PPE, it is likely that ZMYM4 may play a role in the specification of the neural components of the inner ear, the spiral ganglia neurons (SGNs).

Methods: Whole mount and sectioned mouse embryos from embryonic day (E) 10.5 through to adulthood were analyzed to establish a temporospatial timeline of ZMYM4 expression throughout ontogeny. We then collected SGNs at E14.5 and performed scATACseq and CUT and RUN to establish whether ZMYM4 functions as a pioneer factor during neuronal subtype specification.

Results: ZMYM4 is expressed within the sensorineural epithelium from the earliest stages examined and is maintained in the population of cells that delaminate from the sensorineural

epithelium to form the SGNs. By E14.5, ZMYM4 has become restricted to the nucleus of all SGNs. As this corresponds to the stage at which SGNs initiate subtype specification, it is possible that ZMYM4 functions as a pioneer factor during SGN maturation. This nuclear expression of ZMYM4 is then maintained throughout ontogeny. As more reports of patients with congenital neurodevelopmental disorders are presenting with variants in ZMYM proteins, there is strong evidentiary support for its function as a regulator of neuronal maturation. We are currently analyzing scATACseq and CUT and RUN data to determine both whether ZMYM4 is bound to DNA and its potential downstream targets.

Conclusions: These data present only the very first investigation into the putative functions of ZMYM4 during inner ear development. In the future, we plan to investigate the function of ZMYM4 during SGN development and specification via both shRNA-mediated knockdown and overexpression within the ear. Overall, ZMYM4 is an exciting avenue of future research and may represent some of the uninvestigated epigenetic landscape of sensorineural development within the ear.

SA92. Itga8 Deletion From Supporting Cell Disrupts Cytoskeletal Microtubule Stabilization: Possible Role of YAP and ERM Signaling

Dinesh Gawande¹, Iman Ezzat¹, Lyudmila Bataalkina¹, Marisa Zallocchi^{*1}

¹*Creighton University*

Background: Supporting cells in the cochlea provide structural support that is critical for hair cell function. However, it is not well understood how their interactions with the extracellular matrix connect to the organization of their internal cytoskeleton. We examined how loss of integrin $\alpha 8$ (Itga8) in supporting cells affects YAP signaling and ERM protein function, two key regulators of cytoskeletal stability and cell mechanics.

Methods: We used conditional knockout mice (Sox2-Cre $\times$ Itga8^{fl/fl}) to delete Itga8 specifically in supporting cells. We then assessed changes in cell adhesion, cytoskeletal organization, and YAP and ERM signaling using RNA scope and immunostaining approaches.

Results: Loss of Itga8 disrupted junctions in pillar and Deiter's cells, weakening their mechanical connection to hair cells. RNA-scope data showed that Itga8 deletion altered YAP levels, shifting supporting cells toward reduced mechanosensitivity and premature cell cycle exit. From postnatal day 10 to 60, mutants showed progressive breakdown of actin and microtubule structures. In particular, pillar cells lost their characteristic acetylated microtubule bundles, which were nearly absent by P60. Changes in ERM protein levels further impaired their ability to connect actin and microtubules. We also noticed the age dependent hearing loss in mutant mice.

Conclusions: Our study identifies Itga8 as a key regulator linking YAP-driven gene programs with ERM-mediated cytoskeletal stability in supporting cells. This mechanosensing pathway offers a potential therapeutic target for hearing loss, as supporting cell dysfunction can precede and contribute to hair cell degeneration.

SA93. Role of Integrin $\alpha 8$ in Spiral Ganglion Neuron Development

Iman Ezzat¹, Dinesh Gawande¹, Peter Cline¹, Lyudmila Bataalkina¹, Marisa Zallocchi^{*1}

¹*Creighton University*

Background: Integrin $\alpha 8$ (Itga8) is a bi-directional adhesion receptor involved in cytoskeletal signaling, cilia biogenesis, and neuronal development. Although its function in sensory hair cells has been partially described, its role in auditory connectivity particularly in spiral ganglion neurons (SGNs), which relay sound information from the cochlea to the brain remains poorly understood.

Methods: We examined Itga8 expression in SGNs using RNAscope and immunohistochemistry across developmental stages up until after the onset of hearing, which have not been reported before. To assess function, we generated conditional knockouts (Celf4-iCreT2:Itga8^{fl/fl}) and evaluated neuronal morphology with confocal imaging, and quantitative analyses via Python based pipeline. Presynaptic integrity was assessed by CtBP2 synaptic counts, while auditory function was examined using auditory brainstem response (ABR) and distortion product otoacoustic emission (DPOAE) testing.

Results: Itga8 expression persisted in SGNs from birth through adulthood, suggesting a sustained role during auditory maturation. Conditional deletion of Itga8 in SGNs led to significant reductions in presynaptic ribbon counts in both inner and outer hair cells, decreased neurofilament density, and disorganized or misoriented neuronal fibers along the cochlear spiral. Quantitative analysis confirmed reduced neurite integrity in knockout mice. We are currently analyzing our ABR and DPOAE assessments to further elucidate on Itga8 function in auditory circuit.

Conclusions: These findings identify Itga8 as a critical regulator of SGN development and synaptic homeostasis. Loss of Itga8 disrupts neuronal morphology, connectivity, and auditory processing, underscoring its importance in cochlear circuit integrity.

SA94. Lipid-Regulating Drug Fenofibrate as a Candidate Therapy for Aminoglycoside-Induced Hearing Loss in Mice

Vijayprakash Namakkal Manickam¹, Marisa Zallocchi^{*1}, Lyudmila Batakina¹

¹*Creighton University*

Background: Aminoglycoside antibiotics remain indispensable for treating severe infections, yet their clinical utility is limited by a high incidence of permanent sensorineural hearing loss. Despite decades of research, no FDA-approved pharmacological agents currently exist to prevent aminoglycoside-induced hearing loss (AGIHL). The pathogenesis of AGIHL is multifactorial, involving oxidative stress, mitochondrial dysfunction, synaptic degeneration, and metabolic dysregulation, highlighting the need for therapeutic approaches that target multiple mechanisms. Fenofibrate, a peroxisome proliferator-activated receptor alpha (PPAR α) agonist widely prescribed for dyslipidemia, has found to be a lead compound through screening against kanamycin-induced hair cell loss in zebra fish. It has been reported to exert antioxidant and anti-inflammatory effects in extra-auditory tissues, raising the possibility of repurposing this well-characterized drug for otoprotection. However, its bioavailability in the cochlea, efficacy against AGIHL, and impact on inner ear metabolism remain poorly understood.

Methods: Six-to-seven-week-old C57BL/6 corrected for cdh23 mutation were co-treated with 600mg/kg of kanamycin twice a day and fenofibrate 20mg/kg/day for 14 consecutive days. ABRs and DPOAEs were recorded before and at 30 days post kanamycin and fenofibrate co-treatment. Mice were then sacrificed, and cochleae isolated for the analyses of IHC, OHC, and synapses. To avoid the saturation effect, mice were treated for 10 consecutive days and sacrificed after 24 hours of the last treatment, cochlear lysate were prepared to

isolate lipids and polar lipids were analysed using LC/MS, Mid-modiolar sections were prepared to perform RNA scop to analyse PPAR alpha, Acox1, Acs14, ApoE, TNF, IL-6 and MHC1 transcripts. Pharmacokinetic was performed after one-time oral dose of fenofibrate.

Results: Fenofibrate reached peak serum levels of 120 ng/ml and cochlear levels of 380 ng/ml at 3 hours, with prolonged retention in the cochlea at 24 hours. Kanamycin exposure induced ~30 dB SPL ABR threshold shifts, reduced peak-1 amplitudes, and synaptic ribbon loss. Co-treatment with fenofibrate significantly attenuated threshold shifts (10–15 dB SPL), preserved peak-1 amplitudes, and maintained synaptic ribbons across most frequencies, except at 16 kHz. Lipidomic profiling identified 307 species across 12 classes. Kanamycin disrupted cochlear lipid subclasses (ePC, PS, ePS, PA, LPE) without altering systemic levels. Fenofibrate normalized elevated ePC (38:4) and further reduced LPEs, partially restoring lipid balance. Although polar lipids were not fully recovered, these changes correlated with improved hearing sensitivity. RNAscope analysis showed that PPAR α , inflammatory genes (TNF, IL-6, MHC1), and lipid-regulating enzymes (Acox1, Acs14, ApoE) were dysregulated by kanamycin but restored to baseline with fenofibrate co-treatment.

Conclusions: Collectively, these results provide preliminary evidence supporting fenofibrate as a candidate for repurposing to prevent AGIHL. Furthermore, the observed modulation of lipid metabolic pathways highlights a novel mechanism of drug action that may contribute to long-term auditory protection.

SA95. Live Imaging of Presynaptic Ribbons in the Noise-Exposed Juvenile Mouse Cochlea

Peu Santra¹, Sanyukta Oak¹, Ian R. Matthews¹, Dylan Chan¹

¹UCSF

Background: Moderate acoustic exposure leads to cochlear synaptopathy, characterized by the loss of ribbon synapses between inner hair cells (IHCs) and spiral ganglion neurons (SGNs). This form of damage manifests as impaired sound processing despite preserved hearing thresholds. Unlike permanent threshold shifts caused by hair cell death, synaptopathy can be reversible. While live imaging of zebrafish neuromasts have provided key insights into ribbon formation, trafficking, and turnover, they do not reproduce physiologically relevant noise damage. Development of a robust model for direct visualization of synaptic ribbons in the noise-exposed mammalian cochlea is necessary to better understand how noise-induced cochlear synaptopathy develops and can be treated

Methods: To directly observe synaptic changes after noise trauma, we developed an ex vivo model using cochlear explants from 7-week-old RIBEYE-tagRFP mice, in which presynaptic ribbons are genetically labelled with tagRFP. Explants were imaged using a Nikon A1R upright confocal microscope with a 60 $\times$ water immersion objective and stage-top incubation. Mice were exposed to 2-hr, 98 dB SPL 8-16 kHz broadband noise, a stimulus known to induce synaptopathy in vivo. Animals were euthanized at multiple timepoints after completion of the noise exposure, and cochlear explants were dissected and imaged within 10 minutes of euthanasia. Confocal z-stacks of the basolateral poles of inner-hair-cells at the 8-10-kHz region of the cochlea were acquired for up to 30 minutes, and presynaptic ribbons were tracked for dynamic changes over time in number, size, and subcellular location.

Results: This imaging protocol enabled detection of ribbon motion with 3-dimensional subcellular spatial and ~1-minute temporal resolution, such that ribbon movement could be clearly tracked during the 30-minute recording periods. Simultaneous imaging with FM1-43

live dye confirmed overall inner-hair-cell morphological stability without evidence of cell swelling, blebbing, or death. Following noise exposure, presynaptic ribbons on aggregate showed increased motility. Subsets of ribbons demonstrated distinct behaviors, including unanchoring from paired synapses along the cell periphery, directed cytoplasmic transport, and punctal fusion. These events unfolded dynamically over the hours to days following exposure.

Conclusions: This live imaging model reveals that presynaptic ribbons undergo specific significant rearrangements in response to acoustic trauma. The observed motility suggests a window of synaptic plasticity during which targeted interventions may stabilize or restore vulnerable contacts. This system provides a powerful platform for studying synapse recovery mechanisms and testing therapeutic strategies for noise-induced hearing deficits.

SA96. Sec14-Like3, a Lipid Transporter Protein, Attenuates the Cochlear Damage Caused by Intense Noise Exposure

Takeshi Matsunobu^{*1}, Yishihiro Haruna², Daisuke Arakawa², Norihiro Usukura², Minoru Gotoh², Mashito Sakai²

¹National Defense Medical College, ²Nippon Medical School

Background: The cochlea is a crucial organ in sound reception. The cochlear sensory epithelium, along with the outer cochlear wall, plays a vital role in effectively transmitting auditory signals via a delicate mechanism. Recent studies have highlighted the significant role of lipids in intracellular signal transduction within the cochlear sensory epithelium^{1,2}. However, the detailed mechanisms underlying this process remain poorly understood.

To investigate the involvement of lipids in sound reception, we focused on the lipid transporter protein Sec14-like3, which has been implicated in lipid transport in the alveolar and bronchial epithelium³.

Methods: Wild-type and knockout mice with C57/BL6 background obtained from the Department of Biochemistry and Molecular Biology (Nippon Medical School, Tokyo, Japan) were used in this study.

Sec14l3/l4 double-KO mice were created using the CRISPR-Cas9 system by designing sgRNAs in exon5 each of Sec14l3 and Sec14l4. The sequence surrounding exon5 of Sec14l3 is inserted into exon5 of Sec14l4. This insertion causes a frameshift in both Sec14l3 and Sec14l4. Therefore, we decided to use these mice as Sec14l3/l4 double KO mice. ABR measurement and immunohistochemistry for 8-OHdG and 4-HNE were performed. Statistical analyses were conducted using IBM SPSS Statistics version 29.0.2. The data for ABR thresholds, hair cell counts and relative expression (8-OHdG and 4HNE) were compared by unpaired two-tailed Student's t-test.

Results: Immunohistochemical images showing the expression of Sec14l3 (green) protein in the organ of Corti of WT and KO mice. Immunohistochemical images showing the expression of Sec14l4 (green) protein in the organ of Corti of WT and KO mice. Scale bar is 5 μ m. Immunohistochemical images showing the expression of Sec14l4 (green) protein in the spiral ganglion, spiral ligament, and stria vascularis of WT mice. Scale bar is 20 μ m. Cell nuclei are stained blue, and hair cells are stained red. WT: wild type group; KO: knock out group. OHC: outer hair cell; IHC: inner hair cell.

Sec14l3 expression was observed in the organ of Corti (Deiters' cells and inner pillar cells) No clear Sec14l4 expression was observed in the cochlea. Under normal conditions, no

significant differences in auditory brainstem response (ABR) thresholds were detected among the groups. However, following noise exposure, significant differences in the ABR threshold shifts were observed in each group. Across all frequencies, the ABR threshold shifts in KO mice were greater than those in WT mice.

Conclusions: we designed sgRNAs in exon5 of each Sec14l3/14 and created Sec14l3/14 double-knockout (KO) mice using the CRISPR-Cas9 system. Wild-type (WT) and Sec14l3/14 double KO mice exhibited no differences in hearing at steady state. However, significant hearing loss was observed in Sec14l3/14 double KO mice following acoustic exposure. These results suggested that Sec14l3 plays an important role in sound reception.

SA97. Role of Rabs in Regulating Aminoglycoside Ototoxicity in Sensory Hair Cells

Emma Kenyon^{*1}, Rachel George¹, James Bull¹, Corné Kros², Guy Richardson²

¹Swansea University, ²University of Sussex

Background: Aminoglycoside antibiotics are used clinically to treat serious bacterial infections. Unfortunately, they can result in hearing loss, tinnitus and balance disorders. The aminoglycosides enter the hair cells of the inner ear via mechanoelectrical transducer channels in the sensory hair bundle and/or via endocytosis. Both routes of entry eventually lead to delivery of the aminoglycosides to the lysosome with slower delivery causing an increase in toxicity, possibly due to increased impact on other cytosolic structures (e.g., ribosomes). However, the molecular mechanisms whereby ototoxic antibiotics are trafficked through the cells are poorly understood. Intracellular trafficking is heavily dependent on vesicle transport events which are in turn controlled by Rab proteins. This family of vesicle-transport proteins has been well studied, particularly in cell assays, and their association with known cellular pathways and effectors is relatively well described, particularly for those Rabs described as either essential or associated with human disorders. We sought to identify which RabGTPases are associated with intracellular trafficking of the aminoglycosides and therefore which pathway may be involved.

Methods: 5-day post fertilisation (dpf) pou4f3:GFP zebrafish larvae were treated with either 10 μ M gentamicin or control medium for 3 hrs, a time point before any overt hair-cell death occurs. The larvae were then dissociated using trypsin/EDTA and hair cells isolated using fluorescent cell sorting with a FACSMelody Cell Sorter and RNA extracted. Three control and three gentamicin matched samples were sent for QuantSeq. Sequences were analysed using the Galaxy platform and EdgeR. 5dpf AB zebrafish larvae were treated with either 10 μ M gentamicin or control medium for 3 hrs, anaesthetised, fixed in 4% PFA overnight and dehydrated in methanol. RNAscope was performed using probes for a hair cell marker (myo6b) and either rab44 or rab1aa. Larvae were mounted in ProLong Gold onto slides with glass shims and imaged using a Zeiss LSM980 confocal. Images were analysed using ImageJ.

Results: RNAseq data has identified a number of rabGTPases that are differentially expressed in the gentamicin-treated hair cells. Those highly upregulated include rab44 shown to have a role in early endosomes and lysosomal exocytosis, and rab1aa which is involved in endoplasmic reticulum (ER) to Golgi trafficking and autophagy. Expression analysis using RNAscope shows an increase in the total area of rab1aa positive puncta in lateral-line hair cells of larvae treated with gentamicin compared to control larvae.

Conclusions: These data suggest roles for rab1aa and rab44 in the transport of aminoglycosides inside the hair cells. To confirm we are producing rab44 knock-out and

dominant-negative rab1aa knock-in zebrafish to assess how altering Rab-mediated transport affects the survival of aminoglycoside-treated hair cells.

SA98. Activation of Aryl Hydrocarbon Receptor Signaling Rescues Cochlear Hair Cells From Damage

Sujata Pandey^{*1}, Shelley Tischkau¹, Brandon Cox¹

¹*SIU School of Medicine*

Background: Preventing cochlear hair cell damage caused by ototoxins and acoustic trauma remains a major challenge in the auditory field, with limited therapeutic interventions available. Identifying genes and signaling pathways that mediate protective or reparative responses to oxidative stress and injury is critical. The aryl hydrocarbon receptor (AhR) is a ligand-activated transcription factor known to regulate xenobiotic metabolism and cellular homeostasis, but its role in the cochlea and in repair following ototoxic injury remains unexplored. Using a cochlear explant model, we previously found that pharmacological activation of AhR with an endogenous ligand 24 hours after neomycin exposure significantly increased outer hair cell survival in the middle and basal turns compared to controls treated with neomycin only. In this study, we investigated the expression pattern of AhR in the cochlea under physiological and damaged conditions, as well as mechanisms downstream of AhR involving anti-inflammatory and anti-oxidative pathways.

Methods: AhR expression in the cochlea was assessed using the knockin AhRtdTomato mouse model, where tdTomato expression is driven by endogenous AhR regulatory elements. Cochlear whole-mount microdissections and mid-modiolar sections were examined at key postnatal stages. To model injury, cochlear explants from C57BL/6 mice were treated with 600 μ M neomycin for 24 hours, followed by pharmacological activation with the AhR agonist Oto-39. Activation of the AhR target gene, CYP1A1, and the impact on inflammatory responses was assessed using quantitative RT-PCR.

Results: Constitutive AhR expression was observed in supporting cells, Schwann cells, and glial cells surrounding spiral ganglion neurons, with low basal expression in the organ of Corti. Following neomycin treatment, AhR expression was increased in supporting cells specifically in the region medial and lateral to hair cells compared to controls treated with media only. Pharmacological activation of AhR with Oto-39 increased CYP1A1 expression, confirming activation of AhR signaling in the cochlea. Preliminary results further revealed reduced expression of the pro-inflammatory cytokine TNF- α after AhR activation. Studies to further elucidate the contribution of AhR signaling to antioxidant responses (via the AhR–Nrf2 pathway) are ongoing.

Conclusions: Our findings demonstrate that AhR is constitutively expressed in cochlear supporting cells and is upregulated following ototoxic injury. Activation of AhR signaling reduces pro-inflammatory responses and enhances hair cell survival, suggesting a novel reparative role for AhR in the cochlea.

SA99. NADPH Oxidase 3 Inhibition Preserves Hearing in Mice After Stereotactic Radiosurgery

Dimitrios Daskalou^{*1}, Francis Rousset¹, Stéphanie Sgroi¹, Lucie Oberhauser¹, Jean-Philippe Thiran², Constantin Tuleasca³, Ileana O Jelescu⁴, Marc Levivier³, Pascal Senn¹

¹*The Inner Ear and Olfaction Lab, University of Geneva, Faculty of Medicine,* ²*Laboratory of Signal Processing 5, École Polytechnique Fédérale de Lausanne (EPFL),* ³*Neurosurgery Service and Gamma Knife Center, Centre Hospitalier Universitaire Vaudois (CHUV),* ⁴*Lausanne University Hospital (CHUV),*

Background: Stereotactic radiosurgery (SRS) is a standard treatment for vestibular schwannoma but carries a substantial risk of progressive and irreversible hearing loss. NADPH oxidase 3 (NOX3), an enzyme predominantly expressed in the inner ear, has been identified as a key source of oxidative stress driving cochlear injury. We investigated whether genetic deletion or transient inhibition of Nox3 using small interfering RNA (siRNA) could preserve auditory function and cochlear structures following SRS.

Methods: C57BL/6J mice (6 weeks old) received unilateral 32 Gy cochlear irradiation in two experimental arms. In the genotype arm, littermates included wild-type (Nox3^{+/+}; n=8), heterozygous (Nox3^{+/-}; n=8), and Nox3-deficient (Nox3^{-/-}; n=8) mice. In the siRNA arm, wild-type mice were randomly assigned to posterior semicircular canal injection of either siRNA targeting Nox3 (siNox3; n=14) or scrambled control (siScr; n=14) 48 hours before SRS. Irradiation was delivered using the Gamma Knife ICON system with cone-beam CT co-registered to MRI and CT-based mouse atlases for precise unilateral cochlear targeting. Auditory brainstem responses (ABR) were obtained at baseline, 1, and 4 weeks post-SRS. At week 4, cochleae were collected for histological analysis. Statistical analyses employed a two-way repeated measures ANOVA with Bonferroni correction.

Results: Following 32 Gy unilateral SRS, wild-type mice developed progressive high-frequency hearing loss by week 4, whereas Nox3-deficient littermates showed complete preservation of auditory thresholds, with significant differences between groups across 2.8–32 kHz ($p < 0.01$ to $p < 0.0001$). Heterozygous mice exhibited an intermediate phenotype. Contralateral ears showed no ABR threshold shifts in any group. Under suprathreshold stimulation, wave I and III amplitudes were significantly lower in wild-type than in Nox3-deficient mice after click stimulation (both $p=0.02$) and at 32 kHz ($p=0.002$ and $p=0.03$). Histology revealed preserved inner hair cells in all groups. Wild-type mice showed marked outer hair cell (OHC) and ribbon synapse loss with mild spiral ganglion neuron (SGN) reduction at the basal turn, partially attenuated in heterozygous and absent in Nox3-deficient mice.

Similarly, siNox3-treated mice were largely protected from SRS-induced hearing loss, with significant differences in auditory thresholds compared with the siScr-treated group across 5.6–32 kHz ($p < 0.05$ to $p < 0.0001$). Under suprathreshold stimulation, wave I and III amplitudes at 32 kHz were significantly lower in siScr compared with siNox3-treated mice ($p=0.03$ and $p=0.04$). Histology in siScr-treated mice resembled that of wild-type animals. In contrast, siNox3-treated mice showed preserved ribbons and SGNs, with only mild OHC loss at high frequencies.

Conclusions: Genetic deletion and siRNA-mediated knockdown of Nox3 preserved auditory function and prevented cochlear injury following SRS, establishing NOX3-derived oxidative stress as a key mediator of ototoxicity. Given the predictable timing of SRS for vestibular schwannoma in clinical practice, a NOX3-targeted intervention represents a feasible and selective strategy to prevent hearing loss without compromising tumor treatment.

SA100. Effects of Military Service on Auditory Brainstem Response Morphology

William Allen*¹, Jarrod Mau¹, Naomi Bramhall², Brad Buran³, Stephen Neely⁴, Sara Harris⁴, Aryn Kamerer¹

¹Utah State University, ²VA National Center for Rehabilitative Auditory Research, ³Oregon Health and Science University, ⁴Boys Town National Research Hospital

Background: Military Veterans often report hearing concerns despite normal or near-normal audiometric thresholds, which suggest relatively normal outer hair cell function. However, many Veterans experienced significant degrees of loud noise exposure during their military service that may result in neural changes to the auditory system. Efforts to detect neural changes due to noise exposure using the auditory brainstem response (ABR) have produced mixed results. These inconsistencies may reflect the limits of conventional ABR analyses, which typically rely on visual inspection of the ABR to extract features such as peak latencies and amplitudes. While these features are clinically useful, they capture only a small portion of the ABR waveform and may overlook broader morphological patterns. Our automated modeling approach, the Gaussian Mixture Model Feature Extraction Technique (GMM-FET), quantifies a wider set of waveform features and may provide a more sensitive means of identifying cochlear deafferentation and other damage to the central auditory nervous system.

Methods: ABR waveforms generated in response to high intensity tone-bursts at multiple frequencies were collected from 330 adults (95 Veterans and 235 non-Veterans) with audiometric thresholds ≤ 40 dB HL at Boys Town National Research Hospital (BTNRH), Utah State University (USU), and the VA National Center for Rehabilitative Auditory Research (NCRAR). ABR waveforms will be analyzed by both visual inspection and the GMM-FET, which extracts up to 73 features per waveform. Logistic regression will be used to predict Veteran status from the ABR waveform features, controlling for potential outer hair cell damage as measured by standard and high-frequency audiometric thresholds and otoacoustic emissions. The BTNRH and USU datasets will be used to train, reduce features, and cross-validate the logistic regression model, while the NCRAR dataset will be reserved to test the model performance.

Results: Preliminary results using the BTNRH dataset show that prediction of Veteran status using visually extracted ABR waveform features is no better than chance, while GMM-FET extracted features perform significantly better than chance. Important GMM-FET extracted features of the ABR that differ significantly between Veterans and non-Veterans include latency and amplitude, but also area and curvature changes to waves II through IV. The addition of the USU data and testing the model on the NCRAR dataset will evaluate the generalizability of these findings.

Conclusions: Veterans and non-Veterans exhibit clear differences in ABR waveform morphology using our automated feature extraction technique that are not clear using traditional visual inspection. These diffuse changes to the ABR beyond wave I, are not explained by audiometric thresholds or otoacoustic emissions, suggesting the presence of subclinical neural changes associated with military service that may extend beyond outer hair cell loss and cochlear deafferentation from noise exposure.

SA101. Mitochondrial Protection by Oncomodulin: A Key Mechanism in Preventing Noise-Induced Hearing Loss

Santhalakshmi Ranganathan*¹, Janith Hewa Halpage¹, Dwayne Simmons¹

¹Baylor University

Background: Noise-induced hearing loss (NIHL) is a major cause of sensory impairment worldwide, commonly linked to mitochondrial dysfunction and hair cell death within the cochlea. Together, these conditions compromise auditory function and survival of sensory cells. Mitochondria play a central role in maintaining cellular energy metabolism and calcium homeostasis, and their dysfunction often triggers oxidative stress and cell death. Previous studies show that oncomodulin (OCM), a calcium-binding protein, uniquely enriched in cochlear outer hair cells (OHC), modulates intracellular calcium signaling and is important for maintaining auditory function. However, its specific role in mitochondrial stability and protection against cellular stress-induced damage is not understood.

Methods: To investigate the role of OCM in mitochondrial homeostasis, we have employed both in vitro and in vivo approaches. Recent studies in our lab show that OCM knockout (KO) mice had significantly elevated auditory brainstem response (ABR) thresholds following noise exposure (120 dB SPL, 2 hrs) compared to wild-type (WT) controls. This functional decline was accompanied by reduced expression of the mitochondrial marker TOM20, suggesting impaired mitochondrial maintenance. In this study, we used HEI-OC1 cells, which are derived from auditory cells as an in vitro model to investigate cellular and sub-cellular modifications during induced stress. These cells were transfected with OCM or control vectors and exposed to thapsigargin, an endoplasmic reticulum stressor, or hydrogen peroxide, an oxidative stress inducer. Cellular and subcellular responses were assessed using Mitosox live cell imaging for superoxide detection, mitochondrial membrane potential assays, immunofluorescence for mitochondrial markers and cytochrome C release to detect apoptosis.

Results: After transfection with OCM, HEI-OC1 cells showed marked resistance to thapsigargin-induced stress. Specifically, OCM-transfected cells displayed reduced mitochondrial superoxide accumulation, preservation of mitochondrial membrane potential, and maintenance of TOM20 expression at near-normal levels. Furthermore, OCM expression was associated with reduced cytochrome C release, indicating suppression of mitochondrial-mediated apoptotic signaling. Collectively, these findings demonstrate that OCM enhances mitochondrial resilience and limits oxidative injury under stress conditions.

Conclusions: Our study provides compelling evidence that OCM serves a protective role in maintaining mitochondrial homeostasis within cochlear hair cells. By buffering calcium and stabilizing mitochondrial function, we hypothesize that OCM reduces oxidative stress and prevents initiation of apoptosis, thereby preserving OHC viability and auditory function. These findings highlight OCM as a critical factor in reducing susceptibility to NIHL and suggest that strategies to enhance or mimic OCM activity may represent a novel therapeutic avenue for mitigating hearing loss associated with acoustic trauma.

SA102. Repurposing Pravastatin and Metformin for the Treatment and Prevention of Noise-Induced Hidden Hearing Loss in a Mouse Model

Reza Amanipour*¹, Benjamin Shuster², Matthew Ingersoll¹, Beatrice Milon¹, Ronna Hertzano¹

¹NIH NIDCD, ²University of Maryland School of Medicine

Background: Noise-induced hidden hearing loss (NIHHL) is a subtle form of hearing damage in which thresholds recover while synapses between inner hair cells and afferent fibers are permanently damaged. Currently, there are no FDA-approved therapeutics. Using a noise-response molecular atlas and DrugCentral, we identified statins and metformin as

potential NIHL therapeutics. Both target the mevalonate pathway, upregulated in key auditory cells after acoustic trauma. Here we report the completed study evaluating whether these drugs protect against NIHL.

Methods: Seventy-two male and seventy-two female B6CBAF1/J mice were used. Pravastatin (25 mg/kg/day) and metformin (200 mg/kg/day), alone and in combination, were delivered in drinking water beginning at 8 weeks. Baseline ABR and DPOAE thresholds were recorded at 9 weeks. At 10 weeks, mice were exposed to noise (97 dB SPL, 8–16 kHz, 2 h) to induce NIHL without a permanent threshold shift. ABR and DPOAE were measured at 24 hours, 1 week, and 6 weeks post-exposure. Cochlear tissue was collected for histology (OHC loss; IHC synapse counts with CtBP2/GluR2). ABR and DPOAE thresholds were assessed using two-way ANOVA with Tukey's multiple comparisons, and wave-I amplitudes with two-way ANOVA followed by Dunnett's test versus placebo; adjusted p values are reported. Data were analyzed with $\alpha = 0.05$.

Results: Consistent with a hidden hearing loss-inducing exposure, thresholds in all groups returned to baseline by one week post-noise and remained stable at six weeks. The main outcome, ABR threshold shifts at 24 hours post-exposure, showed robust protection in male mice treated with either metformin alone (16 kHz, $p=0.0009$; 24 kHz, $p < 0.0001$; 32 kHz, $p < 0.0001$) or the combination of metformin and pravastatin (16 kHz, $p=0.0009$; 24 kHz, $p < 0.0001$; 32 kHz, $p < 0.0001$). In females, both pravastatin (16 kHz, $p=0.012$; 24 kHz, $p=0.0045$; 32 kHz, $p=0.0005$) and the combination (16 kHz, $p=0.0002$; 24 kHz, $p < 0.0001$; 32 kHz, $p=0.0007$) significantly reduced ABR threshold shifts, while metformin alone was not protective.

The second key outcome, ABR wave-I amplitude at one week post-exposure, showed significantly larger responses in males treated with combination therapy compared to placebo at 32 kHz, mid-level intensities ($p < 0.05$), consistent with partial preservation of auditory nerve function.

Supporting measures from DPOAE analysis showed additional protective effects: in males, the combination improved responses; in females, pravastatin and the combination reduced threshold shifts. Histological analysis is ongoing and will evaluate OHC loss and IHC synaptic integrity to further define protective mechanisms.

Conclusions: After completion with an expanded sample size across sexes, our data demonstrate that metformin plus pravastatin improves early auditory recovery after acoustic trauma. Effects were frequency- and sex-dependent, with combination therapy providing the most consistent protection in males and pravastatin contributing in females. Ongoing histology will clarify synaptic preservation underlying these outcomes and will be presented at February 2026 meeting.

SA103. Electroencephalographic Measurements of Auditory Development in the First Year of Life

Clémence Basire^{*1}, Laurianne Cabrera²

¹CNRS, ²Université de Paris - CNRS

Background: Phonetic features rely partly on temporal acoustic changes in speech, such as frequency modulation (FM) and amplitude modulation (AM). However, many of the neural mechanisms supporting temporal processing are immature at birth due to the protracted development of the auditory system. This study aims to explore auditory development in the first year of life by using electroencephalographic (EEG) methods. Three recordings targeting

different auditory structures, from the auditory nerve up to the auditory cortex are measured in infants using a longitudinal design.

Methods: We recruited a group of 25 3-month-old infants who are following-up at 10-month-olds. We also recruited a group of 31 adults for comparisons. All listeners were awake throughout the EEG recordings and were presented with AM-sound to record AMFR (amplitude modulation following response) and FM stimuli to record FFR (frequency following response). The AMFR was recorded for a 4-min-long pure-tone sinusoidally modulated at 8 Hz (carrier frequency = 1027 Hz) presented via loudspeakers (at 75 dB SPL). The FFR was recorded for a saw-tooth wave sound centered at 220 Hz and presenting FM fluctuations of 4 Hz. This sound was presented via loudspeakers (at 60 dB SPL) in a continuously manner for 4 min with first positive polarities and then another 4 min with negative polarities. We also recorded the wave V of ABRs (Auditory Brainstem Responses) for all listeners.

Results: Wave-V ABRs were consistently observed in all infants while they were awake. We however observed a faster transmission of the sound signal in adults than in infants. For the FFR, adults showed a higher response of neural encoding response to FM than 3- and 10-month-old infants. However, for the AMFR, no difference in amplitude of the neural response to AM was observed with age.

Conclusions: Our results are promising for the clinical assessment of auditory functions in infants. ABR results suggest that the neural transition of sound from the ear to the brainstem is not yet fully developed by the age of 10 months. FFR results suggest that neural phase locking for sounds with FM variations of 4 Hz is not adultlike at 10 months of age, while the neural encoding of slow AM (8 Hz) is by 3 months. Therefore, this study provides information about auditory development in the first year of life from the early to late stages of neural sound processing.

SA104. Targeted AAV Gene Therapy for Genetic Hearing Loss in Pendred Syndrome and DFNB4

K. Domenica Karavitaki¹, André Landin Malt¹, Felicia Gilels¹, May Kwang-Mei Wang¹, Jason Farnsworth¹, Alexander Flynn¹, Marc Johnson¹, William Neidermyer¹, Anjil Giri¹, Shawn Harriman¹, Jodi A. Cook¹

¹*Skylark Bio, Inc.*

Background: Mutations in the SLC26A4 gene are a leading cause of inherited hearing loss, accounting for over 6% of cases. These mutations result in Pendred syndrome and DFNB4, two forms of sensorineural hearing loss for which there are currently no effective treatments beyond supportive care like hearing aids or cochlear implants.

Methods: We have designed an AAV-SLC26A4 vector capable of improving the hearing thresholds and preventing the inner ear pathology in mouse models with SLC26A4 mutations that recapitulate aspects of the human disorder. Human SLC26A4 coding sequence was packaged in the AAV-S capsid, which shows high transduction in native SLC26A4-expressing cells in neonatal mouse and adult NHP cochlea. Vectors were injected into postnatal day 1 (P1) mouse and adult NHP cochlea via the round window membrane (RWM).

Results: To understand the vector transduction efficiency and expression specificity, wild-type (WT) mice were injected with an AAVS-SLC26A4 HA-tagged vector. After ~30 days, cochleas were processed for histology. Cochlear cells natively expressing Slc26a4 produced the HA-tagged SLC26A4 protein, demonstrating cell-specific vector expression.

We tested the vector's efficacy in two different mouse models of SLC26A4-related hearing loss.

(1) Severe SLC26a4 Knockout (KO) Model: Mice with severe-to-profound hearing loss showed a dose-dependent improvement in hearing, with some mice experiencing a remarkable 30-40 dB improvement. This treatment also preserved outer hair cells (OHCs), a key structure for hearing, which were otherwise lost in the untreated mice.

(2) Variable L236P Knock-in Model: In a second model representing a common human mutation, the treatment resulted in a statistically significant improvement of 20-30 dB in median hearing thresholds. Even in animals with high hearing thresholds, OHC loss was significantly reduced by approximately 50%, highlighting the protective effect of the therapy on cochlear anatomy.

Finally, to assess potential efficacy in humans, the AAVS-SLC26A4-HA vector was injected through the RWM of cochleas of cynomolgus monkeys (*M. fascicularis*). As in mouse, HA labeling demonstrated cell-specific expression.

Conclusions: The novel AAVS-SLC26A4 vector successfully and specifically expressed the human SLC26A4 protein in the correct cochlear cells of both mice and NHPs. It demonstrated significant therapeutic effects in two different mouse models of the disease, leading to improved hearing and preservation of critical inner ear structures. These results suggest that AAVS-SLC26A4 is a promising candidate for further development as a gene therapy for SLC26A4-related hearing loss in humans.

SA105. Improvement of Hearing and Prevention of Inner Ear Pathology in a Severe SLC26a4 Mouse Model of Pendred Syndrome/DFNB4

André Landin Malt¹, Felicia Gilels¹, May Kwang-Mei Wang¹, Jason Farnsworth¹, Alexander Flynn¹, Marc Johnson¹, William Neidermyer¹, Anjil Giri¹, Shawn Harriman¹, Jodi A. Cook¹, K. Domenica Karavitaki*¹

¹*Skylark Bio, Inc.*

Background: Mutations in the SLC26A4 gene, encoding pendrin protein, are responsible for Pendred syndrome and DFNB4, two autosomal recessive disorders causing sensorineural hearing loss. Pendrin is essential in the inner ear for regulating endolymphatic pH and maintaining the endocochlear potential. Without functional pendrin inner ear development is severely disrupted, leading to profound deafness. We developed a novel AAVS-SLC26A4 gene therapy to restore SLC26A4 function by directly delivering the functional gene to the ear.

Methods: Human SLC26A4 coding sequence was packaged in the AAV-S capsid, which shows high transduction in native SLC26A4-expressing cells in neonatal mouse and adult NHP cochlea. We used an in-vitro activity assay to ensure that the AAVS-SLC26A4 vector generates functional protein. To test in vivo efficacy AAVS-SLC26A4, we injected the vector into the round window membrane of postnatal day 1 (P1) *Slc26a4* knockout mice that exhibit severe-to-profound hearing loss. Animals were tested by auditory brainstem response (ABR) ~30 days after injection.

Results: To measure the activity of the pendrin protein, we developed an assay using a halide-sensitive YFP mutant in HEK293 Phoenix Eco cells. We measured baseline YFP fluorescence in a high chloride solution, then added a high iodide solution to quantify the quenching caused by pendrin's iodide exchange activity. YFP fluorescence was quenched in a

dose-dependent manner based on the amount of AAVS-SLC26A4 delivered. Cells that didn't receive AAVS-SLC26A4 showed no significant quenching, confirming that the fluorescence reduction was directly caused by the gene therapy. Furthermore, we confirmed that pendrin expression correlated with the observed YFP quenching.

To test the hearing efficacy of AAVS-SLC26A4 *in vivo*, we injected Slc26a4-KO mice with various doses of the AAVS-SLC26A4 vector expressing human SLC26A4 and show that AAVS-SLC26A4 dose-dependently improved hearing thresholds with some animals achieving 30-40 dB improvement compared to the best hearing uninjected KO animal. We then explored whether a vector using the mouse Slc26a4 gene, instead of the human one, might be even more effective. Preliminary findings suggest this is the case, particularly at lower frequencies.

To assess the effect of the treatment on cochlear anatomy, we quantified outer hair cell (OHC) numbers in SLC26a4-KO animals. Untreated Slc26a4-KO mice showed loss of OHCs whereas treated mice had a striking preservation of OHCs with 100% normal OHCs in most animals, making them histologically indistinguishable from the wild-type controls.

Conclusions: We demonstrate that the novel AAVS-SLC26A4 gene therapy vector is highly effective in producing functional pendrin protein. When tested in a severe mouse model of Slc26a4-related hearing loss, the vector showed targeted expression of the human gene and significantly improved hearing thresholds and prevented the loss of OHCs. These findings represent a major step toward a potential clinical treatment for SLC26A4-related hearing loss.

SA106. Preclinical Genome Editing Therapy Safely and Efficiently Restores Progressive Hearing Loss in Kcnq4 G285S Mouse

Wan Du^{*1}, Wenliang Zhu², Wei Wei², Yehree Kim², Jingyi Xu², Natalie Pelon², Xuezhong Liu³, Zheng-Yi Chen²

¹Mass Eye and Ear/Harvard Medical School, ²Mass Eye and Ear, ³University of Miami Miller School of Medicine

Background: Autosomal dominant hearing loss is typically progressive and postlingual, creating a potential window for intervention. Mutations in KCNQ4 gene cause DFNA2A, one of the most common forms that represent ~10% of all DFNA cases. KCNQ4 encodes a voltage-gated potassium channel essential for outer hair cell (OHC) function, and pathogenic mutations exert a dominant-negative effect, abolishing potassium currents and causing OHC degeneration. Standard AAV-mediated gene replacement therapy is unsuitable for dominant mutations, highlighting the unmet need for precision genome editing approaches. A mouse model with the equivalent human mutation Kcnq4 G285S/+ showed a delayed onset and progressive hearing loss, making it an ideal model to develop a gene editing therapy to rescue hearing for DFNA2.

Methods: We used a genome editing strategy by designing and screening gRNAs for diverse CRISPR systems, including SpCas9, SaCas9-KKH, and the adenine base editor SpCas9-NG-ABE8.0e, to specifically target the Kcnq4 G285S mutation. By PiggyBac transposon insertion, we created NIH-3T3 cells and human HEK293 cells engineered to carry the KCNQ4 G285S mutation. Editing outcomes were assessed using next-generation sequencing (NGS). The sgRNA and SaCas9-KKH were packaged into a single AAV2 for injection into adult Kcnq4 G285S/+ inner ear. Auditory function was assessed by ABR and DPOAE.

Results: In vitro screening identified multiple gRNAs for SpCas9 with robust on target editing, but also with modest editing on the WT Kcnq4 allele, leading to the exclusion of the

SpCas9 gRNAs. In contrast, multiple SaCas9-KKH gRNAs exhibited efficient editing targeting the KCNQ4 G285S allele, with undetectable editing in the KCNQ4 WT allele. We constructed AAV2-SaCas9-KKH/sgRNA-Kcnq4 and injected it into 4-week-old Kcnq4G285S/+ inner ear, with the uninjected ears as controls. 12 weeks after the injection, we detected lower ABR thresholds in injected compared to the uninjected control ears, an indication of hearing rescue. Lower DPOAE thresholds were also observed in the injected ears. To assess long-term auditory function by genome editing, hearing tests were conducted at 24 weeks after injection. Significantly lower ABR and DPOAE thresholds were detected in injected ears compared to the uninjected control ears. Greater reductions in ABR and DPOAE thresholds were detected at 24 weeks than at 12 weeks post injection, an indication of long term rescue.

Conclusions: Our study provides proof of concept that genome editing can safely and efficiently restore auditory function in Kcnq4-related dominant hearing loss. By allele-specific disruption of the KCNQ4 G285S mutation, we demonstrate genome editing as a promising therapeutic strategy for DFNA2A and other dominant forms of genetic deafness. AAV2-mediated delivery of SaCas9-KKH/sgRNA-Kcnq4 in an adult DFNA2 mouse model resulted in significant hearing rescue, laying the groundwork for an ongoing IND-enabling study to move the work toward the clinic.

SA107. AAV-Mediated Gene Therapy to Target Vestibular Schwannoma

Lukas D. Landegger^{*1}, Sasa Vasilijic¹, Paul Krumpoeck¹, Ruiqi Zhou², Erdem Yildiz³, Aldine Tu³, Taha A. Jan², Konstantina M. Stankovic¹

¹Stanford University School of Medicine, ²Head and Neck Surgery, Epithelial Biology Center, Vanderbilt Center for Stem Cell Biology, Vanderbilt University Medical Center, ³Head and Neck Surgery, Vienna General Hospital, Medical University of Vienna

Background: Vestibular schwannomas (VSs) represent the most common cerebellopontine angle tumors and typically present with progressive sensorineural hearing loss, tinnitus, and vertigo. Sporadic VSs arise unilaterally, while the genetic condition neurofibromatosis type II (NF2) is typically associated with bilateral VSs. There are no FDA-approved medications specifically for VS or NF2. However, recent preclinical studies and promising trials involving otoferlin gene therapy have suggested that adeno-associated virus (AAV)-based gene replacement therapy may be a viable treatment option.

Methods: Human sporadic and NF2-associated VSs were collected intraoperatively. Expression of AAV receptor (AAVR) was analyzed in VS tissue cryosections using immunofluorescent staining. Results were confirmed with single-cell RNA-seq data. Primary cultures were established and 9 different serotypes/variants (AAV2/1, AAV2/2, AAV2/6.2, AAV2/8, AAV2/9, AAV2/Anc80L65, AAV9-PhP.B, AAV9-PhP.eB, AAV2.7m8) were assessed for their transduction efficiency. Over 4 days, live cell imaging with Incucyte enabled precise visualization of eGFP expression and p75 (CD271) positivity to quantify Schwann cell transduction. The effects of preincubation of human VS primary cultures with anti-AAVR antibody before the addition of AAVs was analyzed. The supernatant of transduced primary human VS cell cultures was examined via ProcartaPlex to determine inflammatory reactions upon exposure to various AAV serotypes.

Results: AAVR is highly expressed in human Schwann cells. AAV2/2, AAV2/6.2, and AAV2.7m8 were identified as the most promising serotypes in terms of eGFP mean intensity and cell-specific double-fluorescent quantification (p75 and eGFP). The above-mentioned

AAVR blocking experiment demonstrated a reduced transduction of both, a natural (AAV2/6.2) and a synthetic AAV (AAV2.7m8). The ProcartaPlex data showed upregulation of several markers with IL-6 being the highest, but statistically significant differences were not observed between the AAV serotypes.

Conclusions: This study demonstrates the potential of AAV-mediated gene therapy to effectively target vestibular schwannoma and should accelerate the development of translational therapeutic interventions to treat this disabling condition.

SA108. A Gjb2:mCherry Reporter Mouse Reveals Spatial and Temporal Expression Patterns of Gjb2

Larisa Antonellis*¹, Kevin Booth*¹, Maryna V. Ivanchenko¹, Olga Shubina-Oleinik¹, Yaqiao Li¹, David P. Corey¹

¹*Harvard Medical School*

Background: GJB2, mutated in the most common human hereditary deafness, is expressed by diverse populations of epithelial cells and fibrocytes in the mammalian cochlea. A successful gene therapy requires expression of a GJB2 transgene in the same cells and at the same time as endogenous expression. Here, we developed a novel Gjb2 reporter mouse to investigate expression during key developmental stages.

Methods: We generated a Gjb2:mCherry reporter mouse by CRISPR-mediated knock-in of donor DNA encoding the mCherry coding sequence, under control of the endogenous Gjb2 promoter and preceding the Gjb2 coding sequence. Three stop codons inserted downstream of mCherry allowed reporter expression but disrupted Gjb2 expression from that allele. Homozygous Gjb2:mCherry/mCherry mice were embryonic lethal, as expected, so we used heterozygous Gjb2:mCherry/+ mice. Auditory thresholds were measured at P30 to determine whether reporter knock-in impaired hearing. We assessed reporter expression with native mCherry fluorescence or with anti-mCherry antibodies. To assess proper targeting of a therapeutic vector, Gjb2:mCherry cochleas were injected at P1 with an AAV9-PHP.B vector encoding wild-type GJB2 with a C-terminal HA tag. Cochleas were harvested at P10 for comparison of viral Gjb2-HA and mCherry expression.

Results: mCherry fluorescence revealed that reporter knock-in was successful. ABR and DPOAE results showed no statistically significant threshold difference between the Gjb2:mCherry/+ mice and Gjb2:+/+ littermate controls. In frozen sections and whole mounts, we observed mCherry expression at P2, P8, P14 and P30. To evaluate the efficacy of viral gene delivery, Gjb2:mCherry/+ mice were injected at P1 with an AAV9-PHP.B vector encoding HA-tagged GJB2. Cochleas harvested at P10 and immunolabeled for the HA tag showed that viral GJB2.HA expression localized to the same cell populations as the mCherry reporter.

Conclusions: Our novel Gjb2:mCherry mouse model provides a powerful tool for visualizing Gjb2 expression over time and confirms that AAV-mediated Gjb2 delivery can target the correct cell populations within the cochlea. This Gjb2:mCherry/+ mouse model can be used as a platform to assess vector efficiency, specificity, and toxicity for the development of therapeutic treatments for GJB2-related hearing loss.

SA109. Inner Hair Cell Synaptic Remodeling Following Otof Gene Therapy

Paul Gratias*¹, Evan Hale¹, Kameron Clayton², Korey Sudana², Jennifer Zhu², Daniel B. Polley¹, Artur Indzhykulian¹

¹*Harvard Medical School / Mass Eye and Ear*, ²*Eaton-Peabody Laboratories, Massachusetts Eye and Ear*

Background: Inner hair cell (IHC) ribbon synapses form the first synaptic relay of the auditory pathway. The presynaptic protein otoferlin is essential for calcium-dependent vesicle release, and mutations in the OTOF gene cause DFNB9 auditory neuropathy. Otoferlin deficiency disrupts synapse maturation, resulting in fewer hypertrophic synapses and profound deafness. Dual-AAV-Otof gene therapy reinstates glutamatergic release and the hearing function. Here, we addressed whether this functional rescue occurs with, or without, restoration of normal synaptic architecture.

Methods: Deaf5 mice carrying a homozygous missense mutation in Otof affecting Ca²⁺-binding and abolishing IHC synaptic transmission were injected at 6 weeks of age with 2 μ L of dual-AAV1-Myo15-myc-mOtof, while uninjected Deaf5 littermates served as untreated controls. Age-matched wild-type mice (WT) were included as normal-hearing control. Analyses were performed at 13 weeks of age. Following auditory brainstem response (ABR) recording and operant behavioral testing, cochleae were immunolabeled for CtBP2 (presynaptic ribbons), Homer1 (postsynaptic densities, PSDs), and a Myc tag (fused to Otof transgene) to verify transgene expression. Samples were then imaged with confocal microscopy, and quantitative as well as morphometric analyses of ribbons and synapses were performed using Imaris-based segmentation.

Results: Uninjected otoferlin-deficient Deaf5 mice were profoundly deaf, as demonstrated by both absent ABR and behavioral responses. Quantitative analysis revealed a ~50% reduction in synapse number per IHC compared to WT, along with hypertrophic synaptic elements: presynaptic ribbon volumes (re: WT) were increased by ~27% in untreated and ~23% in AAV-treated mice, while postsynaptic density volumes were increased by ~53% in untreated and ~9% in AAV-treated mice. Delivery of dual-AAV-Otof restored sound-evoked behavioral responses and ABR thresholds to near-WT levels. However, in treated mice, IHCs contained no more synapses than untreated Deaf5, and ABR wave I amplitudes remained reduced, showing a ~55% decrease at 80 dB SPL for 8 kHz stimulation compared to WT. These data demonstrate that re-establishment of IHC–auditory nerve fiber (ANF) glutamatergic transmission restores hearing thresholds and partially normalizes synaptic element size but does not recover synapse number.

Conclusions: Otoferlin deficiency in Deaf5 mice causes a reduction of IHC–ANF synapses, rendering the remaining synapses functionally silent. Dual-AAV-Otof therapy restores auditory thresholds but not the synapse count, with synaptic morphology only partially restored. Future serial 3D-EM analysis of synapse anatomy in untreated and AAV-treated mice will help assess the relationship between structural rescue and functional recovery, providing essential insight into the durability of synaptic repair and plasticity, and guiding studies on how treatment age, aging, and noise exposure influence the long-term success of gene therapy.

SA110. AAV-Mediated Specific Gjb2 Gene Therapy Restores Hearing in DFNB1 Mouse Models

Qiuhan Sun¹, Fangzhi Tan¹, Liyan Zhang¹, Yicheng Lu^{*1}, Hao Wei¹, Nianci Li¹, Lulu Jiang², Yinyi Zhou³, Tian Chen¹, Ling Lu⁴, Geng-Lin Li⁵, Jieyu Qi³, Shiming Yang⁶, Renjie Chai¹

¹*Southeast University*, ²*Otovia Therapeutics Inc.*, ³*Beijing Institute of Technology*, ⁴*Zhongda Hospital Southeast University*, ⁵*Fudan University*, ⁶*Chinese PLA Medical School*

Background: DFNB1 represents the most prevalent form of hereditary non-syndromic hearing loss to date, accounting for 20% to 50% of all cases. Pathogenic mutations in the Gjb2 gene, which encodes connexin 26, constitute the leading cause of autosomal recessive hereditary deafness. Although adeno-associated virus (AAV)-mediated gene therapy has shown promise in partially restoring auditory function, its application for treating Gjb2-related deficiencies remains constrained by the limited specificity and low efficiency of existing AAV vectors.

Methods: We evaluated multiple AAV serotypes and identified that co-administration of AAV1 and AAV-ie effectively targeted Gjb2-expressing cells in vivo. Furthermore, the SCpro promoter was utilized to drive transgene expression, thereby enhancing specificity and eliminating ectopic expression-induced ototoxicity.

Results: Co-administration of AAV1 and AAV-ie, each carrying the exogenous Gjb2 gene under the control of the SCpro promoter, achieved precise and efficient gene delivery. This combined AAV system successfully restored auditory function in Gjb2 conditional-deficient mouse models, with hearing thresholds improving to a best level of 40–45 dB SPL.

Immunofluorescence analysis confirmed robust recovery of GJB2 protein expression in the cochlea of both models. Moreover, the dual-AAV system mediated efficient transduction in the cochleae of Bama miniature pigs. When administered into the inner ear of cynomolgus monkeys, it induced no auditory impairment or systemic toxicity, supporting its favorable efficacy and safety profile in large animal models.

Conclusions: This study introduces a targeted gene therapy strategy for Gjb2-related hearing loss using a dual-AAV system and a specific promoter to avoid ototoxicity while restoring hearing in DFNB1 mouse models. The approach demonstrated strong efficacy and a favorable safety profile in large animals, supporting its clinical translation. Further studies are needed to optimize long-term stability in humans. Overall, this strategy provides a precise and safe treatment for the most common form of genetic hearing loss, offering promising therapeutic potential for this currently incurable condition.

SA111. Determining Tropism of AAV Serotypes in the Neonatal Mouse Cochlea

Tracy Cheng^{*1}, Alan G. Cheng¹

¹*Stanford University*

Background: Over 170 genetic mutations have been identified to cause hearing loss, with many amenable to replacement via gene therapy in preclinical models. More recently, clinical trials in gene therapy have revealed promising results for otoferlin-related hearing loss.

Adeno-associated viruses (AAVs) have become increasingly popular as a vehicle to deliver gene replacement for genetic hearing loss because of their high tropism and low immunoreactivity. Currently, there are multiple AAVs reported with different tropisms when injected through the posterior semicircular canal (PSCC). We set out to characterize the

tropism of 5 AAVs in neonatal mice after PSCC injection, with the goal of determining one that is most efficient in gene therapy for Tmprss3 KO mice.

Methods: C57Bl/6 postnatal 3-day-old (P3) mice were injected with 1 ul of each virus at 5 nl/s through PSCC injections. 5 different viruses were tested: AAV2/8-CMV.EGFP ($5.32\text{E}+13$ GC/mL), AAV2/9-CMV.EGFP ($7.55\text{E}+12$ GC/mL), AAV2/Anc80L65.CMV.EGFP ($1.89\text{E}+13$ GC/mL), AAV2.7m8-CAG-GFP ($5\text{E}+12$ GC/mL), AAV-ieK558R-CAG-mCherry-3xFLAG -WPRE ($1.33\text{E}+13$ GC/mL). Each virus was mixed with 1:25 trypan blue (1:25 v:v) to facilitate visualization during injection. Mice were sacrificed 7 days after injection, and immunohistochemistry of whole mounts was performed to determine expression of mCherry or GFP using an anti-GFP antibody. Tissues were also immunostained for inner and outer hair cells (IHCs and OHCs, Myo7a) and support cells (SCs, Sox2). Cell counts of hair cells and support cells were performed in each cochlear turn in whole mounts to compare the transduction efficacy of the different AAVs. Saline injection and the contralateral ear were used as controls.

Results: For AAV2/8-CMV.EGFP and AAV2/9-CMV.EGFP, IHC transduction was most efficient in the apical turn ($60.4\pm7.5\%$ and $61.4\pm10.4\%$, respectively) with a decreasing gradient towards the basal turn ($35.9\pm2.6\%$; $17.6\pm3.0\%$). AAV2/8-CMV.EGFP had overall higher transduction of the IHCs, OHCs, and SCs ($46.0\pm4.3\%$, $7.2\pm2.7\%$, $11.7\pm2.4\%$) compared to AAV2/9-CMV.EGFP ($31.2\pm4.3\%$, $6.8\pm3.7\%$ and $5.6\pm4.0\%$). While AAV2/8-CMV.EGFP had minimal transduction efficacy in the contralateral, uninjected ear only in the basal turn ($2.5\pm0.7\%$), AAV2/9-CMV.EGFP had no transduction in the contralateral, uninjected ear. There was minimal toxicity of the AAVs with little to no degeneration of the native IHCs, OHCs, or SCs after injection. Ongoing experiments aim to characterize the transduction efficacy of AAV2/Anc80L65.CMV.EGFP, AAV2.7m8-CAG-GFP, and AAV-ieK558R-CAG-mCherry-3xFLAG -WPRE.

Conclusions: There are significant differences in the transduction efficacy of different AAVs in the IHCs, OHCs, and SCs. The results of this study can guide selection of AAV to deliver gene replacement for Tmprss3 mutant mice.

SA112. Honokiol Attenuates Cisplatin-Induced Hearing Loss in Sirtuin 1–Deficient Mice

JIN LI¹, Yingjie Zhou¹, Prerita Pandya¹, Chail Koo¹, Robert Fuentes¹, Devin Thomas¹, Claus-Peter Richter¹, Xiaodong Tan^{*1}

¹*Feinberg School of Medicine, Northwestern University*

Background: Sirtuins are composed of an NAD⁺-dependent deacetylase family expressed in different cellular compartments which are critical for oxidative stress response. Sirtuin 1 (SIRT1) is one of the cytoplasmic sirtuin, and its roles in hearing loss and protection are studied with contradictory results. We found that SIRT1 is activated by honokiol, a known SIRT3 activator which showed hearing protective effects in different hearing impairments. In this study, the roles of SIRT1 in hearing protection are studied using cisplatin-induced hearing loss as the stressor. Since Sirt1 knockout is embryonically lethal, Sirt1 insufficient (Sirt1^{+/-}) mice are used in this study, combined with gene therapy mediated by adeno-associated virus 2 (AAV2) tagged with green fluorescent protein through posterior semicircular canal (PSCC) injection.

Methods: Wild-type (Sirt1^{+/+}) and Sirt1^{+/-} mice were assigned to four different experimental groups for cisplatin and honokiol treatment: control, honokiol (10 mg/kg),

cisplatin (4 mg/kg), honokiol + cisplatin. Honokiol was given for four consecutive days following auditory testing at 8, 10, and 12 weeks of age through intraperitoneal (i.p.) injection (4 doses/cycle for 3 cycles). Cisplatin was given only one hour after the first dose of honokiol on each cycle (1 dose/cycle for 3 cycles), through intravenous (i.v.) injection. Hearing was assessed by auditory brainstem response (ABR) measurement, in a frequency range of 8–36 kHz. In addition, three more groups will be assigned for gene therapy: AAV2-vector, AAV2-SIRT1 untreated, and AAV2-SIRT1 cisplatin-treated. Viral transfection will be performed on Sirt1^{+/-} mice through PSCC injection at the age of 6 weeks. Same cisplatin treatment protocol and ABR recording procedure will be followed. Immunostaining is used for verifying SIRT1 expression and hair cell loss. Biochemical assays of SOD2 activity and reactive oxygen species will be performed to verify SIRT1 activity. RT-PCR will be used to verify the involvement of SIRT1 downstream genes. Light sheet microscopy will be used to verify the AAV2 transfection profile in the intact cochlea.

Results: SIRT1 insufficiency does not significantly affect the hearing of the animals under normal conditions, as the ABR threshold did not change between the wild-type and Sirt1^{+/-} mice in the control groups. Honokiol alone does not affect the hearing of the animals, either. However, with the stress of cisplatin, Sirt1^{+/-} mice showed significantly elevated ABR threshold at most frequencies after the first cycle (10 weeks), which was not observed in wild-type animals. The average threshold elevation, compared to the wild types, was 20.6 dB. Honokiol pre-treatment alleviated this cisplatin-induced ABR threshold shifts by 19.6 dB. No animal loss due to cisplatin treatment has been observed so far.

Conclusions: SIRT1 deficiency exacerbates cisplatin-induced hearing loss. Honokiol gives protection in Sirt1^{+/-} mice, either through activating SIRT1, other sirtuins, or other mechanisms, which will be further investigated in future gene therapy and RT-PCR.

SA113. Functional Significance of Sirtuin 3 in the Protection Against Cisplatin-Induced Hearing Loss

Chail Koo¹, Devin Thomas¹, Robert Fuentes¹, Yingjie Zhou¹, JIN LI¹, Claus-Peter Richter¹, Xiaodong Tan¹, Chail Koo*²

¹Feinberg School of Medicine, Northwestern University, ²Northwestern University

Background: Sirtuin 3 (SIRT3) is a mitochondrial deacetylase involved in redox maintenance, and its role in hearing protection has gained increasing attention in recent years. We previously reported early-onset hearing loss in male Sirt3 knockout (Sirt3^{-/-}) mice, which was alleviated by honokiol, a known SIRT3 activator. It is unclear how the absence of SIRT3 affects vulnerability to hearing stress such as cisplatin ototoxicity, and whether honokiol can still provide protection. In addition, the molecular pathways underlying honokiol's protective effects via SIRT3 are not well defined. These questions are addressed in this study.

Methods: Male wild-type (Sirt3^{+/+}) and knockout (Sirt3^{-/-}) mice were assigned to experimental groups: vehicle, honokiol (10 mg/kg), cisplatin (4 mg/kg), or honokiol + cisplatin. Treatments were given for four consecutive days following auditory testing at 6, 8, and 10 weeks of age. Honokiol was injected intraperitoneally one hour before cisplatin. Hearing was assessed by auditory brainstem responses (ABR) and distortion product otoacoustic emissions (DPOAE) at 8–36 kHz. Survival was monitored. Immunostaining for SIRT3 expression and cochlear damage, biochemical assays of SOD2 activity and reactive oxygen species, and RNA-seq of outer hair cells are in progress.

Results: Cisplatin significantly elevated ABR and DPOAE thresholds, with more severe threshold shifts in Sirt3^{-/-} mice, both in onset time and frequency range. At the end of the 3rd cycle (week 12), cisplatin treatment induced a threshold elevation of 17 dB and 40 dB at 32 kHz, in wild-type and Sirt3^{-/-} mice, respectively. In honokiol pre-treated groups, this threshold shift is reduced to 5 dB and 23 dB, respectively. DPOAE thresholds showed a similar pattern, with more severe threshold shifts in Sirt3^{-/-} mice. Survival analysis through day 84 showed 76% survival in wild-type cisplatin-treated mice and 55% in Sirt3^{-/-}. With honokiol pre-treatment, survival was 71% in wild-type and 75% in Sirt3^{-/-} mice. Kaplan–Meier analysis confirmed significant differences with cisplatin exposure (log-rank $\chi^2 = 12.4$, df = 3, p = 0.006) but not with honokiol pre-treatment.

Conclusions: Honokiol attenuates cisplatin-induced hearing loss in both wild-type and Sirt3 knockout mice, suggesting that protective pathways beyond SIRT3 contribute to this effect. Ongoing RNA-seq of outer hair cells, combined with molecular and imaging assays, will help define the mechanisms by which SIRT3 and honokiol attenuate cisplatin-induced hearing loss.

SA114. Intracochlear Drug Delivery Mitigates Cochlear Implant Trauma and Promotes Preservation of Synapses

Adrien Eshraghi^{*1}, David Cohen¹, David Elisha¹, Jeenu Mittal¹, Bianca Arocha¹, Kyle Latz¹, Andrea Monterrubio¹, Arian Fesharaki¹, Kamran Djahed¹, Rahul Mittal¹, Sonia Guha¹

¹*Cochlear Implant and Hearing Research Laboratory, University of Miami Miller School of Medicine*

Background: Cochlear implantation (CI) is a highly effective treatment for individuals with severe to profound sensorineural hearing loss. However, insertion of the electrode array can cause electrode insertion trauma (EIT) resulting in damage to sensory cells, which can lead to the loss of residual hearing. Targeted pharmaceutical interventions aimed at these pathological pathways hold significant promise for preserving residual hearing after cochlear implantation. Through a preclinical rat model, we aim to evaluate the potentials of hearing preservation of a novel drug eluting cochlear implant electrode by quantification of the preservation of sensory hair cell populations, synaptic integrity, and neurite architecture as well as potentials of cellular proliferation and regenerative processes using high-resolution immunohistochemistry and confocal microscopy.

Methods: Sprague-Dawley rats (6-8 weeks old) were divided into three groups: nonimplanted (control group), implanted with a standard non-drug eluting electrode (EIT group), and implanted with a drug R eluting electrode (Drug group). CI Electrode administration was performed intraoperatively via cochleostomy. Cochlear dissections were performed for each group at day 30 post CI. The cochlea was then decalcified, and the Organ of Corti (OOC) was dissected into three cochlear turns: Base, Middle, Apex. OOC sections were then subjected to immunostaining using DAPI, FITC, CtBP2 antibody, and Ki67 followed by labelling with Alexa Fluor-conjugated secondary antibodies. Confocal microscopy was used to generate high-resolution z-stacks of the OOC while ImageJ software was used to conduct hair cell quantification. Auditory Brainstem Response (ABR) testing was performed pre-operatively and at endpoint to measure auditory threshold shifts across frequencies.

Results: Hearing thresholds determined through ABR testing demonstrated significantly decreased threshold shifts in the Drug group compared to the EIT group. Through confocal

imaging and analysis of viable hair cell percentages, Drug R significantly improved the preservation of sensory hair cells compared to the EIT group. Drug R additionally induced neurite formation and promotion of cochlear synapses as well as proliferation of Ki67 positive cells within the cochlea demonstrated by way of confocal imaging.

Conclusions: Localized intracochlear delivery of Drug R via drug-eluting electrodes demonstrates potential to attenuate electrode insertion-induced pathophysiological cascades, including synaptopathy, and neurite degeneration. Preservation of sensory hair cells and promotion of neurite outgrowth may enhance electrode–neural interface integrity, potentially improving speech perception outcomes in cochlear implant recipients. This targeted pharmacological strategy addresses a critical unmet clinical need for preserving residual hearing. Future investigations will focus on longitudinal evaluation of neuroprotective effects in chronic implantation models and pharmacokinetic and pharmacodynamic optimization for sustained therapeutic delivery.

SA115. Neuro- And Neurite-Protective Benefits of Proprietary Kv7.4-Activating Otoprotective Drug Candidates Through Mitochondrial Modulation

Jonas Dyhrfjeld-Johnsen^{*1}, Alexandre Henriques², Noelle Calizot², Sonia Poli³, Tim Boelke¹

¹*Acousia Therapeutics*, ²*Neuro-Sys*, ³*Poli Consulting*

Background: Kv7.4 potassium channel activators are considered good candidate otoprotective drugs with additional potential for auditory function enhancement due to the strong expression of Kv7.4 channels in the plasma membranes of cochlear outer sensory hair cells (Rim et al., 2021; Peixoto Pinheiro et al., 2022). However, recent reports have also suggested a significant cardio- and neuroprotective potential of Kv7.4 channel activation in the inner membranes of mitochondria (Testai et al., 2016; Paventi et al., 2022). We here report that our proprietary Kv7.4 activator drug candidate ACOU082, under development for the enhancement and preservation of natural hearing in chronic/progressive disorders such as age-related hearing loss, exhibits significant capacity for neuro- and neurite protection through direct action on mitochondria.

Methods: Primary cultures of dissociated rat cortical neurons from E15 Wistar rat pups were cultured under standard conditions in 96 well plates. On DIV13, after 1h of pre-treatment with control/test compounds, excitotoxic injury was induced with glutamate (20 μ M) in presence of control/test compound for 20 min. Subsequently glutamate was washed out and fresh culture medium with control/test compounds added for additional 24 hours. On DIV14, cultures were fixed with 4% paraformaldehyde in PBS, permeabilized using PBS containing 0.1% saponin and 1% FBS and finally incubated for 2 hours with MAP-2 (mouse, 1/1000 in PBS) and Cytochrome C (rabbit, 1/100 in PBS) antibodies. Neuron survival (MAP-2, # neurons), neurite network (MAP-2, total neurite length in μ m) and Cytochrome C release in MAP-2(+) neurons (overlap MAP-2/CytC, in μ m²) was analyzed using automatic computer-based image analysis (30 pictures/well, 20x magnification, Operetta®, Perkin Elmer).

Results: Untreated rat dissociated cortical neuron cultures (control, no glutamate injury) was compared to glutamate-injury (20 μ M) alone, or in combination with pre/post-treatment with ACOU082 (10/30/100/300/1000 nM), retigabine (3/10 μ M) and BDNF (50 ng/mL). Glutamate injury alone reduced neuronal survival (63.5 $\pm$ 1.2%) and total neurite length (65.3 $\pm$ 1.8%), while increasing cytochrome C release (157.0 $\pm$ 5.3%) compared to control. ACOU082 treatment concentration-dependently improved neuronal survival (statistically

significant for 30-100 nM, $70.5 \pm 3.1\%$ and $71.0 \pm 1.3\%$) and preserved neurites (statistically significant for 30-300 nM, $80.3 \pm 3.5\%$ to $83.9 \pm 1.3\%$) vs glutamate alone. ACOU082 treatment statistically significantly decreased cytochrome C release vs glutamate alone across all tested concentrations except 10 nM ($91.6 \pm 5.1\%$ to $109.8 \pm 11.5\%$). Retigabine only had a statistically significant effect on cytochrome C release ($94.2 \pm 6.1\%$ and $95.2 \pm 5.5\%$), while BDNF as expected significantly increased neuronal survival ($91.9 \pm 1.1\%$) and preserved neurites ($86.9 \pm 1.7\%$) while reducing cytochrome C release ($77.7 \pm 2.8\%$).

Conclusions: These results clearly demonstrate a neuroprotective potential of ACOU082 with reduced cytochrome C release from mitochondria after excitotoxic insult, in addition to the previously reported otoprotective benefits in different hearing loss models. In addition to a potential for CNS benefits with systemic treatment, this also suggests potential treatment benefits in hearing loss from Kv7.4 activators on SGNs and neurites in the cochlea.

SA116. Subtype-Specific Vulnerability of Spiral Ganglion Neurons Across Cochlear Injury Models

Koji Nishimura^{*1}, Yoko Fukunaga¹, Chisato Chikugo¹, Koichi Omori¹

¹Kyoto University Graduate School of Medicine

Background: Type I spiral ganglion neurons (SGNs), which synapse with inner hair cells (IHCs), are essential for auditory perception. Recent transcriptomic and physiological studies have subdivided them into three molecularly and functionally distinct subtypes (Ia, Ib, and Ic), characterized by differences in spontaneous firing rates and threshold sensitivities. These subtypes are not fully established at birth but undergo postnatal maturation, a process dependent on afferent input from IHCs. Type I SGNs degenerate in response to cochlear insults such as ototoxic drugs and aging; however, whether specific subtypes exhibit differential vulnerability remains unclear. This study investigated subtype-specific susceptibility using aminoglycoside ototoxicity and genetic hair cell ablation models.

Methods: Cochlear injury was induced in adult mice by two approaches: (1) aminoglycoside treatment—gentamicin injection into the posterior semicircular canal or systemic co-administration of kanamycin and furosemide in C57BL/6J mice; and (2) genetic ablation—Pou4f3-DTR/+ mice received intramuscular diphtheria toxin to selectively ablate hair cells. Mice were sacrificed 4–8 weeks post-treatment, and cochleae were processed for cryosectioning and immunohistochemistry. SGN subtypes were identified using antibodies against POU4F1 (type Ic), GATA3 (type II marker, aiding subtype delineation), and TUJ1 (pan-type I). The proportion of POU4F1-positive SGNs among total type I SGNs was quantified across cochlear regions.

Results: Both gentamicin and kanamycin–furosemide treatment resulted in significant type I SGN loss. Importantly, type Ic SGNs, identified by decreased POU4F1 expression, showed a disproportionately greater reduction than other subtypes, indicating preferential vulnerability. In contrast, Pou4f3-DTR mice exhibited overall SGN degeneration, but the proportion of type Ic neurons remained stable, suggesting non-preferential loss. These findings support the hypothesis that aminoglycosides exert both indirect effects (secondary to hair cell loss) and direct cellular stress (e.g., mitochondrial dysfunction, excitotoxicity), rendering Ic neurons particularly vulnerable. In contrast, genetic ablation produces uniform loss of trophic support, leading to subtype-independent degeneration.

Conclusions: Subtype-specific vulnerability of SGNs is dependent on the nature of cochlear injury. Type Ic SGNs are selectively susceptible to aminoglycoside ototoxicity, whereas

genetic hair cell ablation causes uniform degeneration across subtypes. Recognition of SGN subtype diversity is essential for understanding cochlear pathology and for developing targeted neuroprotective strategies.

SA117. The Time Course of MHCII Expression and SGN Degeneration in Mice After Hair Cell Death

Zhenshen Zhang^{*1}, Muhammad Rahman², Steven H. Green¹

¹*University of Iowa*, ²*Head and Neck Surgery, University of Iowa Hospitals and Clinics*

Background: Spiral ganglion neurons (SGNs) receive auditory information from cochlear hair cells, the auditory receptor cells, and transmit it to the CNS. SGNs gradually degenerate after hair cell death, potentially adversely affecting the efficacy of cochlear implants. While an inflammatory-immune response in the cochlea appears to be causal to neurodegeneration, it remains unclear which components of the immune response are responsible. Gene expression profiling shows dramatic upregulation of immune response-related genes, including MHCII, a molecule involved in antigen presentation to lymphocytes and adaptive immune response, in the spiral ganglion following deafening. Preliminary data showed the MHCII knockout prevents SGN degeneration, indicating a causal role of MHCII-mediated antigen presentation and adaptive immune response in SGN loss. Here we ask whether the timing of MHCII expression post-deafening is correlated with the timecourse of SGN death in a mouse model of hair cell loss.

Methods: Male and female Pou4f3+/huDTR CBA/CaJ mice (n=24) were intramuscularly injected with a single dose of diphtheria toxin (DT) (5 ng/g) at postnatal day 5, which causes a rapid loss of hair cells. Mice were euthanized at postnatal days 13, 32, 39 and 60 for histological examination of the spiral ganglia to count surviving SGNs, and to detect MHCII expression. Cochlear sections were immunolabeled with the following antibodies: Tuj1 to label SGNs, anti-MHCII antibodies and anti-F4/80 to label macrophages. Quantitative analysis was done on every cochlear turn in every fourth near-mid-modiolar section. Image analysis was performed using IMARIS software. The outline of the Rosenthal canal for each turn was manually traced to measure the cross-sectional area and to calculate cell densities for SGNs and macrophages.

Results: At postnatal days 13, 32 and 39, the number of SGNs and MHCII+ macrophages in DT-deafened mice is not significantly different from control hearing mice. Correspondingly, the number of MHCII-expressing macrophages is not significantly different from that in control hearing mice. In DT-deafened mice at postnatal day 60, the number of SGNs has decreased and the number of MHCII-expressing (MHCII+) macrophages has increased, relative to hearing controls, indicating that between postnatal days 39 and 60, MHCII expression increases and SGN death becomes significant.

Conclusions: We demonstrated by immunolabeling that MHCII expression appears to correlate temporally with SGN degeneration. At P13, P32 and P39, post-deafening SGN degeneration has not yet occurred and upregulation of MHCII expression is not apparent. At P60, SGN degeneration is apparent after hair cell loss as is increased MHCII expression. These results are consistent with a causal association between MHCII expression on spiral ganglion macrophages and SGN degeneration. The function of MHCII expression in this context remains to be elucidated.

SA118. Targeting Nitritative Stress Protects Against Noise-Induced Cochlear Synaptopathy and Hearing Loss

Pankaj Bhatia*¹, Samson Jamesdaniel¹

¹Wayne State University

Background: Noise-induced hearing loss (NIHL) represents a significant public health issue, with limited therapeutic strategies available. Emerging evidence implicates nitritative stress, driven by excessive peroxynitrite generation, in the pathogenesis of cochlear injury. However, the role of nitritative stress as a potential target for preventing noise-induced hearing loss is not fully defined. This study evaluated the otoprotective potential of MnTBAP, a peroxynitrite scavenging metalloporphyrin, against noise-induced cochlear synaptopathy and hearing loss in mice.

Methods: Six-week-old CBA/J mice of either sex were exposed to 90 dB SPL broadband noise for 2 hours daily for two weeks. Permanent threshold shifts were assessed using auditory brainstem responses (ABR) and distortion product otoacoustic emissions (DPOAE) two weeks after the final noise exposure. ABR wave-I amplitude and latency were analyzed as markers of cochlear synaptopathy. To inhibit nitritative stress, mice were treated with daily intraperitoneal injections of MnTBAP (10 mg/kg) for four weeks.

Results: Noise exposure induced a 13 to 18 dB increase in hearing thresholds across multiple frequencies, indicating hearing impairment. Specifically, ABR thresholds were elevated in response to pure-tone stimuli at 4 ($p = 0.002$), 8 ($p = 0.01$), 16 ($p = 0.001$), 24 ($p = 0.01$), and 32 kHz ($p = 0.0005$), as well as click ($p = 0.01$) stimuli. The shift in hearing thresholds was most pronounced at higher frequency (32 kHz) stimuli. OHC function, as measured by DPOAEs, was impaired at 16 ($p = 0.001$), 24 ($p = 0.002$), and 32 kHz ($p = 0.003$). Measurement of ABR wave-I amplitude and latency recorded with pure-tone and click stimuli at 90 dB SPL indicated that noise exposure induced a significant reduction in wave-I amplitudes at click ($p = 0.02$), 24 ($p = 0.0001$) and 32 kHz ($p = 0.0001$) frequencies, indicating impaired auditory nerve activity. Further, the ABR wave-I latency was increased at 24 ($p = 0.0001$), and 32 kHz ($p = 0.0006$) frequencies after noise exposure, showing delayed neural transmission. However, MnTBAP treatment significantly attenuated noise-induced increases in hearing thresholds, loss of OHC function, and cochlear synaptopathy indicating the otoprotective effects of MnTBAP.

Conclusions: Overall, the findings of this study indicate that noise exposure caused hearing loss, OHC dysfunction, and cochlear synaptopathy in mice, which is most severe at higher frequencies. MnTBAP protected against noise-induced auditory dysfunction, indicating that nitritative stress plays a central role in NIHL. These results suggest that peroxynitrite scavenging is a potential interventional strategy to prevent NIHL.

SA119. Screening of Piperlongumine Derivatives Against Excitotoxic Damage

Kathryn Doom*¹, Jadhav Gopal², Chunkai Wang², Jian Zuo³, Marisa Zallocchi³

¹Creighton University, ²Translational Hearing Center, School of Medicine, Creighton University, ³Creighton University School of Medicine

Background: According to the World Health Organization, over 500 million people worldwide live with disabling hearing loss. Despite its profound social and economic impact, the U.S. Food and Drug Administration (FDA) has only recently approved a therapy for

cisplatin-induced ototoxicity, and even then, only for a limited subset of cancer patients. Among the leading causes of acquired hearing loss is excitatory damage from noise exposure. Previous studies from our laboratory identified piperlongumine (PG), a natural compound derived from the Indian long pepper (*Piper longum*), as a promising therapeutic candidate for treating aminoglycoside- and noise-induced hearing loss. Building on this work, we synthesized a second generation of PG derivatives and tested them in a zebrafish model of excitotoxicity. We hypothesize modifications in the PG structure will result in more potent derivatives capable of offering greater protection against excitotoxic trauma.

Methods: We screened 30 PG derivatives using a zebrafish model of excitotoxicity. Zebrafish larvae (5–6 days post-fertilization) were exposed to 600 μ M kainic acid (KA), followed by treatment with one of the PG derivatives. After treatment, the larvae were fixed and immunostained with otoferlin, a hair cell marker, and hair cells were manually counted under a fluorescence microscope.

The top three lead compounds, PG-12, PG-23, and PG-24, were selected for further analysis, which included: 1) dose-response curve generation, 2) quantification of ribbon synapses in the presence of KA and the PG derivatives, and 3) FM1-43 uptake assay to assess mechanotransduction channel activity. Data were expressed as Mean $\pm$ SD, and statistical analyses were performed using Student's t-test or one-way ANOVA followed by Dunnett's post hoc test for multiple comparisons. Results were compared against both vehicle control and kainic acid-only groups.

Results: The majority of the PG derivatives showed protective effects against excitotoxicity at least one concentration. Notably, PG-12, PG-23 and PG-24, demonstrated consistent protection across multiple concentrations. Dose-response analysis revealed sub-nanomolar EC₅₀ values, indicating high potency. Evaluation of ribbon synapses and FM1-43 uptake is currently underway.

Conclusions: By modifying piperlongumine chemical structure we were able to obtain more effective compounds at protecting against KA-induced excitotoxicity. Ongoing and future experiments will explore the efficacy of these lead derivatives in more clinically relevant models of hearing loss.

SA120. Surface Mild Hypothermia for Acute Noise-Induced Hearing Protection in Firefighters

Jean Laguerre^{*1}, Brianna Kuzbyt¹, Kristine Harris¹, Kendall Stern², Curtis King², Suhrud Rajguru³, Hillary Snapp⁴

¹University of Miami, ²RestorEar Devices, ³University of Miami, Restor-Ear Devices,

⁴University of Miami Miller School of Medicine

Background: Noise-induced hearing loss (NIHL) remains a significant occupational hazard for firefighters due to repeated exposure to hazardous noise during active duty. Acute noise exposure triggers inflammatory responses within the cochlea, contributing to hair cell injury and auditory dysfunction. Timely intervention is challenging in real-world settings, limiting opportunities to medicate potential noise induced damage. Surface-applied mild therapeutic hypothermia (MTH) may offer a practical approach to deliver rapid otoprotection in real time and potentially preserving hearing. This study aims to assess the safety, feasibility, and potential protective effects of applied MTH using the ReBound™ device in noise-exposed firefighters, with an emphasis on acute auditory changes and selective frequency protection.

Methods: Twenty-six adult on-duty firefighters (ages 18–55) were recruited. Inclusion required normal tympanometry and no active otologic pathology. Baseline audiometry was performed immediately following 24-hour on-duty shifts, followed by 20 minutes of surface cooling with the ReBound™ device and immediate post-cooling repeat audiometric assessment. Outcomes were compared to a non-noise-exposed control group (n = 25). Participants were monitored for 24 hours post-intervention for safety and tolerability.

Results: Pre- to post-cooling audiometric scores improved significantly across frequencies ($F(1, N) = 49.25, p < .001, \eta^2 = 0.534$), with no significant difference between control and experimental groups ($F(1, N) = 1.33, p = .256, \eta^2 = 0.03$). Scores varied across frequency measures ($F(6, N) = 7.76, p < .001, \eta^2 = 0.744$), and pre-post change differed by frequency ($F(6, N) = 4.26, p < .001, \eta^2 = 0.662$), suggesting selective protective effects at specific frequencies. The Time $\times$ Frequencies $\times$ Group interaction was not significant ($p = .247, \eta^2 = 0.334$). No adverse events were observed during 24-hour follow-up, demonstrating safety and tolerability of the ReBound™ device.

Conclusions: Applied surface MTH via the ReBound™ device is safe, feasible, and shows potential protective effects against acute noise-induced auditory changes in firefighters. Improvements were frequency-dependent, suggesting targeted mitigation of cochlear injury. These findings support further investigation of surface hypothermia as a rapid, non-invasive therapeutic approach for occupational NIHL, with potential translational applications for early intervention following hazardous noise exposure.

SA121. Exploring the Relationship Between the Two Most Abundant Outer Hair Cell Proteins: Prestin and Oncomodulin

Mi-Jung Kim^{*1}, Kazuaki Homma¹, Jing Zheng¹

¹*Northwestern University*

Background: Outer hair cells (OHCs) exhibit somatic electromotility, which is essential for high sensitivity and precise frequency selectivity in hearing. Prestin is the key molecule responsible for the electromotility of OHCs. As the most abundant membrane protein in OHCs, prestin occupies a significant portion of the lateral membrane. Prestin-KO mice exhibit a 40-50 dB shift in hearing thresholds, with their OHCs ~40% smaller than those of WT mice. Oncomodulin (OCM) is the most abundant cytoplasmic protein in OHCs and serves as a Ca²⁺-buffer. The absence of OCM leads to progressive hearing loss and degeneration of OHCs. Both prestin and OCM start to be expressed in OHCs during a similar developmental period, and their expression is regulated by microRNA 96 and the transcription factor Ikzf2. Since prestin's function is affected by Ca²⁺ signaling, there has been a long-standing hypothesis that these two abundant proteins in OHCs might interact and influence each other's roles for normal hearing. To determine whether the absence of OCM affects prestin's function, we used our newly established *Ocm*-KO mouse model to conduct hearing tests and nonlinear capacitance (NLC) measurements in OHCs. NLC is an electrophysiological technique that allows us to evaluate the functionality of prestin.

Methods: We created a new *Ocm*-KO mouse model, *Ocmtm1a/m1a*, using the 'KO-first, conditional-ready' strategy. Hearing was assessed by measuring ABRs and DPOAEs from 1 month to 12 months. Whole-cell recordings were performed in isolated OHCs obtained from *Ocm*-KO and WT littermates (P15–109). NLC data were analyzed by a two-state Boltzmann equation. Isolated OHCs were also visually inspected for morphological abnormalities.

Results: Significantly more OHCs from Ocm-KO mice exhibit atypical morphology compared to those from WT mice after sample preparation for NLC measurement. At P15, OHCs from both WT and Ocm-KO mice have similar NLC values and cell sizes. ABR and DPOAE thresholds of Ocm-KO were WT-like up to 2 months. However, the NLC and OHC size of Ocm-KO were significantly smaller compared to WT at 1 month, although the voltage sensitivity and operating point remained WT-like range from P15 to P109.

Conclusions: The atypical morphology found in OHCs isolated from Ocm-KO mice indicates that these OHCs are more sensitive to chemical/mechanical perturbations, highlighting the importance of OCM for OHC maintenance. The OHCs without OCM begin to show detectable atrophic changes (smaller size) and functional declines (reduced NLC) despite Ocm-KO mice having normal hearing. Since reductions in the sizes of OHCs and NLC are signs of aging OHCs, it remains unclear whether the absence of OCM accelerates the aging of OHCs, resulting in a decrease in prestin, or if the reduction of prestin in OHCs of Ocm-KO is what leads to OHC aging. (Work supported by the Knowles Leadership Fund and NIH R56DC020542 to JZ)

SA122. Can Oncomodulin Act as a Stress Sensor?

Mi-Jung Kim^{*1}, Jing Zheng¹

¹*Northwestern University*

Background: Outer hair cells (OHCs) are the first to suffer from elevated intracellular Ca²⁺ and reactive oxygen species (ROS). To maintain Ca²⁺ homeostasis, OHCs rely on various proteins, the most abundant being oncomodulin (OCM). The absence of OCM in mice leads to progressive hearing loss and OHC degeneration. OCM has been recognized as a primary intracellular Ca²⁺ buffer in OHCs. However, OCM can undergo significant conformational changes between its Ca²⁺-bound and Ca²⁺-free states. Furthermore, OCM is suggested to act as a redox sensor, as oxidizing conditions promote its dimerization through intermolecular disulfide bonding via the Cys18 thiol, and Ca²⁺-bound OCM accelerates this dimer formation. Given that structural alterations are common features of both Ca²⁺ sensors and redox sensors, OCM's properties likely enable it to function as a stress sensor for elevated Ca²⁺ and ROS, which are two common causes of OHC loss. However, little has been studied about OCM's role as a stress sensor or how it responds to stress in OHCs. Our aim is to explore OCM's function as a stress sensor using both in vitro cell line and in vivo mouse studies.

Methods: (1) In vitro system: We transfected OK cells with a plasmid containing the Ocm gene to establish a stable cell line that expresses Myc-DDK-tagged Ocm. We then treated the Ocm-expressing cells with 10 μ M A23187 for 30 minutes. A23187 is a known stressor that increases cytosolic calcium levels. (2) In vivo system: We administered a single intravenous dose of 16 mg/kg cisplatin to WT mice. Cisplatin increases ROS levels in different cells including OHCs. Following treatment, we collected both the A23187- and cisplatin-treated samples, as well as their solvent control counterparts, for SDS-PAGE/Western blotting using an antibody specific to either OCM or Myc. Non-transfected OK cells and cochleae from Ocm-KO mice were used as a negative control for Western blot.

Results: (1) Ocm-expressing cells treated with A23187 showed an increased ratio of OCM dimer to the total of monomer and dimer compared to non-treated Ocm-expressing cells. The OCM band was undetected in the non-transfected OK cells. (2) Cisplatin-treated WT cochleae displayed a higher ratio of OCM dimer to the combined amount of monomer and dimer compared to untreated WT cochleae. The OCM dimer band disappeared when the

reducing agent DTT was added to the cochlear samples, indicating that disulfide bonding likely plays a role in OCM dimer formation. Additionally, the OCM band was not detectable in Ocm-KO cochleae.

Conclusions: These results indicate that stressful stimuli enhance intracellular OCM dimerization, which suggests that OCM may function as a stress sensor for both increased Ca²⁺ and ROS levels. (Work supported by the Knowles Leadership Fund and NIH R56DC020542 to JZ).

SA123. Hair Cell Regulation of the Stereociliary PMCA2 Ca²⁺ Pump Density

Robert Fettiplace^{*1}, Amanda Rolseth¹, Maryline Beurg¹

¹*University of Wisconsin-Madison*

Background: Sound transduction in cochlear hair cells arises by activation of mechano-electrical transducer (MET) channels for which transmembrane channel-like protein 1 (TMC1) is the pore forming subunit. We made mice with mutations in Tmc1 that culminate in hair cell apoptosis and deafness by postnatal day (P) 21. However, mechano-transduction was normal at P6, when TMC1 is fully expressed. The goal is to understand when and how apoptosis is triggered. We hypothesized that apoptotic behavior may stem from an increase in cytoplasmic Ca²⁺.

Methods: We studied four mutations, Tmc1 p.D569N, p.M412K, p.T416K and p.D528N. MET channels in all mutants were gated normally, but with diminished Ca²⁺ permeability at P6, T416K being the least abnormal and D528N the most. Early signs of hair cell apoptosis were assayed in neonatal Tmc1 mutants by labeling with MitoTracker and Annexin V, the latter marking scramblase externalization of phosphatidyl serine. Reduced labeling with MitoTracker indicated degraded mitochondrial function in Tmc1 mutants, even at P6 when MET currents were still present. The reduction in MitoTracker labeling was correlated with the reduced Ca²⁺ permeability of the MET channel. Acoustic brainstem responses established that Tmc1 p.D569N, p.D528N and p.M412K mice were deaf by P15 but hearing was retained in Tmc1 p.T416K until P21. Stereociliary PMCA2 was determined by immunolabeling with the NR2 antibody and visualizing by confocal microscopy.

Results: We tested whether apoptotic behavior was influenced by blocking the stereociliary PMCA2 CaATPase pump to abolish Ca²⁺ extrusion. Scramblase activity was stimulated and MitoTracker labeling diminished by raising external pH from 7.4 to 9.0 or by adding 50 micromolar carboxyeosin to block PMCA2, suggesting apoptosis is triggered by increased hair cell [Ca²⁺]. Reduced PMCA2 in stereocilia was found for all Tmc1 mutants and was correlated with a decrease in Ca²⁺ influx via MET channels ($r = 0.73$). However, in Tmc1;Tmc2 double knockouts with zero Ca²⁺ influx, there was still a residual PMCA2 expression. PMCA2 expression was also increased after birth in parallel with development of the MET current. To directly test Ca²⁺ involvement, isolated cochleae were cultured in reduced (0.45 mM) external Ca²⁺ for 1 hour. This significantly lowered PMCA2 density as did perfusion with 4 micromolar curare to half-block the MET channels. These manipulations influenced PMCA2 density up to P11 but not after the onset of hearing. PMCA2 turnover at P6 was insensitive to cycloheximide, a protein synthesis inhibitor, but was much diminished by Pitstop2, a blocker of endocytosis.

Conclusions: The path connecting Tmc1 mutation to reduced PMCA2 reflects a homeostatic mechanism during the neonatal period due to reduced Ca²⁺ permeability in the mutants. The

results suggest a connection between stereociliary PMCA2 density, hair cell apoptosis and deafness. Funded by grant R01DC01362 from NIDCD

SA124. Dimensions of a Mature Living Cochlear Inner-Hair-Cell Bundle

Katharine Miller*¹, Patrick Atkinson¹, Matthew Kandziora¹, Daibhid O Maoileidigh¹, Nicolas Grillet²

¹Stanford Medicine/Otolaryngology-Head and Neck Surgery, ²University of Kentucky

Background: Cochlear hair cells possess actin-filled membrane protrusions at their apical surface called stereocilia. Stereocilia are arranged stepwise into rows from tallest to shortest, forming the mechanotransducing hair bundle. The mechanotransducing function of the hair bundle is regulated by its dimensions, which include stereocilium heights and widths, the number of stereocilia per row, the distances between the stereocilia, and the shapes of the rows. Previously, we generated a blueprint of a living cochlear inner-hair-cell bundle for a P11 mouse (Miller et al., 2021, Front Cell Dev Biol). By comparing measurements in living and fixed tissues, we generated conversion factors that enabled us to impute living bundle dimensions from lightly-fixed phalloidin-labeled tissue imaged using confocal microscopy and from strongly-fixed tissue imaged using scanning electron microscopy (SEM). Inner-hair-cell bundles continue to change after P11 and are thought to finish development before P31. In this study, we measured the dimensions of P31 inner-hair-cell bundles using multiple imaging techniques. We then compared the dimensions of the mature P31 bundle with those of the immature P11 bundle.

Methods: Comprehensive measurements were performed using three techniques: fluorescent imaging of live inner-hair-cell bundles stained with membrane dye (FM-143), fluorescent imaging of lightly-fixed hair bundles with actin labeled by phalloidin-Alexa 488, and SEM imaging of strongly-fixed bundles. We compared these measurements to determine conversion factors for the dimensions obtained using each technique. Using these factors, we determined the complete set of dimensions for P31 inner-hair-cell hair bundles, focusing on the 90th to 160th inner-hair-cell bundles from the cochlear apex.

Results: Live P31 inner-hair-cell bundle dimensions were either measured directly or imputed using SEM measurements in strongly-fixed tissues and the conversion factors between strongly-fixed and live tissues. This enabled us to generate the first complete blueprint of a mature living cochlear bundle. Comparing the P31 blueprint with the P11 blueprint from the same tonotopical position revealed critical developmental changes. We evaluated the biophysical consequences of these changes using mathematical models.

Conclusions: The dimensions of a hair bundle – stereocilium height, width, number, and spacing, as well as row shape – directly regulate hair-bundle function. These dimensions differ between hair-bundle types, species, cochlear locations, and developmental age. We determined the dimensions of a mature inner-hair-cell bundle and compared the dimensions with those of an immature bundle. By precisely determining bundle dimensions and how they change during development, we gain a better understanding of how hair-bundle structure regulates its function in mammals.

SA125. IQGAP1 Deficiency Induces Progressive Hearing Loss With Early Onset

Corentin Affortit*¹, Jin-Young Koh², Hela Azaiez³, Richard J. H. Smith¹

¹University of Iowa Hospitals and Clinics, Molecular Otolaryngology and Renal Laboratories, ²University of Maryland School of Medicine, ³Medical and Molecular Genetics, Indiana School of Medicine

Background: IQ motif-containing GTPase-activating protein 1 (IQGAP1) is a scaffolding protein that is ubiquitously expressed. It has roles in many different aspects in cell physiology and interacts with numerous proteins. Recent studies have shown a direct interaction between IQGAP1 and proteins coded by genes known to be related to hearing loss (Pendrin, Pejvakian). To investigate the role of IQGAP1 in hearing function, we used an *Iqgap1* knock-out (*Iqgap1*^{-/-}) mouse model.

Methods: In littermate *Iqgap1*^{-/-}, *Iqgap1*^{+/-} and wild-type (WT) mice aged 1 to 12 months, we tested auditory function by measuring auditory brainstem responses (ABR) and distortion product otoacoustic emissions (DPOAE) at regular time intervals. We also evaluated IQGAP1 expression using Western blot and immunolabeling methods. Cochlear hair cell loss was quantified by immunolabeling methods at 12 months of age.

Results: Our results show that *Iqgap1* is highly expressed in supporting cells of the organ of Corti and in the spiral ligament and stria vascularis cells. Young *Iqgap1*^{-/-} mice (1-month-old) display a significant sensorineural hearing loss as evidenced by increased ABR thresholds at the highest (24 kHz, 32 kHz) and lowest (6 kHz) frequencies, associated with a reduced amplitude of DPOAEs. In addition, *Iqgap1*^{-/-} mice show auditory pathway impairment characterized by reduced amplitude and increased latency as measured by ABR. By 6 months of age, the ABR threshold shift and DPOAE amplitude reduction have progressed to impact all frequencies. Morphological evaluation shows substantial apical OHC loss in 12-month-old *Iqgap1*^{-/-} mice compared to age-matched *Iqgap1*^{+/-} and WT controls.

Conclusions: These results demonstrate an essential role for IQGAP1 in cochlear physiology and support its requirement for the maintenance of hearing function and OHC survival during aging.

SA126. CIB2 Regulates Mechano-Electrical Transducer Channels in Mammalian Auditory Hair Cells via Plasma Membrane-Associated Proteins

Isabel Aristizabal^{*1}, Abigail Dragich¹, Arnaud Giese², K. Sofia Zuluaga-Osorio¹, Julie Watkins¹, Garret Davis¹, Shadan Hadi¹, Saima Riazuddin³, Ana I. Lopez-Porras¹, A. Catalina Velez-Ortega¹, Craig Vander Kooi⁴, Zubair Ahmed³, Gregory Frolenkov¹

¹University of Kentucky, ²SENSORION SA, ³University of Maryland School of Medicine,

⁴University of Florida, College of Medicine

Background: Calcium and Integrin-Binding protein 2 (CIB2) is essential for hearing and mechano-electrical transduction (MET) in auditory hair cells (Riazuddin et al., 2012; Giese et al., 2017). CIB2 interacts with TMC1/2 (Giese et al., 2017), pore-forming subunits of the MET channel and is thought to be essential for their transport or retention at stereocilia tips (Liang et al., 2021). Multiple interacting sites between CIB2 and TMCs (Giese et al., 2024; Wu et al., 2025; Li et al., 2025) suggest that CIB2 is an accessory subunit to the MET channel. Thus, in addition to TMCs localization, CIB2 may regulate MET channel activity.

Methods: We generated a new mouse knock-in strain carrying the human deafness-associated variant p.R186W that does not completely abolish CIB2-TMC1/2 interactions, hence, retains some MET currents. Auditory brainstem responses were recorded to determine hearing function. Whole-cell patch clamp recordings assessed MET currents in P4-P7 auditory hair cells. Besides conventional deflection of hair cell bundles with fluid-jet, we used a custom piezo-driven probe capable of deflecting stereocilia within $\sim 5\mu\text{s}$ (confirmed by video recordings at 90,000 fps), which was faster than the speed of MET current activation. Focused-Ion Beam Scanning Electron Microscopy (FIB-SEM) was used to determine ultrastructural changes at the tips of transducing stereocilia produced by the p.R186W variant. Immunofluorescence labeling and confocal imaging were used to investigate localization of known proteins regulating MET function. To confirm the molecular mechanisms, we recapitulated p.R186W effects in wildtype hair cells by mis-localizing some stereocilia proteins with the MET channel blocker tubocurarine and compared p.R186W effects with the ones we recorded in *Tmc1*^{-/-} mice.

Results: Consistent with prior reports, the *Cib2*R186W/R186W mice were profoundly deaf at P16. However, our data are not consistent with a simple decrease of TMC1 in stereocilia but show more profound effects of p.R186W on the MET currents, stereocilia membrane composition, and its ultrastructure. Both inner and outer hair cells of *Cib2*R186W/R186W mice showed larger resting current and steeper MET current-displacement curves, suggesting increased force sensitivity. The p.R186W variant also slowed down MET current activation and eliminated fast adaptation, even though the MET current dependence on intracellular potential (presumably driven by Ca^{2+}) remained intact. Both effects were consistent with the mis-localization of PIP2 observed in *Cib2*R186W/R186W stereocilia. Additionally, we found disrupted lower tip-link densities in second-row stereocilia and mis-localization of the membrane-associated protein BAIAP2L2 from *Cib2*R186W/R186W but not in *Tmc1*^{-/-} stereocilia tips. Pharmacological mis-localization of BAIAP2L2 with tubocurarine in wildtype mice recapitulated the p.R186W effects on MET current activation and force sensitivity.

Conclusions: We concluded that p.R186W variant disrupts the properties of plasma membrane by mis-localizing BAIAP2L2 and PIP2 thus affecting force transmission to the MET channels.

Supported by NIH (R01 DC012564, S10OD025130) and American Otological Society (#1000400113).

SA127. The Temporal Coincidence Between Nuclear Translocation and BK Channel Expression in Mouse Inner Hair Cells

Radha Kalluri^{*1}, Daniel Bronson¹, Juliana Giacomini¹, Zara Mubin¹, Nathaniel Nowak¹

¹*University of Southern California*

Background: Nuclear position is tightly regulated during cell division, migration, and maturation. We previously identified a programmed nuclear translocation in the cochlear inner hair cells (IHCs) of rat and mouse that coincides with their functional maturation around hearing onset. In early postnatal days, the nucleus resides at the basal pole of the IHC—distant from the apical stereocilia but close to nascent afferent and efferent synapses—during a phase of rapid cell growth. After the IHC reaches its final length, the nucleus shifts to a mid-cellular position. Nuclear migration coincides with the surface expression and aggregation of BK channel plaques and signals the final phase of functional maturation. Here, our goal was to define the timeline and relationship between nuclear migration and

expression of BK channels, toward understanding the mechanisms regulating this critical phase of hair cell maturation.

Methods: We examined BK channel protein expression, surface localization, and their relationship to nuclear position in inner hair cells using immunolabeling and western blot analysis. Cochleae were collected from C57BL/6 wildtype mice at P10–P14 and P26, with denser sampling near P12. BK channels were labeled with rabbit anti-BK, cytoplasm with mouse anti-myosin VII or anti-vglut3, and nuclei with DAPI. High-resolution confocal imaging was used to reconstruct inner hair cell morphology and quantify cell size, nuclear position, and BK channel plaque distribution. Western blots for BK channels were performed at intervals from P8 to P14. To perturb nuclear positioning, a subset of animals received AAV-SYNE4 injections at P0–P2. SYNE4 is a gene encoding a nuclear complex linker protein known to be found in the nuclear envelopes of inner and outer hair cells. After auditory function was assessed using ABR and DPOAE, cochleae were fixed and immunolabeled as described above. Antibody specificity and viral transduction were consistent with expected structures.

Results: Western blot and immunohistochemical analysis revealed that BK channel proteins are present in inner hair cells well before hearing onset and before their functional insertion into the membrane. Syne 4 overexpression did not ubiquitously prevent the surface expression of BK channels. However, overexpression of SYNE 4 disrupted the normal nuclear positioning of inner hair cells and altered the cytoskeletal distribution of Myosin VII. These morphological changes, along with a modest elevation in ABR thresholds, were observed in most SYNE4-injected animals but not in sham controls, suggesting that perturbing nuclear position in inner hair cells impacts auditory function.

Conclusions: Nuclear migration at the onset of hearing is a key step in the morphological maturation of IHCs. Our findings indicate that while nuclear positioning influences auditory function, BK channel surface expression is not explicitly dependent on nuclear migration. Their temporal coincidence during natural development suggests that both processes may rely on shared maturational milestones rather than being causally linked.

SA128. Modulation of IHC Calcium Channel Inactivation Kinetics by CaBP2 Variants

Tina Pangrsic^{*1}, Carolin Paula Bräuer², Tatjana Pallinger², Taehee Kim², Alexey Alekseev², Ryo Motosugi², Andreea Larisa Mateias², Esther Marie Grewe², Kathrin Kusch³, David Oestreicher², Nicola Strenzke⁴, Thomas Mager³, Eri Sakata²

¹*University of Goettingen*, ²*University Medical Center Göttingen*, ³*Institute for Auditory Neuroscience and InnerEarLab*, *University Medical Center Göttingen*, ⁴*Göttingen University*

Background: Voltage-gated calcium (CaV) channels undergo voltage- and calcium-dependent inactivation (VDI, CDI) to prevent excessive entry of calcium ions in the cells. In the cochlear inner hair cells (IHCs), and retinal photoreceptors, this inactivation is strongly attenuated to enable persistent signalling of sensory information. The factors that reduce the amount of channel inactivation include calcium-binding proteins (CaBPs), small molecules similar in structure to calmodulin. In the IHCs, CaBP2 and to a lesser extent CaBP1 are strongly expressed and mutations in CABP2 have been identified to cause nonsyndromic hearing impairment DFNB93 in the affected patients. We have previously investigated the phenotype of Cabp1/2 double KO animals and tested the feasibility of gene therapy in DFNB93 mouse models. Hearing of treated animals showed significant improvement upon

gene therapy, which we attributed to partial rescue of IHC CaV1.3 properties and of synaptic IHC exocytosis. Now, we would like to understand, how exactly CaBP2 exerts its function on the CaV1.3 calcium channel that mediates synaptic transmission in the IHCs.

Methods: Using a combination of in vitro biophysical, biochemical and electrophysiological methods and in vivo hearing measurements, we are investigating the effectiveness of different CaBP2 isoforms and mutants in attenuating channel inactivation, and the role of calcium binding for this function.

Results: We determined calcium binding of individual CaBP2 EF hand domains and identified CaBP2 variants with reduced effects on CaV1.3 channel properties.

Conclusions: Our data so far suggests that metal-ion binding of (at least some) EF hands and the N-segment are required to support proper CaV1.3 function, interaction with CaM and hearing.

SA129. Ectopic Mouse TMC1 and TMC2 Alone Form Mechanosensitive Channels That Are Potently Modulated by TMIE

Yulin Li^{*1}, Yixuan Chen¹, Yonghong Liu¹, Pingbo Huang¹

¹*Hong Kong University of Science and Technology*

Background: The mechanotransduction (MT) channel in inner ear hair cells converts sound/head movements into electrochemical signals. TMC1/2 are pore-forming subunits, but functional studies in heterologous cells are limited by poor cell-surface expression. Prior work circumvented this by reconstituting truncated TMC1/2 in liposomes, but whether full-length mammalian TMC1/2 can form MS channels alone, or if TMIE is required, remained unknown. We aims to overcome expression issues and elucidate the function of full-length mammalian TMC1/2 and TMIE in mechanosensitive channel activity.

Methods: We engineered Fyn-TMC1 and Fyn-TMC2 by fusing at the N terminus of mTMC1/2 an 11-residue membrane-anchoring motif (MGCVQCKDKEA) derived from the Src kinase Fyn, which we named Fyn tag (Fig. 1A). This motif serves as a signal for myristoylation and palmitoylation, which aid stable anchoring of proteins to the plasma membrane and thereby promote their cell-surface expression. Then we cultured cell lines, including PIEZO1-knockout HEK293T cells, and transfected them with plasmids encoding mTMC1/2, hTMC1/2, mTMIE, and their mutants. Protein localization was assessed using confocal microscopy and immunostaining. Cell-surface biotinylation assays were performed to quantify protein expression on the cell membrane. Protein-protein interactions were assessed via pull-down assays. Channel activity was measured using whole-cell patch-clamp and single-channel recordings, with mechanical stimulation achieved by cell poking. Intracellular calcium levels were assessed using calcium imaging. Statistical analyses were used to validate the findings.

Results: 1. The Fyn lipidation tag enhances cell-surface expression of mouse and human TMC1/2 in heterologous cells.

2. Ectopically expressed full-length mTMC1/2 alone form functional mechanosensitive channels.

Mouse transmembrane inner ear (TMIE) protein robustly stimulates TMC1/2 channel activity by modulating their gating.

3. The N-terminal 27 residues of mTMIE are dispensable for regulating TMC1/2 in the in vitro functional assay.

4. Mutating mTMIE C76C77, the predicted palmitoylation sites, eliminates mTMIE stimulation of mTMC1/2.
5. mTMC1/2+mTMIE form 18 pS and 24 pS single channels, respectively.
6. mTMC1/2+mTMIE single channels showed biophysical and pharmacological properties similar to those of the MT channel.

Conclusions: This study demonstrates that the addition of a Fyn lipidation tag overcomes the technical hurdle of expressing TMC1/2 in heterologous cells, allowing for functional characterization. The findings confirm that TMC1/2 alone can form mechanosensitive channels and that TMIE enhances their activity through gating modulation. Palmitoylation of TMIE plays a critical role in this regulatory function. The observed single-channel properties align with those of native mechanotransduction channels. These results provide insights into the function of TMC1/2 and TMIE and establish a valuable in vitro assay for future investigations of the mechanotransduction complex.

SA130. Interrogating Domain Contributions to the Function of Transmembrane Channel-Like Proteins

Matthew Mun^{*1}, Irina Marcovich¹, Cristobal Von Muhlenbrock¹, Jeffrey R. Holt¹

¹*Boston Children's Hospital, Harvard Medical School*

Background: Transmembrane channel protein-like 1 and 2 (TMC1/2) are the pore-forming subunits of the hair cell mechanosensory transduction (MT) complex, which transduces mechanical forces at the tips of stereocilia and initiates vertebrate hearing and balance. Despite both contributing to hair cell MT, TMC1/2 differ significantly in their ability to support auditory function, irrespective of their expression during development (Asai et al., 2018; Nakanishi et al., 2018). This suggests that intrinsic properties of TMC1/2 proteins drive their differing ability to sustain normal function in auditory hair cells. Interrogation of specific molecular domains of TMC1/2 may elucidate these differences, how they contribute to MT mechanistically, and what attributes are necessary to support auditory function.

Methods: Capitalizing on the strong homology shared between TMC1/2, we constructed protein chimeras targeting three domains identified with the highest sequence/structural divergence: the N-terminal region extending up to transmembrane helix TM1, the C-terminal region including TM10 that constitutes the TMC dimer interface, and the C-terminus extending to extracellular helices H7/H8, predicted to aid in the domain-swapped configuration of the TMC dimer. Vectors encoding these chimeras were packaged into hair cell-targeting AAVs (AAV2/AAV9-PHP.B), which were directly administered to P3-5 Tmc1/2KO cochlear explants or injected via the utricle into P1 Tmc1KO mice. Mechanosensory transduction of postnatal hair cells was assayed 48 hours after vector exposure via measurement of FM1-43 uptake. Audition was assessed in P25-30 mice by measuring ABR/DPOAEs. C-terminally tagged versions of each chimera were also assessed to evaluate the expression/localization of exogenous protein to the site of mechanosensory transduction.

Results: All TMC2 constructs with a chimeric TMC1 terminus successfully internalized FM1-43 and restored mechanosensory transduction (n=10 explants for XTmc1Nt-Tmc2/XTmc1TM10+Ct-Tmc2, n=2 for Tmc1Di-Tmc2). However, while early postnatal injections of these chimeras appear to promote increased hair cell survival compared to Tmc1KO controls, neither TMC2 with the TMC1 N-terminus (XTmc1Nt-Tmc2, n=6) nor the C-terminus up to TM10 (XTmc1TM10+Ct-Tmc2, n=2) rescued auditory function in adult

mice—both treatment groups displayed highly elevated to no ABR/DP thresholds. Almost none of the reciprocal TMC1 chimeras (XTmc2Nt-Tmc1/XTmc2TM10+Ct-Tmc1, n=10 each), despite tagged constructs properly localizing to stereocilia tips, were able to support hair cell MT and drive FM1-43 uptake. An exception was TMC1 with the TMC2 C-terminus extending to H7/H8 (XTmc2Di-Tmc1, n=2), which was found to restore hair cell MT and permit FM1-43 uptake in contrast to the chimera excluding H7/H8. This may point to the importance of the TMC dimer interface in recapitulating channel function in the TMC1 chimeras.

Conclusions: Our work identifies domain-specific requirements of TMCs in supporting both mechanosensory transduction and auditory function in the inner ear. Further work characterizing the channel features endowed by these domains will enhance our understanding of both TMC proteins, and channel properties important for the MT complex and greater auditory function.

SA131. Is the Distribution of Actin Isoforms Non-Uniform Within the Stereocilium Actin Core?

Juliana Castro Jimenez*¹, Manuela Gomez-Giraldo¹, A. Catalina Velez-Ortega¹

¹*University of Kentucky, College of Medicine*

Background: Auditory sensory hair cells have stereocilia at their apical surface, which are actin-based organelles that detect sound-induced vibrations. The stereocilium cytoskeleton has both beta- and gamma-actin isoforms. While hair cells can develop stereocilia bundles in the absence of either isoform, both actin isoforms are essential for the life-long maintenance of stereocilia. However, the ultrastructural organization and distribution of these actin isoforms within the tightly packed core of stereocilia is currently unknown. Here, we are testing the hypothesis that the stereocilium actin core exhibits small domains that are enriched in one isoform relative to the other.

Methods: Organ of Corti explants were isolated at early postnatal days from C57Bl/6 mice and from mice expressing fluorescent beta-actin in hair cells (FLE β -actin-eGFP x Atoh1CRE). Samples were imaged live or fixed and stained against filamentous actin with fluorescently-labeled phalloidin, or against specific actin isoforms with fluorescently-labeled specific antibodies. Samples were imaged using a Leica SP8 confocal microscope using the following objectives: Leica 100X 1.44 NA and Olympus 60X 1.0 NA or 100x 1.7 NA.

Results: Beta- and gamma-actin are both expressed along the entire stereocilium length in neonate auditory hair cells. However, using our highest resolution objective (1.7 NA), we see non-uniform labeling of beta- and gamma-actin along the stereocilia shafts, with small discrete zones appearing to be enriched in either beta- or gamma-actin. Standard deviations of fluorescence intensity profiles along the stereocilium shaft of stereocilia labeled with isoform-specific antibodies or of stereocilia from mice expressing beta-actin-eGFP were all comparable and significantly higher than those from stereocilia labeled for filamentous actin with phalloidin. We are currently evaluating the staining profiles of stereocilia simultaneously labeled with the same primary antibody but tagged with different fluorophores, or of stereocilia labeled with pan-actin antibodies.

Conclusions: Our preliminary results indicate that the stereocilium actin core is potentially made up of small domains enriched in beta- or gamma-actin. The functional significance of such non-uniform expression pattern of beta- and gamma-actin isoforms within stereocilia remains to be explored.

SA132. The Salamander Inner Ear: A Developmental and Comparative Study

Kimia Feiz^{*1}, Brittany A. Dobbins², Ruben U. Tovar³, Thomas J. Devitt², David M. Hillis², Dana M. Garcia¹

¹*Texas State University*, ²*The University of Texas at Austin*, ³*St. Mary's University*

Background: Hearing loss in humans is usually permanent because damaged inner ear hair cells cannot regenerate. Salamanders, however, can replace lost hair cells, making them valuable models for sensory development and regeneration. Within the genus *Eurycea*, surface-dwelling (*E. nana*) and cave-dwelling (*E. rathbuni*) species exhibit contrasting developmental strategies and ecological adaptations, providing a natural comparative framework for studying inner ear development. The transcription factor PAX6, best known for its role in eye development, has recently been reported in hair cells of neuromast organs in *Eurycea* from a previous study in our lab. Building on these observations, we hypothesize that PAX6 is also present in inner ear hair cells, and that comparing its expression between surface and cave species may reveal conserved versus divergent roles in sensory development. To confirm hair cell identity, we will use MYO7A, a widely known hair cell marker. Double labeling with PAX6 and MYO7A will help us determine PAX6's presence in inner ear sensory cells across species.

Methods: We combined anatomical imaging with immunohistochemistry to compare the salamander inner ear of two species through development. Specimens at various developmental stages were iodine-stained and scanned with micro-CT (DiceCT) to reconstruct inner ear anatomy in 3D. To examine protein expression, specimens were cryosectioned and labeled with antibodies against PAX6 and MYO7A, followed by fluorescent secondary antibodies. Sections were imaged using laser-scanning confocal microscopy, enabling localization of proteins within inner ear hair cells across developmental stages.

Results: DiceCT images provided 3D reconstructions of inner ear anatomy in both *E. nana* and *E. rathbuni*, allowing comparison of overall structure across developmental stages. Immunofluorescence showed that PAX6 protein was localized in the sensory epithelium of the inner ear by the earliest stage examined (1 month post-oviposition) in both *E. nana* and *E. rathbuni*. Preliminary data indicate that PAX6 expression in the inner ear persists into later developmental stages, particularly in the cave-dwelling *E. rathbuni*. In confocal images, PAX6 labeling was localized to the putative hair-cell region of the inner ear, consistent with its presence in sensory cells. The MYO7A labeling is in progress to confirm which cells are hair cells and to assess their co-expression of PAX6.

Conclusions: These results establish that PAX6 is a component of salamander inner ear sensory cells from very early in development and may be maintained throughout life. By combining 3D imaging with molecular markers, we have started building a map of how the salamander's inner ear develops. Completing the MYO7A co-labeling will enable us to determine whether PAX6 is present in hair cells or support cells. This comparative developmental study lays the groundwork for understanding hair cell regeneration mechanisms and could inform strategies for restoring hearing function. Insights from this study may contribute to regenerative approaches for hearing loss.

SA133. Molecular Mechanisms of TMC1/2 Localization in Hair Cells Mediated by Transmembrane O-Methyltransferase (TOMT)

Abby Carney^{*1}, Abigail Sanders², Julia D. Lewis², Brandon Bizup³, Alicia M. Frank², Christopher L. Cunningham²

¹*University of Pittsburgh School of Medicine*, ²*Pittsburgh Hearing Research Center, University of Pittsburgh School of Medicine, Pittsburgh, PA USA*, ³*University of Pittsburgh*

Background: Transmembrane O-methyltransferase (TOMT) is a deafness-linked gene (DFNB63) necessary for hearing and mechanotransduction channel (MET) function in hair cells. Our previous work demonstrated that TOMT is critical for localization of the MET channel pore-forming subunits, TMC1 and TMC2, to the hair cell stereocilia, though endogenous expression patterns and molecular mechanisms of TOMT function are not well understood.

Methods: We generated a TOMT-HA knock-in mouse to evaluate inner ear TOMT expression and subcellular localization with immunohistochemistry. To gain mechanistic insights into the role of TOMT in regulating mechanotransduction and TMC1/2 localization, we created serial 20 amino acid deletions and deafness-causing missense mutation TOMT constructs to identify domains important for protein-protein interactions, normal and pathophysiological mechanisms, and auditory function. We performed co-immunoprecipitation of TOMT constructs with TMC1 and other MET associated proteins in HEK293 cells. To further evaluate TOMT function in vivo, we used adeno-associated viral (AAV) inner ear delivery of TOMT with deletion or deafness mutations into *Tomt*^{-/-} mice followed by immunohistochemistry and auditory brainstem response (ABR) testing to evaluate rescue of TMC1 localization and auditory function, respectively.

Results: We confirmed that endogenous TOMT expression is restricted to hair cells in the cochlea and vestibule and TOMT is localized to the hair cell endoplasmic reticulum (ER) and cytoplasm while excluded from stereocilia. We determined that deletion of the first 20 amino acids (2-21), a putative membrane-associated domain, abolishes binding of TOMT to TMC1 and other MET components. In contrast, deletions in other regions of TOMT and deafness-associated mutations in TOMT increase interaction with MET proteins. We found that the TOMT 2-21 region is critical for stereocilia localization of TMC1 and auditory function. In addition, though TOMT deafness mutations induced increased binding to MET channel components in vitro, they failed to rescue TMC1 localization to the stereocilia or ABRs. Interestingly, using in vitro cycloheximide chase assays, we found that the co-expression of TMC1 with mutant TOMT altered TMC1 protein stability.

Conclusions: In summary, TOMT is an ER-associated protein that is critical for TMC1/2 localization and auditory function. The 2-21 region of TOMT is necessary for interactions with MET channel proteins and TMC1 localization to stereocilia. In contrast, TOMT deafness-linked mutations increase binding to MET components, while failing to rescue TMC1 localization to the stereocilia, suggesting defects in MET protein complex dissociation.

SA134. Does Brief Membrane Permeabilization Cause Morphological Abnormalities in Stereocilia Hair Cell Bundles?

Payton Nies¹, Ana I. Lopez-Porrás¹, A. Catalina Velez-Ortega¹, Payton Nies^{*1}

¹*University of Kentucky*

Background: Detergents are amphipathic molecules often used to permeate the cell membrane to allow for better antibody penetration in immunolabeling experiments. This technique is particularly useful when it comes to antibodies that label the cytoskeleton and other small intracellular proteins. Permeabilization has also been used in live cells for functional labeling. Inner ear hair cells are specialized sensory cells that receive stimulus through unique microvilli-like protrusions called stereocilia. Individual stereocilia are generally less than 10 μm in height and 0.5 μm in diameter and contain an actin-based cytoskeleton. It is known that cytoskeleton remodeling happens in stereocilia as a result of changes in the influx of intracellular Ca^{2+} through mechano-electrical transduction channels (Velez-Ortega et al., Elife 2017). Thus, even a brief incubation in detergent and exposure to a different ionic environment, may be enough to trigger remodeling. Here we used several detergents under a variety of conditions to test if permeabilization affects the morphology of stereocilia hair bundles. Secondly we wanted to explore if a detergent treatment would expose the cytoskeleton of stereocilia for visualization using scanning electron microscopy (SEM).

Methods: Organ of Corti from C57Bl/6 early postnatal mice were dissected in L-15 medium and were treated with varying concentrations of detergent (Triton-X-100, Saponin, Tween-20, CHAPS, NP-40, SDS) before or after fixation. In live cells, treatments took place in different ionic environments (extracellular-like or intracellular-like). Morphology of stereocilia hair bundles was then assessed using SEM.

Results: As was expected there was significant damage to the hair cell bundle morphology, including thinning and potential remodeling of the cytoskeleton, with brief exposure to detergent before fixation in an extracellular-like (L-15 medium) environment. Live cells treated in an intracellular-like (cytoskeleton buffer) environment for up to 7 minutes had more normal hair cell bundle morphology, but there were exaggerated changes at the tips of stereocilia and hollow cores observed in supernumerary stereocilia. In all cases of brief exposure to detergent before fixation, there was an appearance of parallel filaments of approximately 15-20nm center-to-center. Furthermore, the kinocilium membrane was completely removed exposing the microtubule core. Membrane removal after fixation has proven difficult with no observed kinocilium membrane removal or appearance of parallel filaments along the stereocilia shafts.

Conclusions: Membrane removal is easier in live cells than cells that have been fixed prior to treatment with detergent. We are currently testing varied time points and conditions for treatment of samples with detergent prior to fixation. We hope to determine an effective treatment for permeation without causing significant morphological or remodeling changes in the stereocilia hair bundle.

Supported by University of Kentucky College of Medicine and Department of Physiology.

SA135. Simulations of Kanamycin A Permeation Through TMC1 Validate Its Role as the Inner-Ear Mechanotransduction Channel

Harsha Mandayam Bharathi*¹, Marcos Sotomayor¹

¹*University of Chicago*

Background: Aminoglycosides are small-molecule antibiotics widely used as treatment against bacterial infections. A side-effect of aminoglycosides use is dose-dependent hearing loss. This is caused by death of specialized cells called hair-cells that are responsible for sensing sound. Multiple experiments involving manipulations of components of the

mechanotransduction machinery have shown that an important pathway for aminoglycoside intake by hair-cells is their transduction channel pore formed by transmembrane channel-like 1 (TMC1) proteins. Although experiments suggest that aminoglycosides enter hair cells through TMCs, the mechanism and the energetics of this process are poorly understood. We used a variety of computational methodologies to probe the mechanism of aminoglycoside permeation through TMC1.

Methods: We generated AlphaFold2 models of human TMC1 that had ten transmembrane helices labeled $\alpha 1$ to $\alpha 10$, with the pore formed by helices $\alpha 3$ to $\alpha 7$. These models were simulated with and without calcium-and integrin-binding protein 2 (CIB2) in the presence of Kanamycin A (KanA), in 3+ and 4+ charged states. Control simulations were done using curare, a known hair-cell transduction channel blocker. Multiple microsecond scale simulations of these systems were carried out in the presence of applied voltage to enable permeation. We also quantified the free energy of permeation by using an enhanced sampling technique that combines well-tempered metadynamics and extended adaptive biasing forces methods.

Results: Microsecond timescale simulations with applied voltage (-500 mV and -250 mV) showed complete permeation of KanA (3+ and 4+) and partial insertion of curare through the TMC1 pores. We also learnt that the movement of transmembrane helices $\alpha 3$ and $\alpha 4$ of TMC1 along with the formation of a kink in $\alpha 4$ were essential for permeation. These simulations also revealed crucial bottlenecks and interacting residues along the permeation path, some of which are at previously known deafness-causing mutation sites. Quantification of free energy of permeation of KanA 3+ across an open-like conformation of TMC1 system without CIB2 and in the absence of biasing voltages gave a barrier of ~ 10 kcal/mol. This barrier could be overcome in the presence of a resting voltage in the hair-cell environment.

Conclusions: The occurrence of permeation of KanA in simulations supports the notion that TMC1 proteins form the pore of the inner-ear hair-cell mechanotransduction channel. Simulations also demonstrate a potential channel opening mechanism involving the movement of transmembrane helices $\alpha 3$ and $\alpha 4$ of TMC1. Transient interactions formed by KanA with residues at previously known deafness-causing mutation sites provide insights into the roles of these residues in channel function. Average permeation times obtained from simulation repeats point to a more rigid pore of TMC1 in the presence of CIB2. Our work provides an improved understanding about aminoglycoside permeation through TMC1 that can inform the design of new molecules retaining their bactericidal activity while losing their ototoxicity.

SA136. Does Myosin-15a Isoform 1 Contribute to the “Gating Spring” of the Mechanotransduction Machinery in Mammalian Auditory Hair Cells?

Leon Echeverri Rolong^{*1}, Jonathan Bird², Gregory Frolenkov¹

¹University of Kentucky, ²University of Florida

Background: Inner ear hair cells convert sound vibrations into electrical signals through deflections of their mechanosensory stereocilia. These deflections modulate tension in tip links interconnecting stereocilia and transmitting force to mechano-electrical transduction (MET) channels. The tip link and associated molecules form a “gating spring” that governs MET sensitivity (a stiffer spring allows channel opening with smaller deflection). Molecular identity of gating spring remains unknown. Notably, saturation of the MET current typically requires ~ 200 nm of stereocilia deflection, which likely exceeds the elastic limits of tip links. An additional elastic component, possibly a motor protein capable of large movements, may

contribute to the gating spring. Myosin-15a (MYO15A) is a motor protein required for stereocilia growth and maintenance, and mutations in MYO15A cause deafness. MYO15A can link the plasma membrane proteins/complexes to the stereocilia actin core, thereby contributing to the gating spring and providing the compliance needed for large deflections. Hair cells express three MYO15A isoforms. Notably, isoform 1 with an extended N-terminus is the largest variant that is localized at the tips of transducing, 2nd and 3rd row stereocilia, at least in the inner hair cells.

Methods: Using conventional whole-cell patch clamp recordings, we investigated MET currents in the young postnatal (P5-8) cochlear inner hair cells of wild-type and *Myo15 Δ 1/ Δ 1* (lacking MYO15A isoform 1) littermate mice. We used a custom fluid-jet (4.6 kHz piezo-driven, 5 μ m tip) for uniform hair bundle deflections. Hair bundle motion was captured at 2000 frames/s using a high-speed camera (Basler acA720-520 μ m) with a 60 $\times$ /1.0 NA water-immersion objective. We also re-analyzed MET recordings obtained previously in our lab in the same mice but using piezo-driven rigid probe deflecting stereocilia (Fang et al., 2025)

Results: Re-analysis of the previous data from our lab suggests that the lack of MYO15A isoform 1 causes MET currents to saturate at smaller deflections than in wild-type hair cells, indicating reduced gating spring compliance in the mutants. However, rigid probe stimulation is known to artificially broaden the deflection range and underestimate hair cell's mechanosensitivity. Using our fluid-jet system combined with simultaneous high-speed video recordings, we confirmed that MET currents saturate at $\sim$ 200 nm bundle deflection in wild-type inner hair cells, consistent with the previous reports. We were also able to reduce cell-to-cell variability, which could allow estimating the differences in the stiffness of the hair bundles in mutant and wildtype hair cells.

Conclusions: Our results indicate that the fluid-jet approach can be reliably used to test whether MYO15A isoform 1 contributes directly to the compliance of the gating spring.

SA137. Effects of cAMP on the Shape of Mammalian Auditory Hair Cells' Stereocilia

Aileen Khosravi*¹, Abigail Dragich¹, Luis Rendon-Orozco¹, Gregory Frolenkov¹

¹*University of Kentucky*

Background: The exact heights and “staircase” arrangement of the three rows of actin-based mechanosensory stereocilia at the apical surface of the auditory hair cells are essential for their mechanosensitivity and, hence, our hearing. Sound-induced deflections of the hair bundles modulate the tension in extracellular tip links interconnecting stereocilia and gating mechano-electrical transduction (MET) channels located at the lower ends of the tip links. It has been established that the height of stereocilia may be dynamically regulated by the resting current passing through the MET channels; however, the exact molecular mechanisms of this phenomenon have yet to be elucidated. The second messenger cyclic adenosine 3'5'-monophosphate (cAMP) is known to modulate MET in the auditory hair cells and plays a role in the growth and/or disassembly of actin-based protrusions in other cell types. Therefore, this study aims to explore whether cAMP could modulate stereocilia heights in the auditory hair cells.

Methods: Two different experiments were performed: 1) organ of Corti explants dissected from postnatal day 4 (P4) wildtype mice were cultured for 2.5 days and then incubated for 6 hours at 37°C either with 200 μ M of membrane-permeable, nonhydrolyzable cAMP analog 8-Bromo-cAMP or only with the same intracellular medium (DMEM); 2) acutely isolated

organ of Corti explants from postnatal day 5 (P5) wildtype mice were incubated at 37°C with 10 mM of 8-Bromo-cAMP for 4 or 8 hours while the control samples were incubated in DMEM without 8-Bromo-cAMP for the same periods of time. Hair cell bundles were imaged by high-resolution scanning electron microscopy, and stereocilia dimensions were quantified using ImageJ.

Results: The preliminary data reveals that there were no significant changes in the step sizes between the three stereocilia rows after 4 hours exposure of acutely-isolated organs of Corti with a high concentration of 8-Bromo-cAMP. However, after 8 hours incubation at the same concentration, there was a decrease in the step size between the tallest and shortest row of stereocilia in both inner and outer hair cells. A similar effect was observed after 6 hours of incubation with lower concentration of 8-Bromo-cAMP but in cultured organs of Corti (P4 + 2.5 days in vitro). Furthermore, in the latter samples, there was a decrease in step size between the tallest and middle row in both inner and outer hair cells, while the heights of the tallest stereocilia in the bundle were not affected in outer hair cells but decreased in the inner hair cells.

Conclusions: These results imply that the effects of cAMP on stereocilia heights may either require cultured conditions or a certain developmental maturity of hair cells.

SA138. Single-Cell Proteomics and Ap-Ms to Elucidate Auditory Mechanotransduction in Mammalian Cochlea

Ruxandra Bighiu^{*1}, Andrea Lelli², Elise Pepermans¹, Christine Petit³, Geert Baggerman¹, Vincent Van Rompaey¹

¹*University of Antwerp*, ²*Institut Pasteur*, ³*Institut de l'Audition/ Institut Pasteur*

Background: The mammalian cochlea contains two mechanosensitive receptor cell types, inner hair cells (IHCs) and outer hair cells (OHCs), essential for hearing. Despite their importance, the molecular mechanisms driving their distinct function, particularly those underpinning mechano-electrical transduction (MET), remain incompletely understood. This study is the first effort to generate distinct proteomic profiles for IHCs and OHCs, using postnatal day 7–9 (P7–P9) murine cochleae, to uncover key proteins involved in auditory signalling, including novel components of the MET complex.

Methods: Due to the limited number and fragility of cochlear hair cells (~3,500 IHCs and ~12,000 OHCs per cochlea), we employed a suction pipette technique to isolate individual OHCs from enzymatically treated, mechanically dissociated tissue. Isolated cells were cryopreserved and processed using a streamlined one-pot protocol that combines lysis, sonication, denaturation, and tryptic digestion in a minimal volume. We applied TimsTOF SCP with Evosep One for mass spectrometry, identifying up to 500 protein groups per single OHC and 2,200 from pooled five-cell samples. Further analysis will use the higher-sensitivity TimsTOF Ultra 2 system.

Results: Initial work focused on OHCs due to their accessibility. Hair cell-specific proteins were successfully identified in OHCs. We now aim to compare them with recently isolated IHCs. To specifically study the MET complex, we integrate single-cell proteomic data with affinity-purification mass spectrometry (AP-MS) targeting the known MET component protocadherin 15 (Pcdh15). As Pcdh15 is an intrinsically disordered protein (IDP), we apply crosslinking strategies and optimized buffers to capture weak or transient interactions. Potentially interesting protein-protein interactions will be validated using AlphaFold3 and AlphaPulldown.

Conclusions: This study provides new molecular insights into cochlear mechanosensation by profiling key proteins and identifying components of the MET complex. Our approach advances single-cell proteomics in fragile cell types and contributes foundational knowledge for therapeutic strategies in auditory disorders.

SA139. Identifying Key Molecules Involved in the Biogenesis, Transport, and Recycling of Synaptic Vesicles at Ribbon Synapses

Sandeep David*¹, Katherine Pinter¹, Katie Kindt¹

¹*National Institute on Deafness and Other Communication Disorders, National Institutes of Health*

Background: Sensory hair cells utilize specialized ribbon synapses to reliably transmit sensory information to the brain. Ribbon synapses have high rates of spontaneous vesicle release and function without fatigue. To sustain this level of release, a continuous supply of synaptic vesicles (SVs) must be trafficked to the presynapse. Recently we showed that Kif1a-mediated transport delivers new SVs along microtubules to the hair cell presynapse. Loss of Kif1a resulted in a depletion of SVs at the synapse, along with impaired neurotransmission. However, many other factors are needed to ensure that SVs are made, transported and recycled appropriately.

Methods: To study SV distributions, we study the zebrafish lateral-line system. We are using RNA-FISH to investigate expression of candidate genes involved in SV packaging, transport, and recycling. Then, to assess gene function we are using CRISPR-Cas9 to create mutations in candidate genes. In fixed hair cells, we use immunohistochemistry against SV markers including Vglut3, CSP, and Rab3a. To visualize SV populations in vivo, we use the vital dye LysoTracker. To assess hair-cell function, we assay for intact mechanotransduction using FM1-43 label, a dye that enters hair cells through mechanosensitive channels. To assess ribbon synapse function in our mutants, we use in vivo calcium imaging and loose-patch electrophysiology. To examine behavior in our mutants, we will use acoustic startle and rheotaxis assays to monitor lateral-line function.

Results: Currently we are using CRISPR-Cas9 to test the following candidate genes: Ap3, Rab3a/Madd, and Dynamin2, that we hypothesize are critical for SV biogenesis, transport, and endocytosis, respectively. RNA-FISH showed enrichment of Ap3m2, Rab3aa, Rab3ab, Madd, Dynamin2a, and Dynamin2b in zebrafish lateral-line hair cells. Preliminarily, we have found that ap3m2 mutants show less LysoTracker, Vglut3, and CSP label throughout the cell when compared to wild-type zebrafish hair cells, indicating Ap3m2 may be important to produce new vesicles. Additionally, ap3m2 CRISPR mutants show no significant difference in FM1-43 label throughout hair cells, indicating intact mechanotransduction. We are currently testing our other candidate genes using a similar approach.

Conclusions: Characterizing these mutants will allow us to shed light on the process of vesicle packaging, movement, and recycling in hair cells. This work will deepen our understanding of the multiple pathways that converge to supply SVs at ribbon synapses.

SA140. Decreased GABA: Maladaptive Breakdown or Compensatory Shift?

Kelly Harris*¹, James Dias¹

Background: In humans and animals, decreased GABA in auditory cortex contributes to hyperexcitability, and may be maladaptive for speech recognition. If true, then modulating GABA may serve as a novel therapeutic target. We hypothesize that decreases in GABA may also contribute to the compensatory increases in cross-sensory plasticity that are observed in individuals with hearing loss (HL) and the finding that older adults rely on visual speech to understand speech-in-noise to a greater extent than younger adults. However, the age-related neurochemical (GABA) and microstructural (myelin) changes in the auditory system that mediate cross-sensory plasticity remain unknown. We hypothesized that aging and HL contribute to a decrease in GABA in auditory cortex, which is associated with conserved myelination (structural connectivity) between auditory and visual cortices, increasing cross-sensory plasticity and helping to preserve audiovisual (AV) speech recognition. If GABA is to serve as a potential therapeutic target, we need to first understand the extent to which the mechanisms of cross-sensory plasticity relate to previously reported maladaptive hyperexcitability in the auditory system that are also associated with lower levels of GABA.

Methods: Cortical evoked responses, +H-MRS, and Diffusion kurtosis imaging (DKI) were collected in 22 older and 7 younger adults. Cross-sensory activity was calculated as a ratio of cross-sensory activity (i.e., Visual evoked potentials (VEPs) in auditory cortex) relative to unimodal activity (VEPs in visual cortex). Granger causality was used to calculate functional connectivity between auditory and visual cortices. DTI tractography between auditory and visual cortices was used to examine the extent to which decreased GABA may contribute to conserved structural connectivity between auditory and visual cortices, increased cross-sensory plasticity, functional connectivity, and better AV speech recognition.

Results: Greater cross-sensory activity was observed in older adults compared to younger adults and was associated with decreased GABA in auditory cortex. Despite significant age-related decreases in total brain fractional anisotropy (FA), older adults did not exhibit significant age-group deficits in connections between visual and auditory cortices, and higher FA along this tract was associated with decreased GABA in auditory cortex. This relationship remained significant after accounting for whole brain measures of FA. GABA in auditory cortex was not associated with DTI metrics in other fiber tracts examined or whole brain measures. Measures of structural connectivity (FA) were positively associated with functional connectivity (Granger causality) between auditory and visual cortex ($r = 0.710$, $p = 0.001$). Greater cross-sensory activity was associated with better AV SIN.

Conclusions: We previously reported that decreased cortical GABA was maladaptive for auditory speech recognition. In contrast, these preliminary findings in older adults support the hypothesis that decreased GABA in auditory cortex may contribute to conserved myelination, enhancing connections between auditory and visual cortex.

SA141. Asymmetric Binaural Cue Reweighting in Unilateral Hearing Loss

Sara Momtaz Bokharaei^{*1}, G. Christopher Stecker¹

¹*Boys Town National Research Hospital*

Background: Spatial hearing relies on the integration of interaural time (ITD) and level (ILD) differences, with perceptual weighting typically biased toward the more reliable cue.

Methods: To test how asymmetric hearing affects cue weighting, we measured the relative weighting of ITD and ILD cues in 48 adults: 12 within normal limits (WNL) of hearing sensitivity, 24 with simulated unilateral loss via earplug (SHL, left and right ear), and 12 with

chronic unilateral hearing loss (UHL, left and right ear). Participants completed a lateralization task with independently varying ITD and ILD cues. Lateralization slopes, bias, and model fit (R^2) were computed via multiple linear regression. ITD/ILD weight ratios were computed from the fit slopes.

Results: Lateralization slopes were significant for both ITD and ILD cues among WNL listeners ($p < .001$). SHL listeners showed significant but reduced ITD slopes ($p < .05$) and robust ILD slopes (indicating residual sensitivity to ILD and/or the corresponding monaural level cues). In UHL, ILD slopes remained significant, but ITD slopes were not ($p > .1$), indicating impaired timing cue use. Consequently, ITD/ILD weight ratios favored level cues more strongly in SHL ($M = 705 \mu\text{s/dB}$) and UHL ($M = 316 \mu\text{s/dB}$) vs. WNL ($M = 43.8 \mu\text{s/dB}$), with group differences confirmed for WNL vs. SHL and WNL vs. UHL (both $p = .004$).

WNL listeners showed robust fit quality (mean $R^2 = 0.72$) and minimal lateralization bias (-3%). In contrast, SHL produced degraded fits (mean $R^2 = 0.41$) and pronounced bias toward the unplugged ear (mean 46%). Chronic UHL showed intermediate fit quality (mean $R^2 = 0.53$) and reduced bias compared to SHL (mean 26%), although group differences in bias between SHL and UHL were not statistically significant (e.g., SHL-LE vs. UHL-LE: $t(8.11) = 2.22$, $p = .057$, $d = 1.16$; SHL-RE vs. UHL-RE: $t(6.24) = 2.10$, $p = .08$, $d = 1.15$).

Conclusions: These findings are consistent with the view that simulated UHL induces maladaptive, ear-specific reweighting, whereas chronic UHL reflects partial adaptation that reduces but does not fully resolve ear-specific biases, with implications for individualized rehabilitation strategies. [Supported by NIH R01-DC016643, P20-GM1090203, and Boys Town National Research Hospital]

SA142. Investigating the Perceptual Consequences of Low-Frequency Hearing Loss

Elaea Purmalietis*¹, Andrew J. Oxenham¹

¹*University of Minnesota*

Background: Low-frequency sensorineural hearing loss (LFHL) is defined by elevated thresholds below ~ 2 kHz with preserved high-frequency sensitivity. This “reverse-slope” configuration differs from more common high-frequency sloping loss and presents unique challenges for diagnosis and treatment. “Off-frequency listening” can lead to overestimation of apical function on the audiogram and underestimation of perceptual deficits. Amplification within a low-frequency dead region may lead to masking of remaining high-frequency cues, without contributing additional information. The present study aims to explore the perceptual consequences of LFHL, with the long-term goal of providing better diagnostics and more targeted treatment to this overlooked population.

Methods: A battery of behavioral tests were designed to probe specific consequences of LFHL, including identifying potential cochlear dead regions and relating the psychoacoustic outcomes to measures of speech intelligibility. Tests included: Psychophysical tuning curves, designed to identify dead regions through shifts in PTC tip frequency; amplitude and frequency modulation detection, designed to identify deficits in temporal envelope and/or fine-structure processing; pitch discrimination with pure and harmonic complex tones, designed to identify deficits in the processing of spectrally resolved and/or unresolved harmonics; and speech perception in noise with auditory-only and audio-visual speech in broadband as well as lowpass- and high pass-filtered conditions.

Results: Preliminary results from individual participants indicate idiosyncratic outcomes that will be related to theories of underlying mechanisms, including dysfunction of inner and/or outer hair cells. Once complete the findings will provide a systematic study in this previously understudied population.

Conclusions: This project will provide a systematic characterization of the perceptual consequences of LFHL, clarifying how listeners exploit available cues when low-frequency place coding is disrupted. Findings will refine theories of pitch and auditory coding, support better classification of LFHL, and inform the development of an abbreviated diagnostic battery to guide perceptually appropriate management and treatment strategies.

SA143. At-Home Augmented Reality Training Improves Speech-In-Noise Performance in Older Adults

Pooseung Koh^{*1}, Sungyoung Kim¹, Inyong Choi², Hyo-Jeong Lee³, Jeongwoo Park¹

¹*Korea Advanced Institute of Science and Technology*, ²*University of Iowa*, ³*Hallym University College of Medicine*

Background: Age-related hearing decline affects speech comprehension in noisy environments and sound localization abilities, critical for daily communication and safety. While our previous augmented reality (AR) auditory training showed promise in younger adults, implementation in at-risk populations and clinical populations remains unexplored. This study evaluates a home-based AR auditory training system in adults aged 50-60 and introduces its expansion to cochlear implant (CI) users.

Methods: Eleven adults ($M=53\pm3$) with normal hearing completed home-based AR auditory training using our smartphone application featuring 6DoF audio rendering. Participants completed four training sessions and one evaluation session weekly for four weeks, averaging 265 minutes total training time. The gamified training presented two distinct tones in spatial noise, requiring selective attention and localization. Pre/post assessments included the Korean Matrix Sentence Test (KMST) at 0dB, -6dB, and -9dB SNR. Weekly in-game evaluation sessions evaluated training efficacy and performance improvements without feedback confounds. Reliable Change Index (RCI) analysis distinguished true training effects from test-retest variability, while System Usability Scale (SUS) scores evaluated the learnability and ease-of-use of the AR system for this age group. Qualitative user feedback was obtained from exit interviews after the training period. Building on these normal-hearing results, we initiated feasibility testing with CI users to evaluate clinical translation potential.

Results: KMST performance showed significant improvements, with 6/11 participants (55%) demonstrating reliable improvement at -6dB SNR based on RCI criteria (threshold $\geq 9.18\%$), with mean improvement of 10.09% ($SD=6.27$). At -9dB SNR, participants improved by 8.55% ($SD=6.53$), and at 0dB SNR by 3.00% ($SD=2.90$). Importantly, improvements in sound localization accuracy during training sessions significantly correlated with KMST gains at -6dB SNR ($\rho = 0.639$, $p = 0.034$), suggesting shared underlying mechanisms between spatial hearing and speech-in-noise processing. The SUS score of 70.2 validates that older adults can adopt AR technology for training, though the interface and instruction require refinement. User feedback revealed that while training difficulty was appropriate, current gamification elements were insufficient for sustained engagement. Pilot testing with CI users showed promising engagement when training difficulty was adjusted and system hardware accommodated implant requirements.

Conclusions: Home-based AR auditory training improved speech-in-noise comprehension, with over half of participants showing gains beyond test-retest variability at challenging SNRs based on RCI analysis. The significant correlation between in-game localization improvements and speech-in-noise gains suggests that spatial hearing training may enhance speech processing through shared attentional mechanisms. Notably, the usability scores demonstrate that AR technology can be successfully deployed for home-based auditory rehabilitation with minimal guidance. However, maintaining user engagement throughout the 4-week protocol proved challenging, indicating the need for improved gamification strategies. The successful adaptation for CI users represents a critical step toward digital therapeutic implementation. Future work will expand the CI cohort, and enhance engagement mechanisms for sustainable training.

SA144. Hyperbaric Oxygen Therapy for Sudden Sensorineural Hearing Loss

Kiran Ganga^{*1}, Christopher Niemczak², Jay Buckey²

¹*Geisel School of Medicine*, ²*Dartmouth-Hitchcock, Geisel School of Medicine*

Background: Idiopathic sudden sensorineural hearing loss (ISSNHL) is a rapid decrease in hearing ability, typically occurring in one ear. Treatments for ISSNHL are difficult to study as patients can recover spontaneously, making it difficult to separate treatment effects from the natural course of the disease. Current first-line therapies are oral and intratympanic corticosteroids, yet the mechanisms underlying their benefit remain poorly understood. Hyperbaric oxygen therapy (HBOT) has also emerged as a potential ISSNHL treatment, yet it is not clear if it offers benefits beyond steroids. This study assessed the effect of HBOT, in combination with corticosteroids, on hearing improvement following ISSNHL.

Methods: We analyzed data from the HBOT Registry, a global, multicenter collaboration that tracks outcomes of SHL patients treated with HBOT across 33 institutions. Hearing thresholds (pure tone average, PTA, of 0.5, 1.0, 2.0 and 4.0 kHz) were assessed before and after HBOT initiation, with clinically significant recovery defined as ≥ 15 dB improvement in PTA or return to baseline. Patients in both datasets received oral and/or intratympanic corticosteroids prior to HBOT. In addition, we conducted a retrospective case series of ISSNHL patients at Dartmouth-Hitchcock Medical Center, who received HBOT following corticosteroid therapy, to determine if there were cases that showed a clear benefit beyond steroids. Inclusion criteria included documented ISSNHL, prior corticosteroid treatment, and completion of at least 10 HBOT sessions within 14 days of symptom onset.

Results: HBOT Registry data showed that HBOT was associated with overall improvement in measured PTAs among ISSNHL patients (n=256). Specifically, 41.02% of patients were found to have achieved clinically significant hearing recovery. The overall mean improvement in PTA following HBOT, averaged across all patients, was 14.37dB HL. Since most patients typically receive steroids prior to HBOT, this suggests an additional benefit from HBOT. In the Dartmouth-Hitchcock case series, 10 cases were highlighted where HBOT was associated with an additional hearing recovery beyond what the patient had obtained with steroids. This recovery was particularly apparent amongst low frequencies (i.e., 0.5-1.0 kHz). This is a limited case series and additional study on the interaction between corticosteroid therapy and HBOT is needed.

Conclusions: Our findings suggest HBOT improves hearing beyond what is achieved with corticosteroids in some individuals. Incorporating HBOT into treatment algorithms may

improve outcomes in refractory cases, though prospective, controlled studies are needed to guide clinical decision-making and patient selection.

SA145. Stratifying Complex Sensorineural Hearing Loss Using Non-Invasive Biomarkers: A Replication Study

Erin Batik*¹, Shaina Wasileski¹, Courtney Shepler¹, Sharadhi Umesh Bharadwaj², Mary Pierce Barnes¹, Hari Bharadwaj¹, Samantha Hauser³

¹University of Pittsburgh, ²Carnegie Mellon University, ³Purdue University

Background: Sensorineural hearing loss (SNHL) is a complex disorder, often the result of several etiologies accumulated across the lifespan, resulting in variable treatment outcomes. Current audiometric testing cannot distinguish different inner ear pathologies that may contribute to the umbrella diagnostic category of SNHL. As a result, clinical management focuses on audibility and patient reports rather than each patient's cochlear pathophysiology profile. Furthermore, different cochlear pathologies such as damage to cochlear sensory cells (OHCs and IHCs), afferent synapses, or degeneration of the stria, can affect listening outcomes for speech in divergent ways. Recent cross-species studies (Hauser, 2025) suggest that a non-invasive multi-biomarker battery may allow for the stratification of different cochlear pathologies in SNHL and predict listening outcomes. Here, we aim to replicate a portion of these studies by testing whether this multi-biomarker battery can better predict speech-in-noise scores, compared to the audiogram alone.

Methods: Participants aged 18–70 years were recruited across the continuum of normal hearing and symmetric moderate SNHL from a University of Pittsburgh research participant database (N=32 so far). Participants completed air- and bone-conduction audiometry (0.25–16kHz AC, 0.5–4kHz BC), wideband tympanometry, and provided demographic, otologic, and audiology surveys to mirror a clinical evaluation. Then, a battery of non-invasive biomarkers, including envelope following responses to rectangularly amplitude-modulated tones (RAM EFRs) recorded with a 32-channel EEG cap, wideband middle ear muscle reflexes (WB-MEMR), and swept-tone distortion-product otoacoustic emissions (DPOAEs) were acquired on each participant based on pre-clinical results from Hauser (2025). To measure suprathreshold listening outcomes, spectrotemporal modulation thresholds, and speech-in-noise scores were measured across two tasks emphasizing energetic masking and higher cognitive factors, respectively.

Results: Preliminary data are consistent with the notion that the multi-biomarker battery can capture aspects of SNHL pathophysiology that are not discernable from the audiogram. Specifically, after controlling for residual age or cognitive differences, the biomarker battery predicted individual variations in listening performance beyond those predicted by the audiogram.

Conclusions: Our preliminary findings highlight variability in suprathreshold listening abilities that are not fully explained by audiometric thresholds in overt SNHL. Further data collection is ongoing and will supplement the data collected by Hauser (2025) to evaluate the potential of a non-invasive multi-biomarker battery approach for precision diagnostics in audiology and predicting listening outcomes.

SA146. Presynaptic Regulation of Quantal Size at Calyx of Held Synapses Following Conductive Hearing Loss

Tianyi Xiao^{*1}, Youad Darwish¹, Tianhao Wu¹, Hai Huang¹

¹*Tulane University*

Background: In response to decreased sensory input with hearing loss, the central nervous system undergoes compensatory changes. These changes are associated with neuronal activity alteration and map reorganization, as well as modifications in synaptic function.

Methods: Using the mouse calyx of Held, a giant glutamatergic terminal in medial nucleus of the trapezoid body (MNTB) of the auditory brainstem, we examined the synaptic function changes following unilateral conductive hearing loss (earplugging).

Results: Our results showed that the amplitude and frequency of miniature excitatory postsynaptic currents (mEPSCs) increased in hearing loss MNTB compared to the normal side after 2-3 days of earplugging. We also estimated the synaptic properties changes using a high-frequency stimulation protocol, showing an increased release probability upon hearing loss. Lastly, bath application of a low-affinity, rapidly dissociating AMPA receptor antagonist γ -DGG revealed that higher concentration of glutamate is packed into the vesicles of hearing loss calyces.

Conclusions: In conclusion, our results showed that hearing loss induces presynaptic homeostatic plasticity by increasing vesicular glutamate concentration and neurotransmitter release probability.

SA147. Changes in Local and Global Neural Dynamics Across Brain States in Congenitally Deaf Mice

Adrian Armstrong^{*1}, Xue Wang², Andrej Kral², Rüdiger Land²

¹*Medizinische Hochschule Hannover*, ²*Institute of Audioneurotechnology, Hannover Medical School*

Background: Hearing loss may induce global cortical changes beyond local effects on the auditory cortex. These changes may underlie the increased dementia risk and cognitive decline associated with hearing loss. However, the extent of these cortical network changes beyond the auditory system remains unclear.

Methods: To study these changes we combined intracortical multielectrode array recordings and 30-channel topographic EEG in congenitally deaf Otof (deaf5Jcs/Kjn) mice. We compared local changes in the deaf auditory cortex to those in the neighboring somatosensory cortex, as well as to distributed brain-wide global changes in EEG activity. To assess the dynamics of ongoing activity we examined cortical activity during controlled transitions between anesthesia-induced brain states. We then quantified periodic and aperiodic changes in spectral activity, coherence, and connectivity measures between regions.

Results: Deaf mice showed a clear local decrease in gamma and delta activity in the deaf auditory cortex. Importantly, the neighboring somatosensory cortex was unaffected, indicating a localized effect. At the global EEG level, we found a change of gamma activity in occipital regions; however, activity in frontal areas remained similar in hearing and deaf mice. Further, although coherence between cortical areas changed across brain states, there were no consistent differences in coherence between hearing and deaf mice. Effects on functional connectivity were weak and heterogeneous.

Conclusions: The results show that congenital deafness leads to consistent local effects in the auditory cortex. In contrast, the effects on global EEG activity appear weaker and are state-

dependent. The results suggest that brain-wide consequences of hearing loss are subtle and may only be detectable under certain conditions. This underscores the importance of examining neural dynamics across different brain states.

SA148. Mitochondrial Localization of Androgen Receptor in the Organ of Corti: Evidence From Super-Resolution Confocal Microscopy

Yue Li¹, Mengxiao Ye¹, Nasibeh Yousefzadeh¹, Bohua Hu*¹

¹*University of Texas at Dallas*

Background: Sex is a biological factor that influences inner ear homeostasis and disease susceptibility. To investigate the molecular basis of sex differences, we previously examined cochlear gene expression and identified a group of sex-biased genes in the mouse cochlea. Functional analysis revealed that male-biased genes are associated with mitochondrial energy production. Because male hormones are major regulators of male traits, we hypothesized that they contribute to the regulation of male-biased mitochondrial function genes. The androgen receptor (AR), the primary mediator of male hormone action, has been detected in the cochlea. This study was designed to characterize the subcellular distribution of AR in the cochlea, with particular attention to its localization in mitochondria. In addition, we used bioinformatic tools to determine which male-biased mitochondrial function genes have been previously linked to AR.

Methods: Young male and female CBA/CaJ and C57BL/6J mice were used in this study. To examine the subcellular distribution of AR protein, cochleae were dissected to isolate the sensory epithelium. The tissues were processed for immunohistology to assess AR expression in the organ of Corti using confocal microscopy. Colocalization of AR expression with mitochondria, identified by the mitochondrial marker protein Tomm20, was determined using super-resolution microscopy. The acquired images were analyzed using the Imaris image-processing software. To investigate a potential link between AR and male-biased mitochondrial function genes, the web-based transcription factor database TFlink was used to retrieve known AR-responsive genes. This gene list was compared with male-biased genes to identify overlaps, which were then analyzed for functional associations using the Database for Annotation, Visualization, and Integrated Discovery (DAVID).

Results: In the organ of Corti, AR expression was detected primarily in Deiters' cells, with the strongest signal in the superior portion of the cell body near the Deiters' cell cup. Weak immunostaining was also observed in other supporting cell types, including pillar cells and Hensen's cells. The staining displayed a tonotopic gradient, weaker in the apical turn and stronger in the middle and basal turns. AR immunoreactivity was confined to the cytoplasm, showing a granular distribution, while nuclei lacked detectable staining. To determine its subcellular localization, tissues were double-stained with the mitochondrial marker protein Tomm20. Super-resolution microscopy confirmed that AR expression was localized to mitochondria. Bioinformatic analysis revealed that many male-biased mitochondrial function genes are AR-responsive, suggesting that AR may contribute to the male-biased expression of genes associated with mitochondrial energy production.

Conclusions: The study shows that AR is present in the mitochondria of cochlear supporting cells and that many male-biased mitochondrial function genes are AR-responsive. These results suggest that AR may contribute to sex differences in mitochondrial gene activity and energy production in the cochlea.

SA149. Regulation of Mitochondrial Genes by Female Hormones in the Mouse Organ of Corti

Bohua Hu^{*1}, Mengxiao Ye¹, Nasibeh Yousefzadeh¹, Yue Li¹

¹*University of Texas at Dallas*

Background: Mitochondria are energy-producing organelles essential for ATP generation, redox balance, and cell signaling. Our previous studies identified sex differences in the expression of mitochondrial function-related genes between males and females, suggesting that sex hormones may influence mitochondrial gene expression. This study examined how female hormones regulate mitochondrial DNA (mtDNA) copy number in the female cochlea across the estrous cycle. Because hair cells and adjacent supporting cells in the organ of Corti are rich in mitochondria, we also assessed the expression of mitochondrial function-associated genes in this tissue across the estrous cycle.

Methods: Young CBA/CaJ mice were used. Female mice were divided into two groups, proestrus or diestrus, based on the assessment of vaginal cytology. Mice were sacrificed, and the cochleae were collected at these two phases. Whole-cochlea tissues containing the lateral wall, sensory epithelium, and osseous spiral lamina were used to assess mtDNA copy number. In addition, we isolated the organ of Corti tissue enriched for sensory cells and nearby supporting cells using our unique microdissection technique. Total RNA was extracted to quantify mRNA levels of three mitochondrial genes (ND1, ATP8, CYTB) involved in mitochondrial energy production.

Results: Relative mtDNA copy number was determined by calculating the ratio of mtDNA to nuclear DNA and comparing the values between the proestrus and diestrus stages of the estrous cycle. mtDNA copy number was significantly higher in proestrus than in diestrus (unpaired Student's t-test, $p = 0.0142$), suggesting increased mitochondrial abundance and biogenesis. For gene expression analysis, three mitochondrial genes that exhibited sex-biased expression in our previous study were selected. ND1 encodes a subunit of Complex I, ATP8 encodes a subunit of ATP synthase (Complex V), and CYTB encodes a component of Complex III. Slc26a5 (a sensory-cell marker) was used as the reference gene to normalize the expression levels of ND1, ATP8, and CYTB. The analysis revealed that all three genes showed higher expression in proestrus than in diestrus (ND1: 4.86 ± 2.29 fold, $p = 0.0023$; ATP8: 4.97 ± 2.39 fold, $p = 0.0024$; CYTB: 4.75 ± 2.42 fold, $p = 0.0024$). This expression enhancement during proestrus is consistent with the increased mitochondrial DNA copy number observed in this phase of the estrous cycle.

Conclusions: The combined increase in mtDNA copy number and elevated expression of ND1, ATP8, and CYTB during proestrus suggests a phase-specific enhancement of mitochondrial function across the estrous cycle. Such hormone-linked bioenergetic variation may contribute to cycle-related differences in cochlear physiology and vulnerability to stressors.

SA150. Assessment of the Structural and Molecular Integrity of Human Organ Donor Inner Ear Specimens

Zahra Sayyid^{*1}, Hakim Hiel¹, Yassine Balhi², Mohamed Lehar¹, George Liu², Julie Winston², Bryan K. Ward¹, Adam Kaufman³, Amanda Lauer¹

¹*Johns Hopkins University School of Medicine*, ²*Johns Hopkins University*, ³*University of Maryland Baltimore*

Background: Studies of the human inner ear are limited by the difficulty of obtaining high-quality tissue specimens for cellular-level analysis. Traditional post-mortem processing of temporal bones requires delayed time to fixation and prolonged decalcification, which can compromise the molecular integrity of tissue. Developing methods to rapidly harvest inner ear organs from human organ donors while maintaining their structural and molecular fidelity would enable advanced analyses that could provide critical insights into the pathophysiology of hearing and balance disorders as well as the molecular architecture of the normal inner ear.

Methods: Using a novel technique for harvesting human temporal bones from organ donors, inner ear organs were fixed in 10% formalin and dissected using a surgical drill and microsurgical instruments. A brief 24-hour decalcification in 5% EDTA was performed to remove residual bone and otoconia. To assess the structural integrity and expression of proteins commonly used in non-human models, whole mount cochlear and vestibular end-organs were incubated overnight with primary antibodies, followed by incubation with Alexa fluorophore-conjugated secondary antibodies. Secondary antibody solutions were supplemented with the nuclear dye DAPI and Alexa 405 fluorophore-conjugated phalloidin. After several washes, specimens were mounted for confocal microscopy imaging and analysis.

Results: All vestibular end-organs (utricle, saccule, and three cristae) as well as the cochlea were successfully harvested structurally intact. Immunostaining demonstrated preservation of hair cells with stereocilia bundles, supporting cells, spiral ganglion neurons, and afferent and efferent innervation. Confocal imaging confirmed cellular morphology and marker expression comparable to that observed in established animal models.

Conclusions: Harvesting inner ear organs from organ donors within ~1-2 hours postmortem allows structural and molecular preservation of the sensory tissues in their entirety with rapid fixation and a considerably shortened decalcification period. Maintaining the molecular integrity of these specimens is crucial, thus enabling future multi-omic analyses aimed at further characterizing both normal and diseased human inner ear structures.

SA151. Advancing Imaging Approaches for 3D Characterization of Inner Ear Cell Types Across Development

Erica Huey¹, John Lee^{*1}, Sarah Cancelarich¹, Leigh Spencer Noakes¹, Alexandra Kaufman¹, Marilena Prada¹, Johnathon Walls¹, Irina Marcovich¹

¹*Regeneron Pharmaceuticals*

Background: The inner ear is a complex and specialized structure essential for both auditory and vestibular capabilities. It is enclosed inside a very hard bone, making it difficult to access with imaging techniques that are non-invasive or preserve its 3-dimensional structure. Over postnatal development, the mouse inner ear undergoes significant structural and cellular changes that are crucial for its functional maturation. We employed two imaging techniques, magnetic resonance imaging (MRI) paired with micro-computed tomography (uCT), and whole tissue clearing to analyze the structural and cellular morphology of the developing mouse inner ear.

Methods: In vivo mouse skulls from animals ages p1 to adulthood were imaged using MRI followed by uCT. MRI provided visualization of soft tissue, while uCT enabled visualization of bony structures. For whole tissue clearing, temporal bones were first immunostained for markers of various cell types, including hair cells, endothelial cells, and spiral ganglion neurons, then cleared. Samples were imaged using lightsheet microscopy, generating 3D

reconstructions used for quantitative and morphological analysis across developmental stages.

Results: MRI and uCT imaging enabled volumetric quantification of inner ear structures, including the cochlea, vestibular organs, and endolymphatic sac. These volumetric measurements revealed developmental changes to size and morphology of structures over time. Similarly, antibody stained and cleared temporal bones enabled quantification of different cell types and morphologies at different age points within the whole bony labyrinth structure.

Conclusions: This imaging toolkit will be critical for studying the postnatal development of the inner ear. When applied to models of hearing loss, these tools will be useful for revealing developmental emergence of morphological abnormalities, as well as evaluating the efficacy of potential therapeutic interventions.

SA152. Including Pressure Focusing in Time-Domain Transmission-Line Cochlear Models

Alessandro Altoe^{*1}, Christopher Shera¹

¹*University of Southern California*

Background: One-dimensional transmission-line (TL) models are the simplest cochlear models that include an explicit description of the traveling wave. TL models are computationally light, making them suitable for time-domain nonlinear simulations of cochlear mechanical responses. Compared with simpler, faster filter-bank models, TL models can reproduce phenomena that arise from wave propagation—such as otoacoustic emissions and longitudinal coupling of cochlear filters. In recent years they have been employed in practical applications, for example to train AI models that improve sound-processing strategies in hearing aids.

However, TL models struggle to replicate several cochlear nonlinear phenomena, such as the full extent of the nonlinear dynamic range and “high-side” suppression. These shortcomings stem from ignoring the important hydrodynamic pressure-focusing effect, which boosts basilar-membrane (BM) vibration near the characteristic frequency (CF) and naturally emerges in 2-D and 3-D models of cochlear mechanics.

Methods: The pressure-focusing effect in 2-D and 3-D models can be quantified as the ratio between the pressure that actually drives the BM and the average pressure in the scala; this ratio (α) is a function of wavelength and cochlear dimensions. TL models assume that the average and driving pressures are identical and currently compensate for the missing pressure-focusing by making the BM oscillators unrealistically sharply tuned.

By theoretically analysing the behaviour of 2-D and 3-D models, we derived an approximation that expresses the pressure-focusing factor as a rational function of wavelength, whose parameters depend on cochlear geometry. Mathematically this is equivalent to a spatial filter that converts average pressure into driving pressure. The spatial filter can be incorporated into a time-domain TL model, yielding a digital analogue of pressure focusing.

Results: Theoretical results based on WKB solutions of TL and 3-D models suggest that our “pressure-focusing” trick markedly improves TL-model performance—e.g., by expanding the nonlinear dynamic range—so that TL models can operate in all practical respects much like full 3-D models. We implemented the strategy in a state-space solver for a TL model,

demonstrating that it can be added computationally efficiently to a generic cochlear-mechanics model. So far we have tested the time-domain implementation in a passive, linear model.

Conclusions: Our work shows that wavelength- and dimension-dependent pressure focusing, inherent to the 3-D cochlea, can be incorporated into 1-D TL models. This inclusion is expected to substantially improve the performance and quality of TL models. Preliminary results indicate that adding the pressure-focusing term is straightforward in time-domain simulations, especially when using a state-space formalism.

SA153. Tonic Outer Hair Cell Motility in Mice With Little Other Evidence of Active Cochlear Mechanics

James Dewey*¹

¹*University of Southern California*

Background: In response to sound, cochlear outer hair cells (OHCs) undergo both tonic and phasic length changes. These length changes presumably reflect the OHCs' electromotile response to tonic and phasic changes in membrane potential that are driven by the mechanotransduction process. Recently, tonic length changes have been observed in mice with stereociliary defects that lead to varying amounts of phasic OHC activity and the near-total loss of cochlear amplification. These mice include salsa mice, which progressively lose the stereociliary tip links, and Triobp(Δ ex8/ Δ ex8) mice, in which the stereocilia lack rootlets and are prone to damage and degeneration. Though the tonic responses in these mice remain of unclear origin, they could be attributed to the presence of residual mechanotransduction currents that are small but highly asymmetric. If so, the tonic responses should depend on the overall integrity and mechanotransduction capability of the stereociliary bundle. This was addressed here by examining tonic OHC motility in salsa/Triobp(Δ ex8/ Δ ex8) double-homozygous mice, in which stereocilia function is likely to be more impaired than in either of the individual strains.

Methods: Optical coherence tomography was used to image and measure sound-evoked displacements from the cochlear apex in 3- to 4-week-old salsa/Triobp(Δ ex8/ Δ ex8) mice. Mice were first deeply anesthetized, placed on a heating pad, and fixed to a head holder. The left middle ear space was then surgically accessed and a probe used to deliver sound stimuli was sealed over the resected ear canal.

Results: Tone-evoked displacements of the basilar membrane, OHC region, and tectorial membrane exhibited little to no evidence of active amplification or phasic OHC motility in salsa/Triobp(Δ ex8/ Δ ex8) mice. Distortion-product otoacoustic emissions were also essentially absent. Nevertheless, tonic displacements consistent with OHC contractions were elicited in roughly one-third of the mice tested. While the fraction of mice with detectable tonic OHC motility was lower than what was previously found for salsa and Triobp(Δ ex8/ Δ ex8) mice at similar ages, the tonic displacements that were observed in salsa/Triobp(Δ ex8/ Δ ex8) mice could be as large as those recorded in the individual strains. Endolymphatic hydrops was seen in several mice though did not appear to be correlated with the presence or absence of tonic responses.

Conclusions: The lower prevalence of tonic OHC responses in salsa/Triobp(Δ ex8/ Δ ex8) double-homozygous mice compared to in salsa and Triobp(Δ ex8/ Δ ex8) mice suggests that the responses likely depend on stereociliary integrity and residual mechanotransduction currents. Nevertheless, the observation of large tonic responses in mice with no other

evidence of active, nonlinear cochlear mechanics further highlights how tonic and phasic OHC motility can appear dissociated in certain cases of hearing impairment. The mechanisms that drive and shape the tonic responses in such cases remain to be fully determined.

Supported by NIH/NIDCD R01 DC021006.

SA154. Phase or Fade: The Organ of Corti's Internal Phase-Gain Correlation

Francesco Gianoli*¹, Rodrigo Alonso¹, Brian Fabella¹, A. Jim Hudspeth²

¹*The Rockefeller University*, ²*HHMI/The Rockefeller University*

Background: A playground swing rises only when the push arrives in phase with its motion; a mistimed push slows it. The cochlea is likewise a feedback device whose effectiveness hinges on relative timing among elements of the organ of Corti (OoC)—notably the basilar membrane (BM), reticular lamina (RL), and tectorial membrane (TM). In the intact ear, however, a traveling wave sweeps along the partition, accumulating phase and redistributing amplitude. Motion at any single place therefore blends local micromechanics with global propagation, obscuring the lead-lag relations that govern whether the system adds or removes energy. We therefore set out to examine internal phase under conditions that emphasize the local behavior of the OoC.

Methods: We studied stabilized ex vivo gerbil cochlear segments from the middle turn. Each segment was mounted in a sealed two-compartment chamber that preserved the native ionic separation, maintained physiological temperature, and allowed us to impose and monitor a near-physiological endocochlear potential (EP). Acoustic stimuli were delivered to the preparation while we made phase-resolved optical measurements of motion across distinct OoC substructures (e.g., BM, RL, TM). The nature of the preparation ensured the absence of traveling-wave contributions in our recordings.

Results: With the EP present, the organ of Corti exhibits an organized pattern of internal phase relations among its substructures near the local best frequency; when the EP is removed, this pattern disappears in the same preparation. This qualitative dependence on EP is consistent with in-vivo observations that altering the electrochemical drive reorganizes micromechanics.

Conclusions: As with a swing, timing makes gain. Under physiological drive, the OoC settles into an organized phase relationship; remove the drive and that organization collapses. By suppressing traveling-wave effects, the segment approach isolates local timing, clarifying how internal phase is arranged when the system is powered.

SA155. Does an Interaction Between the Estrous Cycle and TRPA1 Signaling Influence Cochlear Responses?

Samantha Radomski*¹, Doris Susana Llanes-Coronel¹, M. Clara D.F. Lobo¹, A. Catalina Velez-Ortega¹

¹*University of Kentucky, College of Medicine*

Background: Transient receptor potential ankyrin 1 (TRPA1) channels are highly expressed in nociceptive neurons and in Hensen's cells of the cochlea. Specifically, TRPA1 gating in Hensen's cells results in prolonged calcium responses across the organ of Corti causing long-lasting tissue displacements. We previously showed that TRPA1 activity is as a component of

the noise-induced temporary threshold shift (TTS) (Velez-Ortega et al., 2023, Nat Commun) and that five days after noise exposure, TRPA1-deficient mice experience a significant reduction in the amplitude of cochlear microphonics measured remotely through scalp electrodes (rCM) (Radomski et al., 2025, Hear Res). Interestingly, our unpublished preliminary data indicate that (a) young TRPA-deficient female mice (5-6 weeks old) have larger auditory nerve activity than both TRPA1-deficient males and wild-type littermates and that (b) wild-type female mice exhibit larger variability in the amplitude of rCM recordings after noise exposure than wild-type male mice. Of note, TRPA1 binds promiscuously to a multitude of ligands including estrogen metabolites (Xie et al., 2022, JCI Insight). Here, we hypothesize that cochlear responses are affected by an interplay between estrogen and TRPA1.

Methods: We utilize anesthetized TRPA1-deficient mice (Kwan et al., 2006, Neuron) and wild-type littermates maintained in a C57Bl/6 background. We record auditory brainstem responses (ABR) to click stimuli as well as rCM responses to an 8 kHz tone burst, with alternating 0° and 180° phases interleaved. In female mice, vaginal swabs are collected daily and hearing testing is performed at designated phases of the estrous cycle.

Results: In young mice (3-6 weeks old), ABR wave I amplitude to loud sound stimuli (> 90 dB SPL) is greater in TRPA1-deficient female than wild-type female mice or male mice of either genotype. As the mice age (4-5 months old); however, TRPA1-deficient male mice also exhibit larger ABR wave I amplitudes to high sound stimulation in comparison to wild-type male littermates. Based on these newly-identified sex differences, we reanalyzed our previously-published data linking TRPA1 activity to TTS and indeed found sex differences in the magnitude of some cochlear responses in the TRPA1-deficient mice. Our recordings of ABR and rCM at specific phases of the estrous cycle are currently undergoing.

Conclusions: Our data indicate a potential interplay between biological sex and TRPA1 signaling that might affect cochlear responses before and after noise exposure.

SA156. Cochlear Vibratory Responses to Voiceless Fricatives

Alberto Recio-Spinoso*¹, John Oghalai²

¹*Keck School of Medicine University of Southern California*, ²*Caruso Head and Neck Surgery, Keck School of Medicine, University of Southern California*

Background: Although human speech can contain spectral energy up to 20 kHz, and listeners can perceive sounds up to 15–20 kHz, much research on speech perception has focused on frequencies below 5 kHz. This reflects the longstanding assumption that high-frequency energy (HFE, > 5 kHz) is unnecessary for intelligibility, based on early views that speech-relevant frequencies end near 4 kHz. Recent evidence, however, indicates that HFE—particularly in fricatives—can enhance clarity, localization, and robustness in noise. The mechanical and neural encoding of these components in the inner ear remains poorly understood. Addressing this gap is important both scientifically and for improving hearing aids. We therefore measured cochlear vibratory responses to fricative consonants in the mouse.

Methods: Vibratory responses were recorded in vivo from intact cochleae of mice (P28-P84) using optical coherence tomography. Measurements were obtained from basilar membrane (BM) sites with characteristic frequencies near 8–10 kHz. Acoustic stimulation included tones across frequency and intensity ranges, as well as two words (“say” and “cease”) spoken by a female native speaker of American English, presented at several intensity levels.

Middle-ear motion was also measured in the same animals. BM response amplitudes were derived using Fourier and short-time Fourier (spectrogram) analyses. Waveform envelopes were estimated via the analytic signal representation.

Results: Nonlinear cochlear filtering of the fricative /s/ was evident from level-dependent spectral changes in BM responses. Both the stimuli and BM responses to /s/ contained spectral energy exclusively above ~4 kHz. While the speech stimuli extended to 15–20 kHz, BM responses were limited to ~10 kHz for softer levels and ~6–7 kHz for the loudest levels, reflecting cochlear filtering nonlinearities. Despite this filtering, BM vibratory responses remained intelligible when resynthesized as sound, regardless of stimulus level. Moreover, the envelopes of BM responses to /s/ closely matched stimulus envelopes, even at the highest intensities.

Conclusions: We present the first direct measurements of cochlear mechanical vibrations evoked by speech sounds. Our findings demonstrate that fricatives with HFE drive nonlinear but intelligible BM responses in the mouse cochlea, with envelopes preserved across levels. These results highlight how the cochlea encodes speech components above 5 kHz, providing new insight into the peripheral basis of speech perception.

SA157. Phase-Sensitive Optical Coherence Elastography for Characterizing Cochlear Micromechanics With Multiple Excitation Methods

Jonathan Oliveira Luiz^{*1}, Yoshiaki Inuzuka², John Rosowski³, Cosme Furlong⁴, Jeffrey Cheng³

¹*Massachusetts Eye and Ear, Center for Holographic Studies and Laser micro-mechaTronics*, ²*Massachusetts Eye and Ear*, ³*Mass Eye and Ear / Harvard Medical School*, ⁴*Worcester Polytechnic Institute*

Background: Optical coherence tomographic (OCT) vibrometry has been successfully applied for measuring sound-induced nanoscale displacements of inner-ear structures, providing important insights into cochlear dynamics. However, it is limited to measure vibrational responses. Phase-sensitive Optical Coherence Elastography (OCE) extends these capabilities by using OCT phase information to measure displacement fields and their spatial and temporal gradients, such as strain and strain rate. Relating these gradients to applied loads or wave-propagation behavior enables estimation of local mechanical properties. This allows non-invasive, non-contact characterization of both surface and sub-surface mechanical behavior of intracochlear structures, advancing our understanding of the cochlear mechanics and supporting improved biomechanical models of hearing.

Methods: We adapted a commercial spectral-domain high-speed OCT system (Thorlabs Telesto, 1300 nm center wavelength, 146 kHz A-scan rate) for elastography and developed custom software for external triggering, acquisition control, and phase-resolved displacement analysis. The methodology for motion and mechanical property measurements was validated in phantom samples by comparison with independent techniques, including Laser Doppler Vibrometry (LDV) and nanoindentation. Experiments on cadaveric human cochleae were conducted non-invasively through the round window membrane (RWM), providing access to internal cochlear structures without disturbing the partition. Excitation methods included acoustic clicks, tones, and point-source pulsed laser stimulation. Pressure sensors positioned near the RWM characterized distributed acoustic loads applied to the cochlea, while laser-induced localized loading of cochlear tissue was calibrated photoacoustically. Nanometer-

scale displacements were extracted from OCT phase signals. The acquisition framework employed phase-locked detection with repeated M-scans at individual points, which were reconstructed as time-resolved B-scans to capture spatiotemporal motion patterns. These data were further analyzed to estimate localized mechanical properties. Computational approaches, including finite element modeling and localized surface and sub-surface wave estimation, were evaluated within this framework.

Results: The adapted OCE system detects nanometer-scale cochlear motions with high fidelity across multiple excitation methods. The accuracy of these motion measurements has been validated against LDV on artificial samples. Elastography results in phantom materials are being compared with independent nanoindenter measurements, and measurements are being extended to cochlear samples. Once completed, elastograms are expected to reveal spatial variations within the cochlear partition that correlate with anatomical structures, supporting the feasibility of assessing cochlear tissue mechanical properties such as elasticity, stiffness, and damping.

Conclusions: Phase-sensitive OCE, with phase-locked detection and multi-modal excitation, extends beyond vibrometry by enabling direct, non-invasive, and non-contact estimation of cochlear micromechanical properties at multiple sites across the cochlear partition. The ongoing work demonstrates the feasibility of combining high-speed OCT, custom elastography software, frequency-domain analyses, and computational modeling to characterize cochlear micromechanics. Continued development is expected to further establish OCE as a reliable tool for the hearing sciences.

SA158. Full-Field Evaluation of Middle Ear Nonlinearities Across Moderate and High-Intensity Sound Levels by High-Speed 3D-Digital Image Correlation and Laser Doppler Vibrometry

Jonathan Oliveira Luiz^{*1}, Yoshiaki Inuzuka², John Rosowski³, Cosme Furlong⁴, Jeffrey Cheng³

¹*Massachusetts Eye and Ear, Center for Holographic Studies and Laser micro-mechaTronics*, ²*Massachusetts Eye and Ear*, ³*Mass Eye and Ear / Harvard Medical School*, ⁴*Worcester Polytechnic Institute*

Background: At everyday sound levels, the middle ear responds in a proportional way: doubling input pressure doubles motion of the tympanic membrane (TM) and ossicles. At intense levels, nonlinearities emerge and this proportionality no longer holds, altering sound transmission to the inner ear. Such behavior may result from large TM deformations (geometric nonlinearity), tissue effects (material nonlinearity), or changes in ossicular coupling. Understanding when nonlinearities appear and what mechanisms drive them is important for biomechanical modeling, hearing protection, surgical graft development, and defining injury thresholds relevant to blast trauma.

Methods: Previously, we validated our methodology in a single cadaveric temporal bone (TB). Since then, we optimized the technique with improved pressure calibration and a dedicated processing pipeline. Here, three TBs with intact middle ears were tested under progressively increasing excitations, from loudspeaker-generated acoustic clicks (50–2000 Pa, ~128–160 dB SPL) to shock-tube overpressures (500 Pa–20 kPa, ~148–180 dB SPL). The external ear canal was removed to expose the TM for high-speed three-dimensional Digital Image Correlation (3D-DIC, 50,000 fps). Input pressures were recorded with calibrated broadband sensors, while TM displacements were measured by high-speed 3D-DIC. Laser

Doppler Vibrometry (LDV) measured umbo and stapes motions for validation and ossicular transmission analysis. TM surface preparations were tested to optimize optical contrast while minimizing alteration. Custom software enabled synchronization of pressure and displacement, filtering, noise-floor estimation, and computation of transfer functions (TFs) and impulse responses (IRs). Full-field TM motion combined with pressure data enabled energy coupling analyses, where the ratio of TM volume displacement to cumulative pressure energy flux was calculated as an additional metric of nonlinear responses.

Results: Reliable TFs and IRs were reconstructed across all TBs under multiple excitations. At low-to-moderate levels, responses were linear, consistent across samples, and in agreement with published data. At higher pressures, evidence of nonlinear behavior appeared. TFs showed compressive growth, with displacements increasing less than proportionally with pressure, and broadened frequency peaks, suggesting greater damping. IRs exhibited stable onset timing but demonstrated amplitude compression and faster decay at higher intensities. Umbo and stapes analysis indicated changes in transmission with increasing load, suggesting ossicular coupling contributes to the nonlinear behavior. Full-field analyses further showed the ratio of TM volume displacement to cumulative pressure energy flux decreased with increasing pressure, supporting nonlinear processes.

Conclusions: This study showed the middle ear nonlinearity at high intensities can be described by compressive growth, broadened frequency peaks, changes in decay, and altered ossicular coupling, which affect middle ear sound transmission. Future work will refine experimental protocols and use the datasets to develop constitutive models of middle ear tissues, which will be implemented and validated in a nonlinear finite element framework to better characterize mechanisms and thresholds for nonlinear behavior.

SA159. Effects of Soft Tissue Thickness on Mastoid Impedance and Skull Bone Velocity Evoked by Bone Conduction at 0.1–25 kHz

Yoshiaki Inuzuka^{*1}, Jeffrey Cheng², Vanessa Zhang³, John Rosowski², Aaron Remenschneider²

¹National Defense Medical College/Massachusetts Eye and Ear, ²Mass Eye and Ear / Harvard Medical School, ³University of Massachusetts Medical School

Background: Bone conduction (BC) testing is a standard audiometric procedure used to estimate cochlear sensitivity by presenting vibration to the head. The skin, muscle, and soft tissue (SMST) between the BC transducer and the mastoid can alter the force transmitted to bone and thereby influence BC hearing sensitivity. Previous work suggests a frequency-dependent elevation of BC thresholds and attenuation of petrous bone vibration with increasing SMST thickness from 4 to 8 kHz. However, effects at extended high frequencies (EHF; 8–20 kHz) remain unclear. We investigated how SMST thickness impacts the force delivered to the temporal bone by measuring mastoid mechanical impedance and BC-evoked temporal bone velocity.

Methods: We used fresh-frozen cadaveric heads without a history of middle-ear disease. For impedance measurements, heads were placed on a scissor jack and a digital scale on a vibration-isolated table with a horizontal mastoid surface. An impedance head (Brüel and Kjær (BK) 8001) coupled to a mini shaker (BK 4810) was contacted on the mastoid with 5 N static force. Mastoid impedance was calculated from force and acceleration recordings during Chirp stimulation by BK 8001 (0.1–25 kHz), with subtraction of the self-impedance. To

approximate clinically observed SMST thickness (2–20 mm), we modified local SMST by serially adding porcine skin layers (2 mm per layer; 1, 2, 4, 6, or 8 layers).

We also measured the BC-induced velocity of the petrous bone and the bony tympanic membrane annulus (TMA). A BC transducer (KLH96) with a headband providing 5 N static force was positioned over the mastoid at the same site as the impedance testing. After elevating the tympanic membrane, a laser Doppler vibrometer (Polytec) was focused transcanally on the promontory and posterosuperior TMA. Petrous and TMA velocities evoked by BC stimulation (Chirp and tones, 1–20 kHz) were measured for each SMST condition and also via direct bone contact following native SMST removal.

Results: With increasing SMST thickness, mastoid impedance at ≤ 3 kHz decreased, consistent with reduced stiffness. In contrast, impedance changes were small at EHF, despite the added mass. TMA velocity was comparable to promontory velocity across frequencies, supporting the TMA as a practical in vivo proxy site for assessing cochlear vibration with BC stimulation. Added skin layers significantly reduced cochlear (promontory) velocity by as much as ~ 20 dB at ≥ 10 kHz. Direct bone contact boosted cochlear vibration across the entire frequency range tested.

Conclusions: Increased SMST significantly reduced mastoid impedance at lower frequencies and depressed cochlear bone velocity driven by a BC transducer at EHF. These cadaveric data motivate human-subject studies that relate mastoid SMST to EHF BC thresholds using transcanal TMA velocity as a proxy for cochlear vibration in vivo.

SA160. Nonlinear Growth of Middle Ear Transfer Function After Ossicular Chain Reconstruction Using Partial Ossicular Replacement Prosthesis and Stapes Piston

Yoshiaki Inuzuka^{*1}, Aaron Remenschneider², John Rosowski², Jeffrey Cheng²

¹*National Defense Medical College/Massachusetts Eye and Ear*, ²*Mass Eye and Ear/Harvard Medical School*

Background: At moderate sound pressure levels (SPL), the ossicular chain (OC) operates as a linear system to transmit sound energy to the cochlea. At high levels, this transmission becomes nonlinear through active muscle reflexes and passive nonlinear mechanics, which mainly leads to compressive growth of stapes velocity, protecting the cochlea from high-intensity sound. Previous studies of human temporal bones with intact OCs demonstrated the onset of passive nonlinear growth of the middle ear transfer function (METF) at frequency-dependent sound pressure thresholds. In clinical settings, damaged OCs can be reconstructed by ossiculoplasty using prostheses to reestablish ossicular continuity. However, the growth of the METF after ossicular chain reconstruction (OCR) has not been well studied, and it remains unclear whether the nonlinear growth of METF persists in reconstructed OCs over a broad frequency range.

Methods: Fresh-frozen human temporal bones without middle-ear disease were prepared in the standard procedure by opening the facial recess and resecting the stapedial tendon for laser Doppler vibrometer (LDV) measurements on the stapes posterior crus. A probe microphone was inserted through a small hole opened in the anterior canal wall to record the ear canal sound pressure (PEC). A second LDV was focused on the umbo through that hole sealed with a clear plastic window. A short silicone tube connecting to a loudspeaker was then sealed to the ear canal opening to deliver broadband stimuli (tones, 0.2–20 kHz). Two types of prostheses were used for OCR. In full-titanium Partial Ossicular Replacement

Prosthesis (PORP) reconstruction, the incus was removed, the prosthesis head plate was coupled to the tympanic membrane with cartilage grafts, and the clip was coupled to the stapes head. In fluoroplastic stapes piston reconstruction, the entire stapes was removed, the piston was rested on perichondrium covering the oval window, and the wire was crimped to the distal incus long process. The velocity of the umbo and stapes (or piston) was simultaneously measured by LDVs and normalized by PEC to derive their METFs at different PEC levels.

Results: PEC increased linearly in general with driving voltages, reaching as high as 140 dB SPL at > 1 kHz. However, nonlinear PEC growth was observed at the highest stimulus voltage, which was excluded for further analysis of nonlinear growth of METF. Umbo and stapes/piston velocity METFs in both PORP and piston reconstructions showed small-scale nonlinear growth at some high stimulus levels within limited frequency ranges, which differs from nonlinear growth of the intact OC.

Conclusions: Though altered from normal, passive nonlinear METF persists after OCR. Our data allow us to separate the nonlinear effects of the annular ligament (removed by stapes reconstruction) and the incudomalleolar joint (removed by PORP reconstruction).

SA161. The Sensitivity of Nonlinear Ogden Parameters in the Middle-Ear Response to High-Intensity Sounds

Hossein Mohammadi^{*1}, Aaron Remenschneider², Lukas Anschuetz³, Sunil Puria¹, Jeffrey Cheng¹

¹Harvard Medical School, Mass. Eye and Ear Infirmary, ²Harvard Medical School, Mass. Eye and Ear Infirmary, Boston Children's Hospital, ³CHUV Lausanne University Hospital, The Sense Innovation and Research Center

Background: For high-level sounds (i.e., > 130 dB SPL), the middle-ear output is nonlinear, and yet the source of such nonlinearities has not been characterized. Recent finite-element (FE) models capture this nonlinear behavior by assigning hyperelastic material properties either to all middle-ear soft tissues or selectively just the tympanic membrane (TM) (Tubelli et al., ARO2025; Mohammadi et al., 2024). These studies have yet to explore the effect of variations in nonlinear mechanical parameters on the FE model output. This study explores how nonlinear parameters in an FE model affect output, which can help us begin to understand variability across ears.

Methods: A previously developed nonlinear time-domain FE model of the human middle ear consisting of ossicles, TM, and other soft tissues was used (Tubelli et al., ARO2025). All soft tissues were modeled as first-order Ogden hyperelastic materials with two parameters; i.e., shear modulus μ and exponent α (Lohr et al., 2022), and a sensitivity analysis was carried out on these parameters. The TM and other structures with the highest level of strains were identified as the structures of interest (SOIs) for incorporating variability in nonlinear parameters. The acoustic elements of the ear canal were excluded for simplicity, and surface pressure excitations at three pure tone frequencies (500, 4000, and 8000 Hz) and three different levels (120, 150, and 170 dB SPL) were applied directly to the TM surface. For this study, variations of μ and α were investigated on a simplified model and extended to the middle-ear model.

Results: The highest level of strain was observed on the stapedial annular ligament (SAL), which was chosen as one of the SOIs along with the TM. A preliminary sensitivity analysis on the simplified model ($0.01 \text{ MPa} \leq \mu \leq 1.0 \text{ MPa}$ and $5 \leq \alpha \leq 30$) suggests that

displacements generally decreased with increasing both shear modulus μ and exponent α , but μ had a more pronounced effect than α . At the low frequency, displacements decreased with α almost uniformly across all μ values, whereas at higher frequencies, they became more sensitive to α at larger μ values ($\mu \geq 0.1$ MPa). Furthermore, displacements were generally more sensitive to changes in α within its lower range ($\alpha \leq 15$), and more sensitive to changes in μ within its higher range ($\mu \geq 0.1$ MPa).

Conclusions: We have homed in on the first-order Ogden model to investigate the effects of parameters in middle-ear nonlinearity. Based on the results from the simplified model, we concluded that stiffness sensitivity to Ogden parameters is frequency-dependent, which guides us to investigate parameter variations of the TM and SAL on the nonlinear responses of the middle ear.

SA162. Autonomic Responses to Transcutaneous Auricular Vagus Nerve Stimulation (taVNS): A Pilot Study

Bernat Miro^{*1}, Ramanamurthy Mylavarapu², Patrick Ganzer², Vivek Kanumuri³

¹University of Miami, ²University of Miami and Miami Project to Cure Paralysis, ³Miller School of Medicine, University of Miami

Background: Invasive cervical vagus nerve stimulation is an established therapy for epilepsy and depression but carries risks and costs associated with implanted medical devices. Transcutaneous auricular vagus nerve stimulation (taVNS) offers a non-invasive alternative by targeting the auricular branch of the vagus nerve. While promising, the mechanism mediating taVNS's effects remain poorly defined. This pilot study seeks to explore the physiological effects of taVNS across both common autonomic measures including heart rate (HR), mean arterial pressure (MAP), heart rate variability (HRV) with other promising autonomic measures such as photoplethysmography (PPG), and galvanic skin response (GSR).

Methods: After obtaining informed consent (IRB#20190769), six healthy participants underwent taVNS (Spark Biomedical, Spark Sparrow Ascent) at the left cymba (20 Hz, 500 μ s pulse width) titrated to their perceptual threshold. The protocol consisted of a 4-minute baseline recording, 16-minutes of stimulation (eight 1min on/off duty cycles), and a 10-minute post-stimulation observation period. Continuous data for ECG, bilateral finger PPG, and bilateral palm GSR was collected to analyze HRV, pulsatile component of the PPG, and eccrine sweat response from GSR respectively. Tukey-Kramer post-hoc analysis of repeated-measures ANOVA (rANOVA) was used for HR and MAP for each epoch (baseline vs. stimulation vs. observation). PPG and GSR data were z-scored with respect to a 10 second pre-stimulation baseline for each duty cycle to account for baseline drift in signal. These standardized traces were averaged across subjects and cycles for further assessment. Quantitative analysis of GSR slope, PPG area-under-the-curve, and HRV are ongoing to investigate the preliminary qualitative assessment that taVNS decreased skin conductance and peripheral blood flow correlates.

Results: Post-hoc Tukey-Kramer analysis found a statistically significant decrease in HR between all epochs suggestive of a lingering effect of taVNS. Specifically, baseline vs. stimulation comparison revealed a decrease of 1.0 beat per minute ($p = 0.044$) and

stimulation vs. observation epochs revealed a decrease of 1.23 beats per minute ($p = 0.04$). rANOVA analysis found no significant effect for MAP ($p=0.809$). Standardized PPG and GSR traces demonstrated clear, time-locked responses to stimulus onset and termination. GSR exhibited a characteristic decrease during stimulation followed by a sharp increase upon cessation. PPG waveforms showed a decrease in amplitude during stimulation which could correlate with transient vasoconstriction with a subsequent rebound in signal upon offset.

Conclusions: taVNS at the left cymba for eight 1min on/off duty cycles (20 Hz, 500 μ s pulse width) elicits a potential decrease in heart rate without altering blood pressure, suggesting a specific modulation of cardiac control. Concurrently, observed GSR and PPG responses indicate a complex interplay with sympathetic pathways. These preliminary results suggest taVNS under this paradigm triggers a mixed autonomic response profile. Further quantitative analysis will better characterize the sympathetic contribution to these effects.

SA163. Mapping the Ossicular Chain Vibrations With 3D Optical Coherence Tomography

Nathan Goedseels^{*1}, Pieter Lievens², Tristan Putzeys¹, Nicolas Verhaert¹

¹ExpORL, KU Leuven, ²Laboratory of Biomedical Physics (BIMEF), University of Antwerp, Groenenborgerlaan

Background: The vibrations of the ossicular chain in the middle ear in response to acoustic stimuli are not yet fully understood because of several technological constraints. Conventional methods to study these vibrations usually involve Laser-Doppler Vibrometry (LDV), and even though three-dimensional (3D) LDV set-ups exist, this technique remains restricted to vibrational measurements of only the dominant reflector along the beam path. Optical-Coherence Tomography Vibrometry (OCTv), in contrast, allows for volumetric imaging and spatially resolved vibrational measurements at a depth below the tissue surface. Hence, the vibrational information is available at the voxel-level, surface and sub-surface.

Methods: To evaluate the complex 3D vibratory patterns of the ossicular chain, we developed a framework for 3D OCTv measurements in a human temporal bone using a single OCT beam mounted on a 6 degrees of freedom robot arm that allows rotating the OCT beam around a fixed specimen. By combining vibrometric measurements from multiple angles using volume registration methods and vector calculus, all cartesian components of the 3D vibrations of the ossicular chain can be expressed in an anatomically relevant orthogonal coordinate system. As some regions of the ossicular chain remain optically inaccessible despite a maximally exposing surgical preparation, the integral evaluation of the ossicular chain vibrations requires some additional processing steps.

Results: Here we present data of multiple 3D OCTv measurements in one fresh-frozen human temporal bone specimen. Optically inaccessible regions were attributed a value through an interpolation method and finite-element modeling. Sub-surface vibrometric data was corrected for refraction. Ossicular oscillations were induced through an ER3+ insert phone in the external ear canal at stimulus frequencies of 0.5, 1, 3, 6 and 10 kHz and ear-canal pressures were measured with a ER7 probe-mic for reference. The presented data has a depth resolution of 4 μ m and a lateral resolution of 8 μ m. The cartesian components of the 3D vibrations are accurate to approximately -20dB re 1mm/s.

Conclusions: Our 3D OCTv set-up allows untangling the complex vibratory patterns of the ossicular chain. It will pave the way for an integral understanding of how the middle ear transfers acoustic energy in response to different sound frequencies. These insights will prove

valuable for the optimization of middle ear microphones and other future hearing technologies that benefit from or augment middle ear functionality.

SA164. Novel Material-Optimized, Ct-Guided 3D Printing of Tympanic Membrane Prostheses

Joseph Chen^{*1}, Nick Castle², Yingtao Liu², Junfen Liang²

¹*Trinity University*, ²*The University of Oklahoma*

Background: Tympanoplasty—reconstruction of the tympanic membrane (TM) and ossicular chain—is well established, yet hearing restoration remains inconsistent. Patient-specific, 3D-printed prostheses may offer superior anatomical fit and functional outcomes.

Methods: A cadaveric temporal bone was imaged using computed tomography (CT). Based on these scans, a custom TM–ossicle prosthesis was designed and fabricated with 3D printing. Experimental eardrum patches were produced using lab-developed ECC FLEX 00-30 material in varying ratios. TM motion in response to 60–90 dB SPL sound stimuli was assessed with laser Doppler vibrometer (LDV), and mechanical properties of the printed TMs were evaluated with standardized mechanical testing.

Results: At 600 and 1000 Hz under 60–90 dB SPL input, the 3D-printed TM demonstrated superior mechanical performance compared to conventional TM patch materials. The mechanical performance is related to the materials and the approach to connection of the TM with ear canal wall.

Conclusions: CT-based, 3D-printed TM–ossicular prostheses incorporating novel materials can be successfully designed and fabricated. These results establish feasibility and underscore the potential of patient-specific, material-optimized 3D-printed TMs as a future treatment for conductive hearing loss caused by TM perforations or ruptures.

SA165. DX243 Weakens Acoustic Trauma-Induced Cortical Brain Oscillation Changes and Distinct Neurocochlear Impairments

Marlies Knipper^{*1}, Stefan Fink², Csaba Harasztosi², Li Xie³, Stephane Silvente⁴, Pierre Attali⁴, Nicolas Caron⁴, Wibke Singer², Lukas Rüttiger²

¹*University Hospital Tuebingen*, ²*Hearing Research Center, University of Tübingen*, ³*Tongji Hospital, Tongji Medical College, Huazhong University of Science and Technology, Wuhan, P.R. China*, ⁴*Dendrogenix S.A.*

Background: A dramatic shift in societal demographics will lead to rapid growth in the number of older people with hearing deficits. The increasing risk of cognitive decline predicted to be associated with hearing loss has become a key challenge for future societies. Over age accumulating acoustic injury contributes particularly to speech discrimination deficits in background noise, a feature predicted to be linked to the high vulnerability of auditory fibers with low spontaneous discharge rate and high activation thresholds.

Methods: We here investigate a new potential drug, dendrogenin, which is predicted to exhibit otoprotective function and balanced neurite outgrowth. We test the effect of dendrogenin on cortical local field potentials (LFP) and peripheral paradigms after acoustic trauma (AT) in the rat animal model.

Results: In line with previous studies, AT reduced acoustic stimuli-induced local field potentials in the auditory cortex 2 weeks after AT, while neither acoustic stimuli nor AT effected LFP in the prefrontal cortex, visual cortex and hippocampus. 2 weeks after daily injection of DX but also 6 weeks after the last DX injection a dose dependent protective effect of DX could be observed on AT induced decline of LFP spectral power. DX did not affect hearing thresholds after AT but exhibited with the same dose response as shown for its effect on LFP, a protective effect on auditory fiber functions. A significant preservation of IHCs ribbon numbers after AT, less impairment of specifically noise-sensitive auditory fiber processing (tested through Notch-noise) and a positive preserving effect on pre-postsynaptic integrity during multi-click responses with decreasing time intervals, suggest a possible selective effect of DX on the most vulnerable low-SR auditory fiber type.

Conclusions: These findings suggest dendrogenin as a potential neuroprotective drug for the treatment and prevention of age-and noise-induced hearing loss.

SA166. Mitochondrial Transplantation as a Strategy to Reduce Noise-Induced Hearing Loss

Mustafa Nazir Okur^{*1}, Adam Ratajczak¹, Hamid Djalilian¹

¹*University of California Irvine*

Background: Hearing loss is a prevalent and disabling condition with no curative treatment, highlighting the urgent need for new therapeutic strategies. Mitochondrial transplantation, the delivery of exogenous mitochondria into cells, has shown promise in mitigating mitochondria-related disorders. However, despite the central role of mitochondria in auditory function, this approach has not yet been explored for hearing loss.

Methods: Exogenous mitochondria were isolated from auditory cells and transferred into a new set of auditory cells following oxidative stress to evaluate their biological consequences. In vivo, isolated exogenous mitochondria were injected into the cochlea of mice, and their localization and impact on hearing after noise exposure were assessed.

Results: Exogenous mitochondria from HEI-OC1 auditory cells were internalized in a dose-dependent manner without inducing toxicity. They enhanced bioenergetics, protected against oxidative stress, and reduced H₂O₂-induced apoptosis. In vivo, injected mitochondria localized to cochlear sensory cells, were well tolerated, and conferred protection against noise-induced hearing loss.

Conclusions: These findings provide the first evidence supporting the feasibility and therapeutic potential of mitochondrial transplantation in auditory cells. If validated in animal models and ultimately in humans, this strategy holds strong promise as a novel treatment for sensorineural hearing loss.

SA167. Dual Photothermal and Magnetically Assisted Transport of Magnetic Nanoparticle Drug Delivery Vehicles

Daniel Sun¹, Thiraj Mohankumar^{*2}, Donglu Shi²

¹*University of Cincinnati College of Medicine*, ²*University of Cincinnati*

Background: Magnetic nanoparticles (MNPs) can enhance round window membrane (RWM) penetration via magnetically assisted transport for cochlear drug delivery. However, custom synthesized MNPs also have photothermal properties that can play a dual role in

augmenting RWM transport by enhancing diffusivity. We investigate the interaction between particle size, temperature, and magnetic field strength in MNP transport across an acellular, semipermeable membrane.

Methods: Superparamagnetic Fe₃O₄ MNPs were synthesized with core diameters of 6-10nm and 10-15 nm to achieve differential magnetic susceptibility, followed by grafting with PEG3000 to achieve hydrodynamic sizes of ~100 nm and ~140 nm. MNP characterization was performed using transmission electron microscopy, and zeta sizer. Decellularized porcine intestinal submucosal (SIS) membranes were mounted in a dual-chamber diffusion device. The microfluidic device, analogous to a Ussing chamber, was developed specifically to allow both application of a magnetic field gradient and laser-induced photothermal activation of MNPs at the membrane. MNP suspensions in phosphate buffered saline were tested under magnetic field application using a neodymium bar magnet and/or laser irradiation (606–1342 nm) tuned to hold interface temperature ranging between 31–45 °C. MNP concentration across the SIS membrane was measured by assaying iron content as a function of time, magnetic field gradient, temperature, and MNP size, with a view towards extending these investigations into an ex vivo guinea pig round window membrane model.

Results: Completed SIS studies yielded measurable transport across MNP size ranges, with the 100 nm MNPs achieving higher cumulative transport and larger permeability compared to 140nm MNPs. Laser-activated photothermal stimulation elevated the temperature at the SIS membrane interface from ~31 °C to ~42–45 °C, with increased MNP transport versus isothermal controls. Superimposing a magnetic field further enhanced delivery (21%) with transport decreasing as magnet–membrane distance increased, consistent with reduced field gradients; across conditions, photothermal and magnetic inputs were additive without evidence of thermal damage at the tested temperatures.

Conclusions: Magnetic and photothermal activation are dual modes of transport augmentation based on chemical physical properties of MNPs that can enhance RWM penetration. We establish a benchtop system to investigate photothermal activation of MNPs in conjunction with permeability measurements. Findings here demonstrate parameters important in designing MNP systems capable of magnetic and photothermal assisted transport, and in an acellular semipermeable membrane, the relative contribution of each to cumulative transport. These findings will serve as a basis for investigations in preclinical ex vivo RWM models and MNP vehicles with therapeutic payload.

SA168. Proteome Comparison Between Endolymph and Perilymph in Mice

Molly McDevitt¹, Mahesh Nayak¹, Miaomiao Du¹, Kristina Ly¹, Justine Renaud*¹

¹*Creighton University*

Background: The precise regulation of inner ear fluids is essential for auditory function, yet the molecular mechanisms that maintain endolymph/perilymph homeostasis remain poorly understood. Endolymphatic hydrops, an abnormal expansion of the scala media, is a landmark of Ménière's disease. Despite the importance of protein to maintain osmotic pressure, the protein composition of endolymph relative to perilymph has not been systematically compared in healthy and disease states. Characterizing these differences is a critical first step toward understanding how dysregulation of fluid compartments contributes to disease pathology. This study defines and compares the baseline protein content of endolymph and perilymph in wild-type mice as a foundation for future comparisons in a hydrops mouse model.

Methods: Endolymph and perilymph samples were collected from the cochleae of 6 adult wild-type mice using a micropipette. Approximately 1 microgram of protein was reduced and alkylated, followed by trypsin digestion. Each sample was then run on a Thermo Q Exactive mass spectrometer coupled to a Waters M-Class nano-liquid chromatography system. The raw files were searched with Proteome Discoverer. GO term analysis was performed in PANTHER.

Results: 569 proteins out of 735 proteins identified were common to both endolymph and perilymph. Our findings suggest that endolymph and perilymph maintain separate protein environments. Our data highlight differences that may be perturbed in pathological states such as endolymphatic hydrops

Conclusions: Our study provides a direct comparison of protein content between endolymph and perilymph, establishing a baseline for future studies in mutant models of endolymphatic hydrops. Protein homeostasis between endolymph and perilymph is likely disrupted during hydrops formation. Understanding these differences will inform hypotheses about how fluid imbalance leads to altered cochlear function and hearing loss. Future research will extend this work to hydrops models to identify disease-specific proteomic shifts.

SA169. Low-Intensity Ultrasound Stimulation Enhances Fluid-Regulating Channels in the Inner Ear

Pei-Hsuan Lin^{*1}, Yen-Hui Chan², Pei-Hua Lu², Ying-Chang Lu², Jaw-Lin Wang³, Chen-Chi Wu⁴

¹National Taiwan University College of Medicine, ²National Taiwan University Hospital,

³Nation Taiwan University, ⁴National Taiwan University Hospital, National Taiwan University Hospital Hsin-Chu Branch

Background: Maintenance of endolymphatic homeostasis is critical for cochlear function and relies on the coordinated regulation of water and ion channels. Aquaporins (AQPs) have been implicated in inner ear fluid balance and in the pathophysiology of disorders such as Meniere's disease. Low-intensity ultrasound (LIUS) has emerged as a non-invasive tool capable of modulating mechanosensitive pathways in various tissues. Our previous work demonstrated that LIUS augmented glymphatic influx through the TRPV4-AQP4 signaling pathway in astrocytes, thereby promoting cerebrospinal fluid influx into the perivascular spaces and enhancing interstitial substance clearance from brain parenchyma without inducing tissue damage. Based on these findings, we hypothesized that LIUS may similarly regulate fluid homeostasis in the cochlea through modulation of aquaporins and mechanosensitive transient receptor potential (TRP) channels.

Methods: Cochlear explants were prepared from postnatal day 6 C57BL/6 mice and exposed to LIUS stimulation. Cochlear explants were fixed at prespecified post-stimulation time points (0, 30, 60, and 120 mins) after stimulation and processed for immunofluorescence. Expression and subcellular localization of AQP4, AQP5, and TRPV4 were evaluated in different regions of cochlear explants (mainly around the organ of Corti) using confocal microscopy. Signal intensity and distribution were compared with non-stimulated controls.

Results: LIUS stimulation induced distinct changes in the expression and localization of water and mechanosensitive channels. AQP4 expression increased in Hensen's cells, Deiters' cells, and Kölliker's organ compared with controls at 30 minutes after stimulation. AQP5 exhibited rapid redistribution from the cytoplasm to the apical membrane of supporting cells, with signal enhancement observed within 30 minutes after stimulation. In addition, AQP5

translocation to the cytoplasm and basal regions was observed in LIUS-treated explants. On the other hand, TRPV4 expression also increased following LIUS immediately (at 0 min) after stimulation, particularly in Kölliker's organ. Together, these findings suggest that LIUS activates mechanosensitive signaling pathways leading to selective trafficking and upregulation of AQP4, AQP5 and TRPV4 in cochlear explants.

Conclusions: Our data demonstrate that LIUS modulates AQP4, AQP5 and TRPV4 expression in cochlear explants, implicating these proteins in ultrasound-mediated regulation of fluid homeostasis. These results provide mechanistic insight into LIUS-mediated control of inner-ear fluid dynamics and support further study of LIUS as a non-invasive strategy to correct endolymphatic imbalance in hydrops-related disorders.

SA170. Utility of Cochlear Perilymph Biomarkers for Hearing Loss - A Systematic Review

Sita Clark^{*1}, Kujani Wanniarachchi¹, Neil Donnelly², Manohar Bance¹, Nathan Creber³

¹*The University of Cambridge*, ²*Cambridge University Hospitals NHS Foundation Trust*,

³*The University of Sydney*

Background: The live cochlea has long been considered a relatively inaccessible and 'sacred' organ with traditional sampling techniques posing a risk to hearing and balance functions. Researchers' ability to investigate the pathogenesis and treatment of sensorineural hearing loss has subsequently been limited, commonly involving in vitro models, translational animal models, and post-mortem analysis instead. Previous human studies investigating sensorineural hearing loss have also been restricted to using peripheral blood, urine, or cerebrospinal fluid samples to indirectly measure inner ear biomarkers. More recently, the establishment of a novel and safe technique for intraoperative perilymph sampling has enabled the collection of a 'liquid biopsy' of the cochlea while still preserving inner ear function. This crucial development has opened avenues for more accurately characterising the complex cochlear microenvironment and investigating the mechanisms of sensorineural hearing loss more directly. Perilymph sampling also has the potential to provide insight into why postoperative outcomes may vary between cochlear implant users who have otherwise similar preoperative clinical characteristics. The present systematic review therefore aimed to elucidate the gap in the literature regarding the utility of perilymph biomarkers in sensorineural hearing loss diagnosis, treatment, and prognosis.

Methods: A search was conducted using the Medline, Embase, Web of Science, and Scopus databases from inception to April 2024, in keeping with PRISMA-S guidelines. Keywords were divided into two groups according to biomarker type (biomarker; metabolome; proteome; RNA; miRNA; inflammasome) and sensorineural hearing loss pathologies (hearing loss; deafness; Ménière; otosclerosis). Of the 7471 studies initially identified, 15 met the inclusion criteria. A ROBINS-I tool was used to evaluate the risk of bias in each of the included studies.

Results: All 15 studies included were correlational in design, with the majority of studies sampling perilymph in sensorineural hearing loss patients via the round window during cochlear implantation. Due to the functional diversity of perilymph biomarkers identified in this review, biomarkers were grouped into six main categories according to their underlying pathological processes: heat shock proteins (HSPs), immune/inflammatory mediators, microRNAs, neurotrophic proteins, metabolomes, and structural proteins. For each category, key potential biomarkers were identified and analysed for consideration in future studies

utilising perilymph sampling. In particular, HSP-70, HSP-90, complement components, miR-1299, miR-1270, and brain-derived neurotrophic factor regulated proteins may help to direct future studies focused on characterising the biomarker profile in patients with sensorineural hearing loss.

Conclusions: Future targeted studies with larger cohorts and clearer hearing loss aetiologies are required to help further characterise the prevalence and functional role of these perilymph biomarkers. Such studies may help to pave the way towards a more accurate understanding and diagnosis of sensorineural hearing loss pathologies, improved prediction of cochlear implantation prognosis, and targeted therapeutic management.

SA171. Immune Response in the Spiral Ganglion Following Kanamycin-Induced Hair Cell Loss

Adrianna Caro*¹, Steven H. Green¹

¹*University of Iowa*

Background: Spiral ganglion neurons (SGNs) of the cochlea gradually die after neonatal kanamycin-induced hair cell loss in rats, resulting in the death of >80% of all SGNs over the course of ~14 weeks, apparent by postnatal day 39 (P39). We have previously shown that macrophages increase in abundance and activation by P21, well prior to the start of significant SGN death. Concurrent with the apparent onset of SGN death, there is an increase in lymphocytes in the ganglion, including CD4+ helper T cells, CD8+ cytotoxic T cells, and CD161+ NK cells. To determine whether the lymphocyte component of this inflammatory response is causal to SGN death, we evaluated SGN survival after hair cell loss in two immunodeficient rat strains: 1) RNU nude rats lacking T cells and 2) SRG rats lacking T, B, and NK cells.

Methods: Sprague-Dawley (SD), Crl:NIH-Foxn1^{rnu/rnu} (RNU nude, T cell deficient), Crl:NIH-Foxn1^{rnu/+} (heterozygotes, normal T cell population), and Rag2^{em2}hera^{fl2}rgem1^{hera}/HblCrl (SRG, T, B, NK cell-deficient) rats were intraperitoneally injected 1x/day with kanamycin from P8 to P16. Cohorts of deafened and hearing control rats were euthanized at various ages and cochlea were sectioned for immunohistochemistry to label hair cells, neurons, leukocytes, macrophages, T cells, B cells, and NK cells.

Results: We found that SGN survival in RNU nude rats is not significantly different than in RNU+ rats, indicating that T cells are not required for SGN death after hair cell loss. Genetic ablation of T, B, and NK cells in SRG rats does not prevent SGN death after hair cell loss but does moderately improve survival in the basal half of the cochlea relative to kanamycin-treated wildtype conspecific controls. For all strains evaluated, we also found that the mutations do not affect the typical increase in macrophage number in kanamycin treated groups.

Conclusions: We directly assessed the role of T cells in SGN death after deafening using T cell deficient RNU nude rats and found that T cells are not required for SGN death after hair cell loss. Using SRG rats, we found that lack of all lymphocytes improves SGN survival in the basal, but not apical, half of the cochlea, revealing regional differences in the role of immune cells in cochlear neurodegeneration. As we have previously reported, the increase in macrophage number and activation within the cochlea precedes significant neuronal death, implying that macrophages are not simply responding to increased need for phagocytosis of neuronal debris, but rather may be casual to the death of SGNs. Studies using the CSF1R

inhibitor, PLX5622, are currently underway to assess the role of macrophages in SGN death after hair cell loss.

SA172. Hearing Loss–Associated Variant p.V60L (c.178G > T) in P2RX2 Alters Calcium Flux in Human Inner-Ear Organoids

Pei-Ciao Tang*¹, Abimael Ramos¹, Xue Liu¹

¹*University of Miami School of Medicine*

Background: Mutations in P2RX2, which encodes an ATP-gated ion channel, are responsible for a disease known as autosomal dominant deafness 41 (DFNA41) and contribute to susceptibility to noise-induced hearing loss (NIHL). Herein we examined the impact of the first human P2X2 channel mutation identified, the p.V60L substitution, in human inner-ear organoids.

Methods: The P2RX2 p.V60L variant was introduced by CRISPR/Cas9 into human induced pluripotent stem cells (hiPSCs) to an isogenic control line. Inner-ear organoids were derived from both lines. Hair cell induction was monitored by immunocytochemistry, and calcium flux was assessed using Fluo-4 dye.

Results: Organoid induction was not affected by the P2RX2 variant. Hair cells were present in both wild-type (WT) and P2RX2 p.V60L organoids without evidence of degeneration through day 60 of culture. Calcium imaging assays showed reduced baseline calcium activity, as well as a diminished response to ATP, in organoids carrying the p.V60L variant.

Conclusions: Human inner ear organoids provide a useful platform for studying the functional consequences of hearing loss–associated genetic variants. The P2RX2 p.V60L variant reduces calcium signaling in human inner ear cells, which implicates the role of the P2RX2 gene in the proper function of inner ear.

SA173. Characterizing the Role of P2Y Metabotropic ATP Receptors in Medial Olivocochlear (MOC)-Mediated Effects on DPOAEs

Choongheon Lee¹, Joseph Holt*¹

¹*University of Rochester*

Background: Originating in the superior olivary complex, medial olivocochlear (MOC) neurons project across the brainstem and out cranial nerve VIII to synapse on outer hair cells (OHCs) along the cochlear spiral. MOC activation produces a characteristic suppression and enhancement of distortion product otoacoustic emissions (DPOAEs), presumably through actions on the cochlear amplifier. During MOC stimulation, MOC-mediated suppression (MMS) occurs within seconds, whereas the onset and offset kinetics of MOC-mediated enhancement (MME) are distinctly more protracted. MMS requires the release of ACh from MOC terminals and activation of postsynaptic $\alpha 9\alpha 10$ nicotinic ACh receptors ($\alpha 9\alpha 10$ nAChRs) on OHCs. While response kinetics suggest metabotropic receptor signaling, the mechanisms underlying MME have not been identified. Beyond ACh, existing data have revealed that MOC neurons may express nearly a dozen other transmitters including ATP, catecholamines, GABA, glycine, serotonin, CGRP, opioids, and neuropeptides. Previous studies, however, have revealed that MME does not appear to rely on adrenergic, CGRP, dopaminergic, GABAergic, glycinergic, muscarinic ACh, or opioid signaling. Motivated by the metabotropic-like kinetics of MME and evidence that MOC efferents co-release ATP, we

have focused our efforts on investigating if ATP and its activation of P2Y metabotropic receptors (P2YRs) play any role in the generation of MME.

Methods: To evaluate the role of ATP and P2YRs on MOC-mediated effects, we recorded DPOAEs in urethane/xylazine-anesthetized C57Bl/6 mice while stimulating MOC neurons in the 4th ventricle before, during, and after the administration of selective P2YR agonists and antagonists. DPOAE stimulus generation and measurements were made using Tucker-Davis System hardware and custom software, using F1 and F2 frequencies (10 and 12 kHz, respectively) delivered to the ear through Etymotic ER2 earphones and recorded via an ER-10B+ microphone. To isolate MME, we eliminated MMS using selective $\alpha 9\alpha 10$ nAChRs antagonists or by performing parallel experiments in $\alpha 9$ KO mice. Most P2YR compounds were delivered directly into the perilymph using an intracanal (IC) cannula inserted through the bony posterior semicircular canal.

Results: Previous studies have indicated that the P2YR subtypes P2YR1 and P2YR4 are found on OHCs while P2Y2Rs are restricted to several classes of supporting cells. Guided by this, we used subtype-selective agents to probe each receptor subfamily. P2YR1 antagonists enhanced MMS while P2YR1 agonists attenuated MMS suggesting there may be some interactions between P2YR1s and $\alpha 9\alpha 10$ nAChRs on OHCs. The IC administration of P2YR2 and P2YR4 agonists mimicked MME and, in some instances, appear to reduce it at later time points, in what might be evidence for desensitization. P2YR2 and P2YR4 compounds appear to also have varying effects on MMS.

Conclusions: This study attempts to characterize the role of P2YRs in MME and preliminary data suggesting that P2YR2s and possibly P2YR4s are involved. Further pharmacological assessment and complementary genetic approaches are warranted to define receptor-specific mechanisms and kinetics.

SA174. Cholinergic Modulation of Membrane Properties of Type II Vestibular Hair Cells

Jason Cote^{*1}, Soroush G. Sadeghi²

¹*The Johns Hopkins University School of Medicine*, ²*Johns Hopkins University*

Background: In the mammalian peripheral vestibular system, cholinergic efferent fibers from the brainstem innervate type II hair cells (HC-II) and afferent terminals in the inner ear. Previous studies have established that HC-II express $\alpha 9$ -containing nicotinic acetylcholine receptors (nAChRs), which trigger rapid hyperpolarization through activation of small conductance calcium-activated potassium (SK) channels (Poppi et al., 2017; Yu et al., 2020). In contrast, very little is known about muscarinic receptor (mAChR) signaling in HC-II, particularly in mammals. The only available data come from studies on enzymatically dissociated guinea pig HC-II, where the investigators themselves note that the dissociation process significantly alters the cells' physiological properties (Kong et al., 2005; 2007). Here, we examined whether HC-II cells respond to mAChR activation and characterized the nature of their response.

Methods: We used a whole tissue preparation and performed whole-cell patch-clamp recordings from HC-II in the cristae of the horizontal and anterior semicircular canals of wild-type C57BL/6 mice or mice lacking large conductance potassium (BK) channels at P13–P17. Pharmacological agents included IBTX (150 nM), oxotremorine methiodide (Oxo-M, 20 μ M), and apamin (300 nM), all bath-applied during experiments. Putative HC-II were identified by the absence of surrounding calyces under differential interference contrast

(DIC) optics and subsequently confirmed by their characteristic current profiles in response to depolarizing steps.

Results: HC-II displayed voltage-dependent potassium currents when subjected to voltage steps from -124 mV to $+16$ mV in 20 mV increments. These responses included I_h currents at -124 mV, small currents near the resting potential of -59.2 ± 3.5 mV ($n = 12$), and large outward currents (up to 3 nA) during depolarizing steps. Application of Oxo-M significantly reduced these outward currents ($n = 9$) at the most depolarized steps (two-way repeated measures ANOVA, $p < 0.0001$; Bonferroni post hoc: $p < 0.0001$ for steps > -20 mV). Occlusion experiments with IBTX followed by Oxo-M plus IBTX demonstrated that IBTX alone reduced outward currents at steps > 16 mV, and co-application of Oxo-M did not cause further reduction ($n = 8$). Furthermore, apamin failed to block Oxo-M effects ($n = 5$). Confirming these findings, HC-II of BK KO mice (Meredith et al., 2004) showed smaller outward currents at depolarized membrane potentials compared to WT mice and were not affected by Oxo-M.

Conclusions: Our results show that mAChR activation inhibits BK channels at depolarized potentials, increasing HC-II excitability at > 0 mV during large cilia deflections. In contrast, activation of $\alpha 9$ -containing nAChRs engages SK channels to suppress excitability below 0 mV. Therefore, simultaneous activation of mAChRs and nAChRs by efferent input may act as a high-pass filter, enhancing responses to strong stimuli while dampening weaker ones.

SA175. Do Hensen's Cells in the Organ of Corti Signal Tissue Injury Through Type II Spiral Ganglion Neurons?

Yvan Pacheco Romero^{*1}, Samantha Radomski¹, A. Catalina Vélez-Ortega¹

¹*University of Kentucky*

Background: The cochlea, a spiral-shaped structure in the inner ear, contains the organ of Corti, which converts mechanical vibrations into electrical signals through specialized sensory hair cells. Spiral ganglion neurons (SGNs) innervate hair cells to relay information to the brain and are categorized into type I or type II neurons. Type I neurons are myelinated, innervate inner hair cells (the 'true' auditory hair cells), and represent most of the spiral ganglion neurons ($\geq 90\%$). Type II neurons are unmyelinated, innervate multiple outer hair cells simultaneously (the cells responsible for sound amplification within the cochlea), and their function is not well understood but they appear to respond to potentially damaging stimuli (nociception) like loud noise. The transient receptor potential cation channel A1 (TRPA1) is a well-established sensor of tissue injury found in pain-sensing neurons throughout the body. TRPA1 is also expressed in the cochlea, exclusively in Hensen's cells. Notably, type II SGNs have been shown to make electron-dense contacts with Hensen's cells in guinea pigs, but whether these contacts represent functional synapses and/or are present in other mammals is unknown. Here, we are exploring the potential innervation of Hensen's cells by type II SGNs in mice.

Methods: We are using immunolabeling against neurofilament heavy chain (NF-H) and confocal microscopy of the adult (> 4 weeks old) organ of Corti from wild-type mice (C57Bl/6). To explore the innervation patterns of SGNs along the entire cochlear length (with focus on the outer hair cell region and the neighboring supporting cells) we are using fiber tracing features in Imaris software. We also use whole cochlear mounts from 2- to 3-week old

mice that express the calcium indicator GCaMP6s in neurons to assess calcium activity in SGNs upon the delivery of TRPA1 agonists.

Results: Immunolabeling and confocal imaging revealed the presence of presumed type II SGNs within the Hensen's cell region in the mouse cochlea, and we are currently exploring the anatomical presence of potential synapses. Our preliminary results with the application of the potent TRPA1 agonist para-benzoquinone to the apical turn of the organ of Corti show long-lasting calcium responses in the soma of a small subset (~10%) of SGNs. We are currently evaluating morphological features of these neurons to see whether they indicate a type I or II phenotype.

Conclusions: Our data indicate that Hensen's cells detect injury in the cochlear epithelium and might transmit nociceptive signals to the central nervous system via type II SGNs, making Hensen's cells a novel component of the elusive cochlear nociceptive pathway. Current efforts are focused on determining the cellular and molecular mechanisms of the potential interaction between Hensen's cells and type II SGNs.

SA176. Surface “Painting” of Extracellular Vesicles to Enhance Inner-Ear Tropism

Athanasia Warnecke*¹, Peixin Huang², Xiaoshu Pan³, Yanjun Li⁴, Mei He³, Hinrich Staecker²

¹*MED-EL Elektrode. Geraete GmbH*, ²*Univeristy of Kansas Medical Center*, ³*University of Florida, School of Pharmacy*, ⁴*University of Florida*

Background: Extracellular vesicles (EVs) are promising carriers for regenerative therapy in the inner ear, but their native biodistribution favours clearance organs (liver/spleen) and yields limited, non-selective cochlear uptake after intratympanic delivery. We propose post-production surface functionalisation (“painting”) of EVs to increase tropism for key cochlear targets while preserving vesicle integrity and safety. To engineer EV surfaces with carboxylic linker targeting ligands that enhance binding and uptake by the organ of Corti, spiral ganglion neurons and supporting cells, thereby improving delivery and therapeutic efficiency.

Methods: Machine learning-adapted peptide design was used to increase properties as desired to enhance EV trafficking efficiency. To train prototype deep learning model, we used a range of 12 amino acid peptides that bind to hair cells and components of the organ of Corti as identified via phage panning experiments. EVs produced under controlled conditions were “painted” by introducing carboxylic conjugation to anchor the tissue targeting peptides on the surface of EVs. Characterisation included nanoparticle tracking analysis and assessment of efficacy in in vitro and in vivo models.

Results: When compared to unmodified EVs, an increased up-take in HEI-OC was observed. In vivo, selective localisation to hair cells and spiral ganglion neurons or glial cells was achieved with a markedly reduced off-target accumulation.

Conclusions: Current investigations are now focused on critical quality attributes such as ligand identity, density, orientation, vesicle size/charge and binding potency in addition to preservation of hearing thresholds and local tolerability. Although still in its infancy, surface-painted EVs provide a modular, GMP-compatible route to precision delivery in the inner ear, enabling lower doses, fewer off-target effects and clearer mechanism-of-action readouts.

SA177. Bridging the Translational Valley of Death in Auditory Gene and Drug Therapies

Donald Hodges^{*1}, Ellie Khadir¹, Aurore Marie², Marie-Pierre Padelou², Gaelle Naert², Rami Tzafriri¹

¹CBSET, ²CILcare

Background: Gene therapies targeting OTOF mutations represent the most advanced and clinically validated approach, showing functional recovery in children. Despite this and exciting advances in auditory science, ototoxicity prevention, and regenerative approaches, approved pharmacological therapies for hearing loss remain scarce due to high attrition rates. The only FDA-approved drug, sodium thiosulfate (PEDMARK®), is limited to preventing cisplatin-induced ototoxicity in pediatric patients. For most individuals, hearing aids and cochlear implants remain the standard of care. High attrition rates in therapeutic development programs are seen across disease areas and often referred to as the translational valley of death, attributed to a disconnect between basic research and the development of safe, effective therapies.

Methods: We drew on our collective experience supporting drug development from discovery through IND-enabling studies to identify recurring barriers and strategies to mitigate translational risk in auditory gene and drug therapies.

Results: Translation failures arise from multiple factors, including animal model limitations, endpoints/biomarkers, scientific culture, novel modalities, and logistics.

Species and model limitations: Animal models differ markedly from humans in cochlear size, hair cell distribution, hearing range, regenerative capacity, and round window permeability. These differences hinder extrapolation of pharmacokinetics and efficacy.

Endpoints and biomarkers: Standard preclinical measures are animal-specific, e.g., ABR and DPOAE need to be aligned to capture subjective human outcomes (e.g., speech discrimination, tinnitus). Post-mortem histopathology often cannot be aligned with clinical symptoms.

Scientific and cultural misalignments: industry focus on translation builds on a prioritization of reproducibility, scalability, and effect size. Conversely, academia's focus on publications prioritizes novelty and statistical significance over robust translational foundations.

Novel modality challenges: Gene and cell therapies introduce risks of off-target effects, immune responses, and vector-related toxicity that are poorly modeled in small animals. Limited species cross-reactivity for biologics and oligonucleotides necessitate surrogate systems with uncertain predictive validity. Regulatory frameworks for these modalities remain underdeveloped.

Operational and logistical hurdles: GMP manufacturing, formulation stability, and inner ear delivery introduce complexities absent at the bench. Clinical trial execution is slowed by patient recruitment, endpoint selection, and statistical design.

Conclusions: The translational gap in auditory therapeutics is especially acute for academic startups, and reflects intertwined scientific, methodological, cultural, and operational challenges. Success requires early and sustained integration of basic scientists with translational experts, including toxicologists, pharmacologists, and regulatory specialists, so that promising discoveries can be de-risked and advanced efficiently toward clinical application. Consistently bridging the translational valley for auditory therapies will require strategic use of large animal models, novel translational biomarkers, and patient-derived

systems to improve human relevance. Emerging in vitro, in silico, and AI-based approaches hold promise, but broad validation and regulatory acceptance are still needed. Early integration of these tools can help de-risk development and accelerate safe, effective therapies to patients.

SA178. Deep Learning Techniques Enable Spatiotemporal Analyses of Cochlear Dynamics

Conner Kojima^{*1}, Patricia Quinones², Zihan Yang², Brian Applegate², Michael Serafino², John Oghalai²

¹*Keck School of Medicine*, ²*Caruso, Keck School of Medicine, University of Southern California*

Background: Due to its ability to visualize structures and characterize motion in the ear, optical coherence tomography (OCT) has emerged as a popular modality to measure cochlear mechanics. Most existing studies characterize the motion of structures within the organ of Corti by plotting tuned responses from single points or multiple selected points. However, OCT offers the ability to measure vibrational data from every point within a volume image stack, and for the most part, these data have remained largely unused due to the massive amount of data available and the time it would take to analyze it. Here, we present a deep learning model that can automatically segment inner ear regions from OCT volumes thus enabling analysis of motion within a complete volume of the cochlea across different anatomic structures.

Methods: We used our 1D-OCT system to image volumes (1mm x 1mm x 1.2mm) of the apical cochlea in 28 mice. In 27 volumes, we manually segmented Reissner's membrane, spiral limbus, tectorial membrane, outer hair cell region, inner hair cell region, Deiters' cell region, tunnel of Corti, lateral compartment, and basilar membrane. The data was split into train, validation, and test sets of 20, 4, and 3 volumes respectively. We trained a 2.5D U-Net model on patches (0.24mm x 0.18mm) sampled from cropped versions of each volume to balance background and foreground regions. After training, the model generated predictions for each patch of a volume using a sliding window approach and retaining the most confident prediction at overlaps. Model predictions were refined using filtering and smoothing to improve consistency across slices. We used the model to segment the 28th volume and analyzed the vibratory patterns of different cochlear structures.

Results: Reflecting its ability to locate structures, the model achieved a foreground dice score of 0.73 and a foreground 95th percentile Hausdorff distance of 26.2 micrometers. We segmented a cochlea dataset with vibrometry measurements across one-third of an apical turn. Within each structure, points at a given radial location were grouped into 3-unit XY bins and averaged to yield a single magnitude and phase, which were then used to create a movie of the vibratory patterns. Movement of the Reissner's membrane and the spiral limbus lacked the appearance of a traveling wave whereas the other structures exhibited an apically traveling wave, with the tectorial membrane showing the greatest vibratory magnitude.

Conclusions: Here, we demonstrate the ability of deep learning methods to segment structures in OCT volumes of the inner ear. In doing so, we leverage deep learning to facilitate spatiotemporal analysis of our vibrometry data for better understanding of cochlear mechanics. The model framework serves as a foundation for future projects leveraging deep learning to analyze biological datasets at scale.

SA179. Deep Learning–Based Classification of Cochlear Pathologies Using ABR Waterfall Plots From Chinchilla Models

Prasad Shivaji Darveshi*¹, Afagh Farhadi², Samantha Hauser³, Andrew Sivaprakasam⁴, Michael Heinz³

¹*Purdue University - West Lafayette*, ²*Speech, Language, and Hearing Sciences, Purdue University*, ³*Purdue University*, ⁴*Indiana University School of Medicine*

Background: Accurate diagnosis of specific cochlear pathologies remains challenging. Although Auditory Brainstem Response (ABR) testing is widely used to assess hearing function, certain auditory deficits such as cochlear synaptopathy (CS) and inner-hair-cell (IHC) dysfunction can remain “hidden” when analyses focus primarily on thresholds. In animal models, moderate noise exposure can produce Temporary Threshold Shift (TTS) that often reflects synaptic loss without overt hair-cell damage or permanent threshold elevation. In chinchilla, carboplatin (CA) preferentially targets IHCs and their stereocilia, yet leaves behavioral/physiological thresholds largely unchanged. Nonetheless, quantitative analysis of suprathreshold waveform morphology (timing, amplitude, slope, inter-wave relationships) is commonly used to measure hidden hearing loss that differs from person to person and is highly time-consuming. We tested whether a compact deep-learning model can confidently detect these subtle differences in ABR waveform morphology to differentiate sensorineural hearing-loss subtypes.

Methods: Preclinical chinchilla datasets were used, representing three groups: normal hearing (Baseline), CS/TTS (noise exposure), and IHC dysfunction (carboplatin). ABRs were recorded using sub-dermal electrodes (vertex, mastoid, nose/ground), amplified 20,000×, band-pass filtered, and digitized at 48 kHz. For 2, 4, and 8-kHz stimuli, 500 repetitions per level were averaged; level-stacked traces were rendered as “waterfall” images that visualize time-domain morphology across levels. Images were standardized with consistent y-axis scaling.

We fine-tuned EfficientNet-B0 (ImageNet-initialized) for a two-stage pipeline: Stage 1 (gate) classified Normal vs Abnormal; Stage 2 assigned abnormal samples to CA (IHC dysfunction) or CS (synaptopathy). Training used targeted augmentations (minor rotation/contrast jitter), early stopping, and regularization to mitigate overfitting. Evaluation used sensitivity/precision and confusion matrices for both stages.

Results: Morphology encoded clinically relevant information beyond thresholds.

- Stage 1 (Normal vs Abnormal): high sensitivity and strong precision, indicating reliable detection of hidden loss from waveform morphology alone.
- Stage 2 (CA vs CS among Abnormal): High overall accuracy. Per-class metrics showed very high precision and sensitivity for IHC dysfunction, whereas strong sensitivity and decent precision for CS. Misclassifications occurred primarily between IHC dysfunction and CS, consistent with nuanced, overlapping suprathreshold morphology rather than gross differences.

Conclusions: A lightweight, morphology-aware pipeline based on EfficientNet-B0 can learn subtle suprathreshold patterns in ABR waterfall images. This enabled sensitive detection of hidden hearing loss and preliminary differentiation of across sensorineural hearing-loss subtypes (IHC dysfunction, CS) even when thresholds are unchanged. Ongoing work targets (i) expansion and balancing of the dataset across animals/conditions, (ii) refinement of image-construction choices (dynamic-range normalization, windowing tuned to physiologic landmarks). This approach has the potential to complement standard audiograms with an

automated analysis of ABR waveform morphology to provide individualized diagnostic insight.

SA180. POD-Vis: Interactive Hypothesis-Based Exploration and Visualization of Pure Tone Audiometry and Middle Ear Data in Clinical and Research Study Populations

Jonathan Crabtree*¹, Ronna Hertzano², Adam Kaufman³, Pranav Kulkarni⁴, Daniel Lesperance⁵, Anup Mahurkar⁵, Gayla Poling⁶, Kristal Riska⁷, Lisa Shulman³, Akira Watanabe⁸, Christopher Zalewski⁶

¹University of Maryland School of Medicine, ²National Institutes of Health, ³University of Maryland Baltimore, ⁴University of Maryland College Park, ⁵Institute for Genome Sciences, University of Maryland, Baltimore, ⁶Auditory and Vestibular Clinical Research Section, NIDCD, ⁷Duke University, ⁸Ultima Genomics

Background: Clinician researchers wanting to compare their own data with published studies or collaborators' datasets are faced with several challenges, including the need for data extraction and harmonization, study design, statistical support, data visualization and figure generation. We present POD-Vis (Probing Outcomes Data with Visual Analytics), a web-based data repository and analysis platform that eases the burden of performing these tasks. Originally agnostic with respect to both the clinical measurements and disease/condition of interest (e.g., Parkinson's disease, cancer), POD-Vis has been enhanced to account for audiometric data and underlying health conditions.

Methods: Audiometric datasets are harmonized and loaded into a MySQL database. Audiometry and middle ear variables are renamed as needed, and hearing threshold values processed to ensure consistent handling of masked and unmasked thresholds and no response (NR) values. Demographic data, health metrics, and other test results are handled similarly, with ICD-10 codes used to record diagnostic information. Once datasets are harmonized and loaded, a VueJS-based web application guides end-users through a scripted analysis workflow to combine datasets, select variables, and create and compare study groups (cohorts). Statistical analyses, including multivariable regression, can be performed using the Python SciPy and statsmodels packages. Data visualizations are displayed as interactive plots and charts based on Apache ECharts, Plotly, and D3.js. For pure tone threshold data specifically, a custom interactive audiogram has been developed. It displays cohort-level pure tone threshold data, with options for error bars and boxplots, extended high frequency data, and bone conduction data. This display can also overlay individual patient audiograms (e.g., for potential clinical use.)

Results: POD-Vis has been used to harmonize and analyze various datasets, including clinical, retrospective study, and general health survey data. Specifically, we have created an instance of POD-Vis for the HearShare Consortium. The consortium includes clinicians/scientists from Duke University, Massachusetts Eye and Ear, Medical University of South Carolina, University of Maryland Baltimore, University of Maryland College Park, the National Institute of Deafness and Other Communications Disorders clinical center, and Oregon Health Sciences University. For this consortium we have harmonized and loaded data from population-based studies such as the National Health and Nutrition Examination Survey (NHANES), the Framingham Heart Study, the Baltimore Longitudinal Study of Aging (BLSA), and the Hispanic Community Health Study (HCHS/SOL), plus clinical datasets from University of Maryland School of Medicine and Duke University. This comprises over

62,000 subjects with audiograms containing associated demographic and health information. POD-Vis has been deployed in both the Azure and Google Cloud environments, and pilot projects are ongoing with several collaborators.

Conclusions: POD-Vis is a data visualization and analysis platform that allows clinicians and researchers the ability to interact with large harmonized audiometric datasets and generate hypothesis-based explorations, without needing extensive prior experience in either data science or statistics.

SA181. The Sound of Safety: Why GLP Ototoxicity Testing Must Be Standard

Ellie Khadir^{*1}, Gaëlle Naert², Marie-Pierre Padelou², Aurore Marie², Rami Tzafriri¹, Donald Hodges¹

¹CBSET, ²CILcare

Background: Hearing loss affects approximately 1.5 billion people worldwide, with ototoxicity representing a leading cause of acquired hearing loss globally. The number of ototoxic drugs is estimated between 150-600, with over 200 marketed medications documented to cause ototoxicity. While FDA guidelines define otic assessments for drugs delivered directly to the ear, testing for systemically administered therapies remains optional, leaving critical regulatory gaps despite the potentially devastating consequences of auditory dysfunction

Methods: Current FDA regulations for Good Laboratory Practices (GLP) (21 CFR Part 58) govern nonclinical studies, with guidance for otic administration specifying auditory brainstem response (ABR) and cochleogram as primary endpoints. However, for systemically administered therapies, no dedicated guidance exists, leaving assessments to case-by-case evaluations and underscoring the need for transparent dialogue between sponsors and regulatory authorities. Study designs utilize 10 animals per sex per group with preferred species including rats (Wistars in Europe and Sprague Dawley in North America), CBA/CaJ mice (age-stable hearing characteristics), and Hartley guinea pigs (enhanced ototoxic sensitivity). Three doses are tested: low (pharmacological), intermediate, and high, with reversibility periods to assess effect permanence. Key assessment methods include ABR measuring cochlear and neural pathway functionality through synchronous neuronal discharge; and cochleogram providing histological assessment of hair cell loss across 4 rows. In addition, DPOAE, electroacoustic measure, assessing outer hair cell integrity through acoustic signals from cochlear epithelium can be performed. ; Clinical interpretation follows ASHA criteria defining significant hearing change as ≥ 20 dB decline at any frequency or ≥ 10 dB decline at two adjacent frequencies. Key components of GLP include an effective quality assurance program, proper management and staff training, adequate facilities and equipment, clear and documented procedures, and meticulous record-keeping to provide traceability and reproducibility of study results, with compliance ensured via regulatory agency audits and inspections.

Results: Preclinical data demonstrate that small threshold shifts (5-10 dB) without histopathological changes may represent normal test-retest variability, requiring integrated interpretation of ABR, DPOAE, and cochleogram findings. Therapy-specific study designs include: small molecules utilizing standard repeated-dose protocols with functional testing at baseline, interim, and terminal timepoints; gene therapy requiring specialized round window/cochleostomy injection with 3-6 month observation periods and biodistribution

studies; cell therapy employing local delivery approaches with engraftment monitoring and immune response evaluation; local delivery necessitating trans-tympanic or intracochlear routes demanding specialized surgical expertise

Conclusions: Ototoxicity assessment is established for local otic administration but remains optional for systemic dosing, reflecting on regulatory gaps. Comprehensive evaluation requires integration of electrophysiological and histological expertise and, for otic delivery, surgical proficiency. Given the devastating impact of auditory dysfunction and the absence of formal regulatory requirements, incorporating ototoxicity testing into standard GLP safety guidelines would enable earlier detection of auditory risk, prevent irreversible hearing loss, and strengthen the evidence base for therapeutic decision-making.

SA182. Adaptive Sampling of Dpoae Level Maps and Their Relation to Conductive Hearing Loss and Ear Canal Calibration

Stepan Kempa^{*1}, Ernst Dalhoff¹, Anthony Gummer¹, Katharina Bader¹, **Anthony Gummer²**

¹*Section Physiological Acoustics & Communication, University of Tübingen, Germany,* ²*University of Tuebingen*

Background: Distortion-product otoacoustic emission (DPOAE) measurements are strongly influenced by middle-ear transmission properties, thus, making conductive hearing loss a critical factor in clinical assessments. Complete characterization of the L1, L2-parameter space, referred to as DPOAE level-maps (LMs), allows for distinguishing between linear and non-linear losses, provided that forward and reverse transmission losses are closely correlated (approximately 1:1). The underlying theory asserts that anterograde conductive loss at f₁ and f₂ is reflected in a correspondent shift of the LM in the L₁, L₂-plane, and that retrograde loss at f DP is reflected in a correspondent reduction of the semilogarithmic slope along the LM ridge. Here, we show in (1) data from patients with suspected otosclerosis, and (2) data from different ear-canal calibration methods, that the underlying theory is largely confirmed by experiments.

Methods: DPOAE level maps were obtained from two groups: (1) 10 patients with conductive hearing loss (CHL) in at least one ear, based on air-bone gap (ABG) measurements, and (2) 11 normal-hearing (NH) subjects who underwent two sessions with shallow and deep probe insertions and four calibration methods (IPL, FPL, +EPL). The frequency range examined was 1–6 kHz for CHL patients and 1–14 kHz for NH subjects. For the ear-canal calibration analysis, inter-session changes in DPOAE LM parameters for the IPL, FPL, and IPL+EPL methods were correlated with inter-session variations in speaker calibration transfer functions (SPL) between the shallow and deep probe insertions.

Results: In conductive-loss patients, the change in LM ridge slope significantly correlated with ABGs at f DP, with an SDresidual of 4 dB (R²=0.56, N=39). The offset of the LM towards higher L1 levels also correlated highly significantly, but with a slightly higher SDresidual of 5 dB.

In the calibration study, inter-session changes in the calibration transfer function at f₁ significantly correlated with the shift of the optimal L1 value toward higher L1, with an SDresidual of 4.5 dB (R²=0.91, slope a=0.96). Similarly, inter-session changes in the calibration transfer function at f DP correlated significantly with the decrease of the semilogarithmic slope of the LM ridge, s. with a SDresidual of 3 dB (R²=0.43, slope a=0.95).

The DPOAE LM parameter L2,EDPT correlated with total hearing loss (conductive plus cochlear loss). This was verified using data from 9 ears (5 patients) with cochlear hearing loss from an independent study. The correlation between L2,EDPT and Békésy tracking audiometry from NH and CHL group is highly significant and yields an SDresidual of 6.8 dB ($R^2=0.61$, slope $a=0.96$) consistent with previous findings.

Conclusions: Accumulated hearing loss from conductive loss (whether pathological or due to calibration changes) and cochlear amplification loss (which behaves nonlinearly) can be differentiated by analyzing three key parameters of the DPOAE LM, namely L1,EDPT, L2,EDPT, and s.

SA183. Impact of Anesthesia on Otoacoustic Emissions and Blood Oxygen Saturation in Rats

Mathieu Petremann^{*1}, Valentina Kaden-Volynets², Karolina Charaziak³, Hubert Löwenheim⁴, Jonas Dyhrfeld-Johnsen²

¹*Translational Hearing Research Center, University of Tübingen*, ²*Acousia Therapeutics*,

³*University of Southern California*, ⁴*Translational Hearing Research, University of Tübingen*

Background: Distortion-product (DPOAEs) and stimulus-frequency otoacoustic emissions (SFOAEs) are both considered as early, objective biomarker of subclinical hearing loss with outer hair cell (OHC) dysfunction receiving increasing attention in age-related hearing loss (ARHL), speech discrimination and early onset dementia. Preclinically OAE measurements are typically performed under deep anesthesia, mostly to complement ABRs. In our recent studies with extensive OAE measurements over 45 min utilizing a Fentanyl-based anesthetic regimen, we observed instability and inconsistency in the measurement amplitudes associated with low blood oxygen saturation (SpO₂). Here we report a comparison between Fentanyl and the Zoletil (Zolazepam-Tiletamine)-Xylazine regimens on OAEs, including a systematic monitoring of SpO₂ and DPOAE.

Methods: Ten 9 month-old male Wistar rats were monitored for SpO₂ and fast DPOAEs during two 60 min long recording sessions, 2 weeks apart. Anesthesia was successively induced using i.p. administration of either Zoletil/Xylazine 20-40/3.5-5 mg/kg or Fentanyl/Midazolam/Medetomidine 0.005/2.0/0.15 mg/kg. Unilateral audiometric characterization was performed in a soundproof chamber including swept-tone stimulus OAEs [4-42] kHz with high and low level DPOAEs, SFOAEs and ABR [8-32] kHz. The monitoring was performed every 5 min from 15 to 60 min of anesthesia. Lastly supplementary oxygen flow was added in the end of the OAE session to allow a final DPOAE measurement under 98% O₂.

Results: After 15 min of anesthesia the SpO₂ from both groups dropped to 88-89%. From 25 min the Fentanyl group was as low as 83 % O₂ whereas the Zoletil group maintained close to 86-87 % O₂ until 60 min. Low level DPOAE and SFOAE amplitudes from the Zoletil animals were markedly higher across the entire frequency range, with differences increasing from low to high frequencies, and an average 7 dB improvement on DPOAEs between [13.7-36] kHz and 9 dB on SFOAEs between [6.5-27] kHz. The average difference on high level DPOAE amplitudes were not as marked. Comparing the fast DPOAE monitoring before and after the supply of oxygen flow, showed an initially 5 dB higher output in the Zoletil group with no effect of supplementary oxygen, whereas supplementary oxygen in the Fentanyl group lead to DPOAE amplitudes matching the Zoletil group for most of the tested

frequencies. ABR thresholds showed only 0.3 to 3.9 dB difference across frequencies between anesthetic regimens.

Conclusions: These data suggest that DPOAEs and SFOAEs are highly sensitive to blood oxygen saturation and middle ear transmission. The Zoletil-Xylazine mixture seems better suited for this aging model. The choice of the anesthetics appears to have a significant, direct impact on the amplitude and the stability of these measurements and should be carefully determined for each animal model, perhaps depending on the sex and the age of the species, to facilitate analysis and comparison over time and across experimental groups.

SA184. Probes and Paradigms: Serial Observations of Extended Bandwidth Distortion Product Otoacoustic Emissions (DPOAEs) in Healthy Adults

Gayla Poling*¹, Talah Wafa¹, Christopher Zalewski¹, L. Noelle Allemang¹, Jennifer Chisholm¹, Julie Christensen¹, Laura Dreisbach²

¹*Auditory and Vestibular Clinical Research Section, NIDCD, ²San Diego State University*

Background: Basal cochlear regions associated with higher frequencies of hearing are selectively damaged by factors such as aging and therapeutic treatments known to cause hearing loss. Identifying the tools to best reflect and identify this damage across the lifespan is critical to the identification and clinical management of patients. One such tool, distortion-product otoacoustic emissions (DPOAEs), has the potential to identify cochlear damage that has not yet been observed on the audiogram at both conventional and extended high frequencies (EHF; > 8 kHz).

The value of testing EHF-DPOAEs for earliest detection of cochlear dysfunction is well established; however, it is not standard clinical practice. This is in part due to challenges associated with complex ear canal acoustics in the EHF range and availability of transducers optimized for EHF assessments. While the reliability and repeatability of DPOAE measures at conventional frequencies obtained using clinical tools have been explored, comparable evidence is lacking for EHF stimuli. Until recently, commercially available DPOAE tools with the potential for expanded EHF stimuli (>=10 kHz) were not readily accessible for clinical translation. Thus, this study aims to characterize test-retest variability of a DPOAE test battery across an expanded frequency bandwidth in healthy participants for serial measurements and to further elucidate what constitutes a clinically meaningful change.

Methods: This study (NCT01629108) characterizes and compares serial measurements of standard (up to 8 kHz) and EHF (up to 16 kHz) DPOAE amplitudes from the same ear using four different probes across two systems (Interacoustics and Intelligent Hearing Systems). Testing was completed in each ear over three test sessions 2-3 weeks apart.

Participants (n=10; M/F=5/5; age range 19-63 years) completed a comprehensive audiological test battery in each ear including but not limited to hearing thresholds (up to 20 kHz), middle ear measures, as well as standard and EHF DPOAE measures. Inter-test and intra-test variability was determined for each probe and across probes when possible.

Results: Preliminary DPOAE outcomes are similar across sessions and equipment, with increased variability above 4 kHz. Stability of measures based on probe and paradigm (including discrete- versus swept-frequency) will be presented. Proposed clinical monitoring parameters and navigation of technical barriers to using EHF stimuli to enhance clinical utility will be discussed.

Conclusions: Preliminary findings support favorable test-retest variability across EHF-DPOAE probes investigated and the potential for enhancement of serial measurements for optimal clinical translation based on study outcomes. Future monitoring strategies and clinical applications of serial measurements will be discussed.

This work was supported by the Division of Intramural Research at the National Institute on Deafness and Other Communication Disorders (ZIA DC000064).

SA185. Development of a Ferret Model for Investigation of the Neural Correlates of Binaural Fusion of Vowel Sounds

Michéla Mondesir*¹, Jonah Stickey¹, Lina Reiss¹, Stephen David¹

¹*Oregon Health and Sciences University*

Background: Human listeners with hearing loss often experience abnormally broad binaural fusion, the perception of two spatially separated sounds with pitch differing by as much as 1-4 octaves as a single object (Reiss et al., 2017). Broad binaural fusion is associated with difficulties segregating voices and understanding speech in noise (Oh et al., 2019). The goal of this study was to develop a method of measuring binaural fusion behaviorally in an animal model and determine the neural correlates. Previous human behavioral studies have shown that two dichotically presented vowels are sometimes fused and perceived as a third vowel, distinct from either of the component vowels (Reiss and Molis, 2021). We have developed a go/no-go behavior to measure this fusion percept in ferrets.

Methods: Vowel fusion was measured in 10 normal hearing (NH) human subject listeners and 2 normal hearing ferrets. Synthetic vowels with fundamental frequencies (F0) 106 Hz and 151 Hz were used. The stimuli were presented through loudspeakers angled +/-60 degrees in the azimuth. Both parties were first trained to report the identity of a single vowel, either in a 6 AFC task (humans) or a go/no-go task (ferrets). During the experimental task, subjects were introduced to double vowel pairings, differing in vowel identity, and presented at either the same or different F0s. Double vowel presentations were interleaved with previously experienced single vowel presentations. Human subjects reported the one or two vowel(s) they heard during a trial through 6 options on a touch screen, with perception of a single vowel indicating fusion. Ferrets were trained to respond to indicate perception of AE or EH vowels (go) or OO, EE or AW vowels (no-go), with the perception of go stimuli for an AH-EE double vowel pair indicating fusion.

Results: Human behavioral data showed that double vowel pairs with the same fundamental frequency were often perceived as a single vowel, resembling the spectral average of the constituent vowels, consistent with previous experiments using stimulation over headphones. Ferret behavioral data show evidence of spectral averaging in line with the human subject data. Preliminary findings from neurophysiological recordings in the auditory cortex of ferrets suggest that neural responses to the fused double vowels are similar to those of the single vowel percept reported behaviorally.

Conclusions: Comparison of vowel fusion between human subjects and the ferret model suggests that both groups experience similar binaural fusion. Ongoing neurophysiological recordings will describe neural mechanisms producing binaural fusion and may provide insight into mechanisms and treatment of abnormal fusion following hearing loss.

SA186. Cortical Projection-Specific Processing of Infant Vocalizations for Mouse Maternal Behavior

Amy LeMessurier^{*1}, Gurket Kaur¹, Julia Paraiso¹, Ayat Agha¹, Janaye Stephens¹, Robert Froemke¹

¹*New York University School of Medicine*

Background: How does the brain derive meaning from social vocalizations and drive behavior in response? Vocalizations are complex stimuli that require integration across multiple time-scales and appropriate contextualization. Top-down modulation of feed-forward auditory processing is likely needed for these computations. To test this we took advantage of a robust mouse behavior, in which parental animals search for lost pups in response to infant ultrasonic vocalizations (USVs). Experienced moms are experts at this behavior, but nulliparous females can learn to respond to infant distress calls after cohousing with lactating moms and litters, and emergence of pup retrieval behavior is correlated with oxytocin-dependent plasticity in the left auditory cortex (Marlin et al. 2015, Schiavo et al. 2020).

Results: We asked whether projections from auditory cortex to subcortical areas are important for pup retrieval behavior in experienced maternal mice by chemogenetically silencing activity in left auditory cortex layer 5 during retrieval. Pup retrieval was reduced after CNO treatment vs vehicle control sessions (N=6 mice, $p < 0.05$). Silencing only neurons projecting to inferior colliculus led to a similar decrease (N=6, $p < 0.05$), while silencing only neurons projecting to the tail of striatum had no effect (N=6, $p > 0.05$), indicating that corticocollicular (CC) projections are particularly critical for linking perception to behavior in this context. We next used 2-photon Ca²⁺ imaging in awake head-fixed mice to compare USV responses of corticostriatal (CS) and CC neurons. CC neurons in expert retrievers (N=4 mice) had sustained increases in activity during USVs compared to pure tones, while activity was similar during USV and tone presentation in CS neurons (N=3 mice). This was corroborated with in vivo whole-cell recordings from optotagged projection neurons.

To examine whether sustained activity in corticofugal neurons develops with experience, we tracked activity in CC and CS neurons with 2-photon imaging over several days of co-housing. Robust responses to USVs were present on each day; however, responses were variable across neurons and days. In CC neurons, delayed and sustained responses to USVs increased over experience with pups, which may reflect upregulated activity in recurrent auditory circuits.

To examine how cortical projections modulate activity across auditory areas with precision for spike timing, we performed simultaneous silicon probe recordings from auditory cortex, inferior colliculus, and thalamus (N=6 mice). Subpopulations of neurons in each area integrated over sequences of call syllables. To test whether cortical feedback facilitates temporal integration, we optogenetically silenced corticofugal projections, which altered the timing of call-evoked spikes in inferior colliculus.

Conclusions: We found that corticofugal projections to the auditory midbrain are essential for vocalization-guided maternal behavior, and that neurons in this pathway integrate acoustic cues over behaviorally relevant timescales. Optogenetic inactivation further revealed that vocalization-evoked activity in the midbrain depends on top-down modulation rather than simple feedforward processing.

SA187. Auditory Cortex Function Can Be Characterized by Recurring Spontaneous Activation Patterns

Maria Hakonen*¹, Kaisu Lankinen², Parker Kotlarz², Jonathan Polimeni², Tori Turpin², Jianxun Ren³, Danhong Wang², Hesheng Liu³, Jyrki Ahveninen²

¹*Massachusetts General Hospital and Harvard Medical School*, ²*Athinoula A. Martinos Center for Biomedical Imaging, Harvard Medical School/Massachusetts General Hospital*, ³*Division of Brain Sciences, Changping Laboratory*

Background: Determining the functional organization of the auditory cortex (AC) has been difficult with conventional task-based approaches due to the broad responsiveness of auditory subregions to various acoustic properties. Moreover, most studies have assumed that the functional organization of AC is fixed, even though whole-brain research has shown that brain function is organized into constantly changing functional networks. These functional networks can be estimated from functional magnetic resonance imaging (fMRI) data by identifying coactivation patterns, groups of brain areas that are activated at the same time, under the assumption that simultaneous activation reflects functional cooperation. We hypothesized that coactivation patterns similar to those identified at the whole-brain level could also be reliably identified locally within AC. We further anticipated that the AC patterns identified during the resting state would represent fundamental functional processing modes, showing strong spatial similarity to patterns identified during auditory and audiovisual stimulation.

Methods: The AC patterns were estimated from high-resolution 7T fMRI data of 30 healthy volunteers, each of whom participated in three 2-hour fMRI sessions. The generalizability of the AC patterns was tested using the Human Connectome Project 7T fMRI dataset (N = 177). In the coactivation pattern analysis, individual fMRI volumes (time points) were clustered across participants using k-means based on their spatial similarity, and template coactivation patterns were generated by averaging the fMRI volumes within each cluster. Thereafter, within each participant, each of the fMRI volumes was classified into one of these templates based on spatial similarity. The coactivation patterns were compared between and within participants and datasets based on their spatial similarity and occurrence rate. An eight-pattern solution was selected for closer examination based on its high reproducibility values, which were 0.86 for the occurrence rates and 0.79 for the spatial topography.

Results: Dynamic AC patterns successfully captured interindividual variability, as indicated by significantly higher variability between than within individuals for the AC pattern occurrence rates and spatial topographies. The coactivation patterns shared similarities between resting-state and auditory-task data, as indicated by the group-level similarity of 0.84 and individual-level similarity of 0.71 in the spatial topographies. Furthermore, the occurrence rates of AC patterns identified in the task data, using pattern templates derived from resting-state data, correlated with specific task contrast regressors.

Conclusions: Our results indicate that the AC function can be characterized by a set of constantly varying coactivation patterns, presumably reflecting brain networks, that are consistently observed during resting state and auditory stimulation, and that get synchronized with auditory input. These findings enhance our understanding of the relationship between spontaneous and stimulus-driven activity in the AC and support the development of more time-efficient paradigms for studying its functional organization.

SA188. A Narrow Path for Long-Term Potentiation of Cortical Inhibitory Circuits

Anna Guo^{*1}, Kameron Clayton², Bshara Awwad², Daniel Polley³

¹Harvard University, ²Eaton-Peabody Laboratories, Massachusetts Eye and Ear, ³Eaton-Peabody Laboratories, Massachusetts Eye and Ear, Harvard Medical School

Background: Following sensorineural hearing loss (SNHL), weakened inhibition fails to stabilize excitatory pyramidal neurons (PyrNs), leading to hyper-responsivity, hyperactivity, and hypersynchrony. A recent study from our lab has shown that PyrN hyperactivity and loudness hyperacusis can be sustainably reversed in mice with noise-induced SNHL via a single brief bout of 40-Hz activation of parvalbumin-expressing cortical inhibitory neurons (PVNs). Here, we addressed whether sustained dampening of PyrN activity is unique to PVN activation or whether it might also result from 40-Hz activation of another cardinal class of cortical inhibitory neuron: dendrite targeting somatostatin_{x0002}-expressing interneurons (SOM) or through non-specific activation of all cortical inhibitory neurons.

Methods: High-density translaminar single-unit recordings were made in the high-frequency regions of the primary auditory cortex of awake, head-fixed mice before and after 16 min of 40-Hz optogenetic activation of PVN, SOM, or pan-inhibitory activation in VGAT-ChR2-EYFP mice (N = 6/6/2 mice; 90/70/60 sound-responsive regular spiking units). Sustained changes in excitability were assessed by measuring changes in the efficacy of optogenetically induced feedforward inhibition of putative PyrNs 30- and 60-minutes following 40-Hz activation compared to pre-activation baseline recordings.

Results: We found that 40-Hz activation of PVN-, SOM-, or VGAT-expressing inhibitory neurons elicited a robust gamma rhythm in the cortical local field potential and entrained photo-tagged single units spiking at 40 Hz. Whereas VGAT and PVN activation entrained the spike phase of regular spiking (RS) and fast spiking (FS) units in the canonical pyramidal-interneuron gamma (PING) rhythm, 40-Hz SOM activation did not. One hour after the cessation of 40-Hz PVN activation, PVN-mediated inhibition of RS units spiking was significantly enhanced, and sound-evoked RS spiking was significantly reduced without any change in spontaneous firing rate. Conversely, one hour after 40-Hz activation of SOM or VGAT neurons, the spontaneous firing rate was elevated without any change in feedforward RS unit inhibition or sound-evoked RS unit spike rate.

Conclusions: We found that 40-Hz activation of any cortical inhibitory neuron type elicited a robust gamma rhythm but only PVN or pan-inhibitory activation generated the characteristic FS-RS spiking dyad—a hallmark of the PING rhythm. Long-term potentiation of cortical inhibition was only observed with 40-Hz PVN activation, with no change following VGAT or SOM activation. When considered alongside our prior study showing that inhibitory potentiation was specific to 40-Hz PVN activation, our findings highlight a remarkable specificity for dampening hyperactive cortical circuits via temporally patterned activation of inhibitory circuits. That long-term inhibitory potentiation is effective at reversing hyperacusis in mice with irreversible cochlear sensorineural damage identifies new therapeutic avenues for treating suprathreshold hearing disorders like tinnitus and hyperacusis. That long-term inhibitory potentiation is specific to PVNs at specific activation rates may explain why systemic administration of GABA agonists has been ineffective as treatments for tinnitus and hyperacusis.

SA189. Robustness to Noise Reveals Cross-Culturally Consistent Properties of Pitch Perception for Harmonic and Inharmonic Sounds

Malinda McPherson-McNato*¹, Eduardo Undurraga², Aidan Seidle¹, Olivia Honeycutt³, Josh McDermott³

¹*Purdue University*, ²*Escuela de Gobierno, Pontificia Universidad Católica de Chile*,

³*Massachusetts Institute of Technology*

Background: Pitch is a building block of speech and music, but the extent to which pitch perception abilities are shared across cultures is unclear. Evidence from Western participants suggests that pitch perception relies on multiple representations. For instance, harmonic tones are easier to discriminate in noise than inharmonic tones (that lack a clear fundamental frequency) despite comparable discrimination in quiet, suggesting that different representations are used in noise and quiet. However, parallel work comparing participants in the USA and Tsimane, a group of hunter-agriculturalists living in the Bolivian Amazon, has suggested that some pitch-related behavior varies in at least some respects across populations. When asked to reproduce brief melodies by singing, USA listeners tend to sing back notes where the f_0 matches the stimulus frequency ('pitch matching'), as well as notes that are related to the stimulus notes by integer numbers of octaves ('chroma matching', i.e., frequency ratios that are powers of two), suggesting that notes related by octave ratios are treated as musically equivalent by USA listeners. By contrast, Tsimane' listeners exhibit no such tendency to chroma match, and a reduced tendency to pitch match. This set of findings left open the extent to which pitch perception varies in other respects across cultures. We sought to resolve this issue by assessing other aspects of pitch perception cross-culturally.

Methods: USA and Tsimane' participants heard two-note melodies and reproduced the melody by singing. Tones were either harmonic or inharmonic and were presented in noise at either high or low signal-to-noise ratios (SNRs).

Results: USA and Tsimane' participants both exhibited two characteristics of pitch perception previously seen in US listeners: the direction of pitch changes could be reproduced with equal accuracy for harmonic and inharmonic tones at high SNR, but was better for harmonic than inharmonic tones at low SNR. However, replicating prior results, Tsimane' did not exhibit the tendency of US participants to match the absolute pitch or chroma of the stimulus notes.

Conclusions: The basic structure of pitch perception appears to be shared across cultures despite other differences in pitch-related behavior; both US and Tsimane showed signatures of having two distinct pitch mechanisms, and to use the two mechanisms in the same way, despite differences in pitch and chroma matching tendencies during singing.

SA190. Multiple Statistical Integration Windows in Auditory Perception

Richard McWalter*¹, Josh H. McDermott¹

¹*MIT*

Background: Sound textures, as arise from swarming insects or falling rain, are believed to be represented with time-averaged statistics. Texture statistics show signs of being averaged over an integration window spanning multiple seconds. However, many different statistics are needed to account for texture perception. It remains unclear whether there is a single global integration window for all statistics, or whether integration windows vary across statistics.

We investigated the extent of time-averaging for individual classes of statistics from the auditory texture model of McDermott and Simoncelli (2011). We divided the statistics into fourteen classes spanning different audio and modulation frequencies, and marginal as well as correlation statistics.

Methods: We conducted an adaptive threshold experiment in which listeners judged which of two synthetic sound textures was most similar to a reference texture. The two textures on a trial were designed to differ in one of the fourteen classes of statistics. We measured discrimination thresholds for stimuli of different durations, ranging from 20ms to 10s.

Results: For each statistic class we tested, texture discrimination thresholds decreased with stimulus duration and then leveled off, potentially corresponding to the duration at which the stimulus exceeded the time-averaging window used to estimate the relevant class of statistics. The performance asymptote occurred at different durations for different statistics, and a model with statistic-specific integration windows provided the best account of the results.

Conclusions: The results suggest the extent of time-averaging varies across texture statistic classes, revealing a continuum of statistical integration windows in auditory perception.

SA191. Modeling Musical Pitch Perception With Mild to Moderate Sensorineural Hearing Loss

Jackson Graves^{*1}, Kayla Lang¹, Tess Starr¹, Sophia Riegle², Daniel R. Guest³, Kelly Whiteford⁴, Anahita Mehta¹

¹Kresge Hearing Research Institute, University of Michigan, ²Rochester Institute of Technology, ³University of Rochester, ⁴University of Minnesota

Background: Pitch is a key auditory feature for music perception and appreciation, providing the basis for melodies (from isolated pitches) and harmonies (from combinations of pitches). Mild to moderate sensorineural hearing loss (HL) degrades spectrotemporal cues and adversely affects perception of single pitches, but less is known about how HL affects multiple-pitch perception. In computational models of hearing, the perception of single pitches has been well studied, but fewer studies have investigated multiple-pitch perception. Our study tested listeners with and without HL on pitch perception tasks ranging from simple pitch discrimination to chord perception in musical context. These data allow us to measure the impact of HL on multiple pitch perception and compare it against established effects on perception of single pitches. We also developed novel stimuli based on a physiologically grounded computational model of the auditory system, to simulate effects of hearing loss on perception of single- and multiple-pitch stimuli.

Methods: In the behavioral study, we measured pitch discrimination thresholds in listeners with mild to moderate HL for four pitch perception tasks involving single-pitch stimuli and multiple-pitch combinations. Specifically, listeners were instructed to (1) compare two sounds and chose the sound with the higher pitch, (2) determine whether a target pitch in a chord is higher or lower than an isolated reference pitch, (3) discriminate major from minor chords, and (4) rate chord sequences for expectation. In the modeling study, we created rate-place metamers of pitch stimuli using the average rate output of a well-known auditory model (Zilany, Bruce, and Carney, 2014). Model parameters were adjusted to include HL that matched the profiles of listeners with HL in the behavioral study. The resulting stimuli were then tested on the same battery of behavioral tasks with NH and HL listeners, to measure effects of HL on pitch cues carried in the rate-place code.

Results: Preliminary data suggest that HL results in mild deficits in single-pitch perception (task 1), with severe deficits for discriminating a target pitch masked by concurrent pitches (task 2). However, some HL listeners retain ability to discriminate chords (task 3) and perceive chords in musical context (task 4). Overall, modeling results suggest that degraded rate-place cues can account for worsened pitch perception in all tasks.

Conclusions: Our findings suggest that although mild-to-moderate HL impairs discrimination of a single pitch in a mixture of pitches, ability to perceive chords and harmony is relatively spared, suggesting that higher-level processes may compensate for degraded sensory input. Potential mechanisms underlying perception of chords and harmony may differ from single pitch perception mechanisms and warrant further study.

SA192. Mid-Bandwidth Loudness Depression for Sinusoidally Amplitude-Modulated Tones

Yi Shen^{*1}, Erik Petersen¹, Calista Shohet¹, Stephen Neely²

¹*University of Washington*, ²*Boys Town National Research Hospital*

Background: Previous research has shown that the loudness of narrowband noise varies with its bandwidth. As bandwidth increases while fixing the center frequency and overall sound pressure level, the perceived loudness of the narrowband noise initially decreases, falling below that of the pure tone, and then increases again at higher bandwidths. This non-monotonic relationship, characterized by a reduction in loudness at mid-bandwidths relative to pure tones, is referred to as mid-bandwidth loudness depression. The present study investigates this phenomenon across a wide range of stimulus levels and frequencies using sinusoidally amplitude-modulated (SAM) tones to precisely control envelope fluctuations associated with bandwidth variations.

Methods: Twenty participants with normal audiograms were tested monaurally using insert earphones in a sound-treated booth. A rapid quick-Categorical-Loudness-Scaling (qCLS) procedure was used to assess loudness profile across five levels (20, 40, 60, 80, and 100 phons) and frequencies ranging from 250 to 8000 Hz. Stimuli were SAM tones with bandwidths defined by the spacing between upper and lower sidebands: 0 (unmodulated pure tones), $\frac{1}{4}$ octave, 1 octave, 40 Hz, and 200 Hz. The modulation depth was fixed at 100% and the modulation rate was half of the stimulus bandwidth. On each trial, the participant rated the loudness of the presented SAM tone using 11 categories ranging from “Can’t Hear”, “Very Soft”, to “Very Loud” and “Too Loud”. The qCLS procedure adaptively updated a parametric model of the participant’s loudness profile and optimized the frequency and level of the stimulus for the subsequent trial.

Results: The findings confirmed the presence of mid-bandwidth loudness depression in normal-hearing listeners. The effect was most pronounced at lower sound levels and higher frequencies, with the largest differences in equal-loudness contours exceeding 10 dB. The specific bandwidth at which the greatest loudness depression occurred varied depending on both stimulus level and frequency.

Conclusions: These results replicate and extend previous findings, demonstrating that mid-bandwidth loudness depression occurs across a broader stimulus space than previously studied. The findings underscore the critical role of temporal envelope fluctuations in shaping loudness perception.

SA193. Cues in Auditory Discrimination and Identification of Time of Day for Natural Soundscapes

Frederic Apoux^{*1}, Karine Malysheva², Halyna Chernenko², Veronika Kondratieva², Anton Kurapov², Jérôme Sueur³, Sylvain Haupert³, Brian Moore⁴, Christian Lorenzi⁵

¹*Ecole Normale Supérieure*, ²*Taras Shevchenko National University of Kyiv*, ³*Muséum national d'Histoire naturelle*, ⁴*University of Cambridge*, ⁵*Ecole normale supérieure*

Background: Previous work suggests that human listeners can detect structure in natural soundscapes, and that spectral information is involved in the discrimination of these ecological scenes (e.g., Apoux et al., 2023). The present study extended this work to the perception of time of day, and assessed which acoustic cues (fine spectral detail, temporal envelope, temporal fine structure) mediate performance.

Methods: Normal-hearing adults were asked to perform time of day identification and discrimination for four broadly defined moments: Dawn, Midday, Dusk, Night. Identification used a single-interval 4AFC task; discrimination used a three-interval oddity task. Soundscapes were scenes recorded in three natural habitats (two temperate forests, one tropical) with minimal anthropogenic noise. To probe cue use, scenes were processed with a noise vocoder to alter temporal fine structure (TFS) cues and selectively degrade spectral or temporal information by manipulating the number of bands and the cutoff of the envelope filter.

Results: Participants showed poor identification of time of day, even when provided with feedback and after several hours of familiarization. In contrast, soundscape discrimination based solely on the time of recording was always very reliable. In fact, all the manipulations performed to degrade the signals generally resulted in limited effects. Overall, discrimination was especially robust to manipulations of envelope and TFS. Selective degradations of spectral information reduced performance in some extreme conditions, suggesting that decisions relied on gross spectral cues (e.g., ambient-noise). The impact of spectral degradation varied by habitat, indicating that the effective spectral resolution used by listeners depends on scene statistics specific to each forest type.

Conclusions: Human listeners struggled to identify time of day based on 1-s samples of natural soundscapes. However, they could discriminate these short samples very reliably. This was found to be true for soundscapes recorded from three different habitats. The soundscape recorded closer to the equator led to the best discrimination performance, perhaps partly because of greater biodiversity. The identification-discrimination dichotomy suggests that while human listeners are sensitive to acoustic variations related to differences in time of day, they cannot consistently label these variations.

Despite inconclusive data, it is suggested that biophony – the collective sound produced by animal vocalizations – did not play a critical role in time of day discrimination, probably because this cue was often inconsistent in the short duration of the samples used here.

Consistent with previous work, the present results suggest that human listeners can use spectral and temporal cues, but that they base their decisions primarily on spectral cues, the resolution of which depends on the habitat. However, none of these cues were essential for performance of the task.

Future work should test individuals with hearing loss and evaluate device algorithms that maintain spectral integrity in complex, naturalistic scenes.

SA194. Source-Location Binding Errors in Auditory Scene Perception

Sagarika Alavilli¹, Lakshmi Narasimhan Govindarajan², Josh McDermott²

¹*Harvard University*, ²*Massachusetts Institute of Technology*

Background: Where was my phone ringing from? Humans have some ability to discern both what sounds are present in a scene and where sounds are located. However, little is known about how identity and location are jointly represented ("bound" together), especially in multi-source scenes. In particular, it remains unclear whether humans make auditory binding errors in which source identities and locations are individually represented accurately but then mis-associated.

Methods: We probed for binding errors using an auditory search task. Participants listened to auditory scenes composed of between 1 and 5 natural sounds (e.g., applause, fireworks, laughter). Sounds were played from a speaker array, with sources being presented a minimum of 20 degrees apart. Participants were cued with a target sound either before or after the scene and were instructed to report the location of the target. We measured binding errors as errors in which the reported source location was close to the location of one of the other sources in the scene. To assess whether these errors could be explained without binding-specific failures, we simulated a null model that made errors either due to noise about the true source location or guessing (as if the target source was not heard).

Results: On average, localization error increased with the number of sources in the scene, and was higher in the post-cue compared to the pre-cue condition. In the post-cue conditions with 4 or 5 sources, participants made substantially more binding errors than the null model, suggesting that some such errors are caused by a failure to correctly associate sound identity with spatial location. By contrast, binding errors in the pre-cue conditions were no greater than predicted by the null model.

Conclusions: Humans maintain a joint representation of sound identity and spatial location for auditory scenes, but this representation becomes susceptible to errors in large scenes. In conditions without directed attention, some such errors appear to be due to binding failures, suggesting a limitation on auditory feature integration.

SA195. How Timbre and Harmonicity Affect Voice Perception in Polyphonic Music: A Comparison of Voice Enumerability and Discrimination Across Listener Groups

Lisanne Bogaard¹, Juraj Mesik¹, Andrew Oxenham¹

¹*University of Minnesota*

Background: Listeners use multiple cues for stream segregation in speech and music. While well studied in speech, these cues are less understood in music. Previous work has shown that inharmonicity impairs listeners' ability to count the number of voices and hear out individual voices in polyphonic music, when all the voices share the same timbre. Here we tested whether differences in timbre improve performance and mitigate the detrimental effects of within-voice inharmonicity. Performance was tested in both hearing-impaired (HI) listeners and age-matched listeners with normal hearing (aNH).

Methods: Participants listened to short polyphonic instrumental passages with voices that were either of the same timbre, similar timbre (i.e., same family of instruments), or different timbres. The voices in each passage were either all harmonic or all inharmonic (with harmonics randomly jittered by $\pm 30\%$ of the fundamental frequency, F0). Two tasks were

tested: (1) voice counting, where the number of voices could be between 1 and 4, and (2) melody tracking, where listeners judged whether a probe tone matched the last note of a cued voice within a passage consisting of 2 to 4 voices.

Results: In the counting task, preliminary results confirm earlier studies, indicating that accuracy declines with increasing number of voices, and that inharmonicity degrades performance, particularly for small numbers of voices. Timbral differences between voices within each passage seem to improve performance, with early data suggesting improvements both for similar-timbre and different-timbre conditions in the aNH group, but only for the different-timbre condition in the HI group. In the melody tracking task, performance dropped overall with inharmonicity, with preliminary data suggesting a relatively weak trend toward benefits based on timbral differences for both listener groups.

Conclusions: Preliminary results suggest that timbral differences between voices may support stream segregation differently for aNH and HI listeners: whereas aNH listeners may benefit already from subtle timbral differences, HI listeners may require more salient differences. Overall performance in both tasks and in both groups decreased with increasing number of voices and with inharmonicity.

[Supported by NIH grant R01 DC005216.]

SA196. Auditory Roughness Drives Subjective Aversion and Sustained Neural Synchronization

Noémi Gonçalves^{*1}, Boris Gourévitch², Luc Arnal¹

¹*Institut de l'Audition, IHU reConnect*, ²*Institut de l'Audition, INSERM, Institut Pasteur, CNRS*

Background: The ability to detect salient sounds and react rapidly is vital for survival. Among acoustic features, loudness (sound intensity) and roughness (fast amplitude modulations between 30–150 Hz) are particularly effective at capturing attention, as exploited by screams and alarm signals. Previous work has shown that roughness non-linearly enhances auditory aversion and accelerates reactions, possibly via sustained auditory steady-state responses (ASSRs) in non-classical auditory pathways linked to startle circuits. Since this reflex typically activates above 60 dB, we investigated whether aversive responses to roughness depend on sound level. We tested two hypotheses: (i) increasing sound level amplifies sensitivity to roughness, and (ii) heightened aversion to roughness reflects stronger ASSRs.

Methods: We measured behavioral (subjective aversion) and EEG responses in 29 normal-hearing participants exposed to click trains (10–250 Hz) at four intensities (40, 50, 60, 70 dB).

Results: Aversion increases linearly with sound level. Notably, the non-linear sensitivity to roughness emerges only at higher intensities, peaking around 40 Hz. EEG revealed robust ASSRs with maximal responses at 40 Hz. However, unlike aversion, 40 Hz ASSR amplitude increases linearly with sound level. Across participants, stronger roughness aversion correlates with larger ASSRs.

Conclusions: These findings show that roughness drives sustained neural synchronization and that sound level enhances roughness sensitivity at higher intensities. Entrainment around 40 Hz may explain why rough sounds are attention-capturing and supports the use of ASSRs as individual markers neural markers of salience sensitivity.

SA197. Auditory Processing of Acoustic Cues and Speech Recognition in Noise in Children With Mild to Moderate Hearing Loss

Charlotte BENOIT*¹, Laurianne Cabrera²

¹CNRS-Université Paris Cité, ²Université de Paris - CNRS

Background: Sensorineural hearing loss (SNHL) is associated with reduced speech perception in noise, a difficulty thought to arise from impaired temporal and spectral resolution in addition to reduced audibility. Understanding how congenital mild-to-moderate SNHL affects auditory development in children is critical, as speech-in-noise perception underpins language learning. This study aimed to characterize auditory processing, speech-in-noise perception, and related cognitive skills in children with SNHL compared to age-matched peers with normal hearing (NH).

Methods: Twelve French-speaking children with mild-to-moderate bilateral SNHL (ages 4.5–10 years) completed a battery of auditory and cognitive tasks. Auditory measures included slow (4 Hz) and fast (20 Hz) amplitude modulation (AM) and frequency modulation (FM) detection, and spectral ripple discrimination (0.5 and 2 Ripple Per Octave). Speech-in-noise (SIN) perception was assessed using fricative consonant and disyllabic word identification tasks, each presented in stationary speech-shaped noise (SSN) and two-talker babble noise. Stimuli were amplified to compensate for audibility losses, with a maximum presentation of 85 dB SPL. Cognitive assessments included non-verbal working memory (Corsi blocks) and receptive vocabulary (PPVS). Performance was compared to a normative dataset of 66 age-matched children with NH, using z-scores to situate SNHL outcomes relative to the distribution of children with NH.

Results: Children with SNHL demonstrated AM detection thresholds comparable to NH peers, with some children performing slightly better. In contrast, FM detection thresholds were consistently elevated, especially at 20 Hz. Spectral resolution was also reduced, with a task almost unfeasible. For SIN perception, children with SNHL required substantially higher SNRs than NH peers to identify both consonants and words, across both SSN and babble conditions. Group with SNHL z-scores confirmed these observations with SIN identification and FM detection thresholds far outside the NH range. Vocabulary scores were reduced in nearly all children with SNHL, whereas non-verbal working memory seemed to be preserved. Preliminary correlation analyses revealed no significant associations between pure-tone thresholds and auditory or SIN outcomes, suggesting that audibility alone cannot account for the observed variability.

Conclusions: This preliminary study shows that children with mild-to-moderate SNHL present specific auditory processing deficits—namely in FM and spectral resolution—alongside preserved AM detection. These deficits translate into poorer SIN perception, regardless of target or masker, and are accompanied by reduced vocabulary knowledge. Importantly, the absence of a strong link between audibility and performance emphasizes the role of supra-threshold auditory and linguistic mechanisms in shaping communication outcomes. Clinically, these findings underscore the need for comprehensive assessments that extend beyond audiograms to include auditory processing and language evaluations. Future work with a larger sample will clarify developmental trajectories and inform rehabilitation strategies aimed at improving everyday communication in children with SNHL.

SA198. Listening Effort During Speech Perception in Noise: A Comparison of Binaural and Monaural Listening

Julia Gallagher^{*1}, Stephanie Bronfman¹, Tomo Curran¹, Chloe Danley¹, James Lawler¹, Xingyu Zhang¹, Hari Bharadwaj¹, Aravindakshan Parthasarathy¹

¹*University of Pittsburgh*

Background: Speech perception deficits are often overlooked in individuals with single sided deafness (SSD) because the “better ear” is assumed to compensate. Yet, SSD removes binaural benefits such as summation and spatial release from masking, and the individuals with SSD tend to have poorer academic performance and report psychosocial difficulties compared to binaural listeners. Additionally, binaural listeners exhibit a right ear advantage for speech, reflecting left-hemisphere language dominance. Since the side of deafness varies across SSD, here, we asked if unilateral hearing (as a proxy for SSD) differentially taxes speech perception in noise (SPIN) performance and attentional control.

Methods: Fifty-seven right-handed, normal hearing, native English-speaking adults aged 18-40 years were recruited using an online platform (Prolific). Participants completed a headphone check, and were tested using a custom, open source online psychophysical testing platform developed by us. Tests included speech perception in noise tests under informational masking (Matrix Sentences) and energetic masking (Modified Rhyme test) paradigms, and tests of distraction suppression (Auditory Stroop). Each participant completed these tests in a binaural condition, monaural-right condition, and monaural-left condition randomized in presentation order.

Results: Improved performance in binaural conditions compared to monaural conditions, and improved performance in the right ear compared to the left was observed for SPIN performance under informational masking, consistent with binaural and right ear advantages. This binaural advantage in behavioral performance was not present under energetic masking. However, participants exhibited slower reaction times in the monaural-left condition, consistent with increased listening effort. Auditory Stroop cost did not differ between binaural and monaural-left conditions but was larger in the monaural-right condition, indicating greater distraction suppression demand when relying on right ear input.

Conclusions: These findings from a unilateral-listening paradigm suggest that ear of input has a significant effect on SPIN. Under informational masking, right-ear listening confers an accuracy advantage over left-ear listening, while also exhibiting greater Stroop costs, suggesting a trade-off in attentional control demands, while energetic masking may reveal subtler effects in listening effort. Because participants self-reported normal hearing and testing was conducted online, results should be interpreted as simulated SSD, with ongoing studies testing the generalizability of these results in listeners with SSD. Clinically, quantifying listening effort alongside SPIN may inform counseling and intervention decisions and reveal hitherto hidden listening deficits in individuals with SSD.

SA199. Six1 and Eya1 Reprogram Postnatal Cochlear Supporting Cells Into Hair Cells

Xiaohui Ma¹, Pin-Xian Xu^{*1}

¹*Icahn School of Medicine at Mount Sinai*

Background: Mammalian cochleae fail to regenerate hair cells (HCs) after damage because postnatal supporting cells (SCs) lack regenerative capacity. We previously showed that Six1

and its cofactor Eya1 can induce nonsensory epithelial cells to differentiate into HCs in embryonic cochlear explants.

Methods: Using Sox2-CreER, we induced Six1 or Six1-Eya1 in SCs at postnatal day (P)5-P7 and analyzed cochleae 2 weeks later. To assess whether HC loss sensitizes SCs to reprogramming, we performed diphtheria toxin-mediated HC ablation at P7.

Results: In undamaged ears, Six1 alone converted a small percentage of SCs into Myo7a⁺ cells, whereas Six1-Eya1 together induced more SCs into Myo7a⁺ cells, indicating that Eya1 enhances the ability of Six1 in reprogramming SCs into HCs. In damaged cochlea, Myo7a⁺ cells induced by Six1 or Six1-Eya1 together were increased compared to those in the undamaged cochlea. EdU tracing indicated direct SC-to-HC conversion rather than proliferation-mediated replacement. Notably, a small subset of regenerated Myo7a⁺ cells induced by both Six1-Eya1 in the damaged cochlea was Sox2⁻/Prestin⁺, indicating maturation toward outer HCs.

Conclusions: These findings demonstrate that Six1-Eya1, promotes postnatal SC-to-HC reprogramming.

SA200. Early BMP4 Modulation Alters Electrophysiological Activity in Human iPSC-Derived Otic Organoids

Nathaniel Carpena^{*1}, So-Young Chang², Ji-Eun Choi³, Jae Yun Jung³, Min Young Lee³

¹*Dankook Institute of Medicine and Optics, Dankook University*, ²*Beckman Laser Institute Korea, Dankook University*, ³*Dankook University Hospital*

Background: Human induced pluripotent stem cell (hiPSC)-derived inner ear organoids offer a powerful model for investigating early otic development and hair cell function in vitro. While BMP4 is known to play a key role in ectodermal patterning, its dosage-sensitive influence on neurosensory specification and functional maturation in organoid systems remains incompletely characterized. Although low BMP4 levels favor neural ectoderm and high levels promote non-neural or epidermal fates, it is the intermediate BMP signaling window that is thought to best support otic induction. However, how such modulation impacts downstream electrophysiological output has not been fully explored.

This study evaluates the effects of graded BMP4 exposure during early ectodermal induction on the morphological, molecular, and functional development of hiPSC-derived otic organoids, with a particular focus on spontaneous extracellular activity assessed via multi-electrode array (MEA) platforms.

Methods: Organoids were generated using a stepwise differentiation protocol, in which BMP4 concentrations were varied during the first three days of culture. Samples were collected at multiple timepoints for imaging and immunofluorescent staining with epithelial and hair cell markers, including E-cadherin and Myosin VIIa. Between Days 75 and 100, organoids were transferred to MEA chips to record spontaneous spike activity, allowing comparison of firing frequency, burst organization, and network synchrony across conditions.

Results: Organoids exposed to intermediate BMP4 levels exhibited organized epithelial structures, strong E-cadherin localization, and a higher frequency of Myo7a-positive cells. These groups demonstrated robust and temporally structured MEA signals, including consistent spike trains and coordinated bursting across multiple electrodes. In contrast, both low and high BMP4 treatments produced irregular epithelial morphologies and either weak or asynchronous MEA signals. While lower BMP4 levels appeared to enhance general neural

excitability, they often lacked clear epithelial domains, suggesting an imbalance in neurosensory architecture. Excess BMP4 exposure reduced overall activity, likely due to lineage diversion away from both neural and otic fates.

Conclusions: Early modulation of BMP4 signaling exerts a lasting effect on the functional output of otic organoids. Optimizing BMP4 exposure supports balanced otic epithelial and neural specification, leading to more robust electrophysiological maturation. These findings advance our understanding of morphogen-guided inner ear development and contribute to the refinement of stem cell-based auditory disease models and therapeutic platforms.

SA201. Robust Hair Cell Regeneration out of LGR5+ Primary Cochlear Progenitor Cells Derived From Adult Mice

Tobias Pieper¹, Georgina Fenton¹, Robert J. Stokroos², Louise Straatman¹, Natalia Smith-Cortinez^{*1}

¹University Medical Center Utrecht, ²Head and Neck Surgery, University Medical Center Utrecht

Background: Supporting cells (SCs) in the cochlea give rise to hair cells (HC) in embryonic development. SCs in adult mice express the adult-tissue derived stem cell marker LGR5. Promoting hair cell (HC) regeneration using neonatal mouse models has been the focus of extensive research. Neonatal SCs have increased progenitor potential compared to adult and only a few studies (including ours) have shown survival of LGR5+ SCs after severe HC loss in adult mice. In mammals, there is no evidence for spontaneous HC regeneration in adulthood. However, three-dimensional cultures have allowed the expansion and experimentation of cochlear organoids. Here, we evaluated HC differentiation from cochlear organoids from primary LGR5+ progenitor cells derived from adult mice.

Methods: Adult (postnatal day 40-60) male and female *Lgr5-eGFP-IRES-creERT2* heterozygous normal hearing mice were used. Cochleas were harvested and digested to single cell suspension. Cells were filtered, mixed with Matrigel and 3D drops were made. Cells were grown on expansion medium (EM) for 10 days and differentiation medium (DM) for an extra 10 days. Organoids were fixed, permeabilized and processed for immunofluorescence confocal microscopy. We compared the published EM-M and DM-M (McLean et al 2017, doi: 10.1016/j.celrep.2017.01.066) and EM-X and DM-X (Xia, et al 2023, doi: 10.1016/j.stemcr.2022.11.024), to optimized media developed in our lab (OptiEM and OptiDM). The OptiEM contained surrogate wnt and r-spondin, to activate Wnt signalling; and the OptiDM contained recombinant sonic hedgehog and LY411575, to inhibit Notch signalling.

Results: We observed similar number of cochlear organoids 10 days after isolation in the different EM evaluated; however the size (area) of organoids was significantly larger in OptiEM. We found enhanced LGR5 expression in OptiEM compared to EM-M and EM-X. Importantly, in contrast to DM-M and DM-X, we observed robust expression of MYO7A in a structured row of cells located at the rim of the organoids, most of which had HC-like shape, in OptiDM. We are currently characterizing prestin expression, FM1-43 uptake, phalloidin staining and analyzing transcriptomic data in our newly developed culture conditions.

Conclusions: LGR5+ progenitor cells derived from adult normal hearing mice are able to produce cochlear organoids in different EMs. Enhanced LGR5 expression was observed in expansion conditions when culturing with surrogate wnt and r-spondin compared to published media containing CHIR99021 (EM-M and EM-X). Robust MYO7A expression,

indicative of sustained and organized HC generation out of LGR5⁺ progenitor cells, was achieved after activating sonic hedgehog and inhibiting Notch signalling. These results suggest that LGR5⁺ cochlear progenitor cells can be activated to promote HC regeneration even when derived from adult mice.

SA202. Clonal Dynamics Reveal Distinct Populations of Proliferative Cells in the Mouse Utricle Post Injury

Sushobhan Biswas^{*1}, Macey Soltis¹, Ruiqi Zhou¹, Samuel J. Leonard¹, Taha A. Jan¹

¹*Vanderbilt University Medical Center*

Background: The utricle is a vestibular sensory organ in the inner ear that plays a vital role in maintaining balance and spatial orientation. It contains specialized mechanoreceptors known as hair cells (HCs), which detect linear acceleration. In mammals, regeneration of HCs from interdigitated supporting cells (SCs) primarily occurs during early postnatal development. Following in vivo damage, the utricle exhibits a regenerative response in which SCs give rise to new HCs through two mechanisms: transdifferentiation and mitotic regeneration. The mitotic mechanism of regeneration is important for tissue homeostasis during injury. Whether there are intermediate cell states with a hierarchy of asymmetrical cell division and replenishment of existing cells in the mouse utricle post injury in vivo is currently unknown. Here, we investigate the clonal dynamics of mitotically regenerated cells following in vivo hair cell damage.

Methods: The molecular mechanisms governing lineage segregation of injury-activated proliferative cells remain poorly understood. To investigate this, we examined cellular heterogeneity within the injured utricle using an established in vivo hair cell ablation model (Pou4f3DTR), combined with two different inducible Cre recombinase lines and a mitotic cell division marker. Hair cell damage was induced at postnatal day 1 to selectively ablate hair cells. To study mitotic regeneration, we employed a triple transgenic model (Pou4f3DTR; Ki67CreERT2; Rosa26mTmG) for fate mapping of proliferating cells. Single-cell RNA sequencing (scRNA-seq) was performed following lineage tracing to interrogate clonal cells.

Results: Adult utricles in the damage model exhibit significant hair cell loss compared to undamaged wild-type controls. Cell proliferation, as indicated by EdU incorporation, is elevated in both the hair cell and supporting cell layers relative to wild-type utricles. Histological analysis using our triple transgenic model (Pou4f3DTR; Ki67CreERT2; Rosa26mTmG) reveals that cells undergoing mitosis undergo a permanent color switch to EGFP. Quantitative assessment of clonal fate and proliferation dynamics identifies distinct clusters of proliferative cells organized in a hierarchical structure, involving both transient amplifying and long-term proliferative populations.

Conclusions: In mammalian utricles, where regenerative capacity is limited, clonal tracing studies using transgenic animal models have advanced our understanding of cell fate behavior and its regulation under injury conditions. Through these studies, we demonstrate that clonal dynamics may converge toward a critical state defined by characteristic clone sizes, offering valuable insights into the mechanisms governing clonal behavior in damaged utricles in mice.

SA203. GSK3 β –EGF–TGF β Crosstalk Drives Vestibular Supporting Cell Proliferation

Jun He^{*1}, Tian Wang¹, Yuheng Cai¹, Ahmad Mahmoudi¹, Jessica Fuhriman¹, Alan Cheng¹

¹*Stanford University*

Background: The mammalian utricle displays limited spontaneous hair cell (HC) regeneration and proliferation. Wnt/ β -catenin pathway plays diverse roles in the inner ear, including supporting cell (SC) proliferation and HC differentiation in both the cochlear and vestibular organs. Previous studies showed that overexpression of β -catenin, the central mediator of canonical Wnt signaling, increases proliferation and HCs regeneration in the neonatal utricle. GSK3 β functions to phosphorylate β -catenin, rendering it unstable and thereby inactivating the Wnt/ β -catenin pathway. However, GSK3 β also acts on numerous other pathways, such as NF- κ B synthase and mTORC1 pathways. Previous research showed that a combination of factors (including GSK3 inhibitors) increased proliferation in the neonatal cochlea (McLean et. al., 2017) and utricle (Kozlowski et al., 2020), but whether this occurs through Wnt/ β -catenin signaling remains unclear. Here, we examined the mechanisms by which GSK3 inhibition regulate SCs proliferation in the neonatal mouse utricle.

Methods: Utricles were dissected from postnatal (P) 3 C57BL/6 wildtype mice in aseptic conditions. Whole organs were cultured in serum-free media with CHIR, EGF, bFGF, IGF-1, VPA, pVc, TGF β i, and EGFR inhibitor. Neomycin was added for 24 hours to induce HC loss, followed by 5 days of culture with EdU to label proliferating cells. Tissues were stained for EdU, Myosin7a, Sox2 and counterstained with DAPI. EdU+ Sox2+ SCs were quantified in the striolar and extrastriolar regions. Furthermore, utricles from UBCCreERT2/+; Ctnnb1^{fl(exon3)}/+ and UBCCreERT2/+; Ctnnb1^{flox/flox} mice were treated by 4-hydroxy-tamoxifen to ablate or stabilize beta-catenin.

Results: The combination of seven factors robustly increased EdU+ Sox2+ SCs in both the striolar and extrastriolar regions of the neomycin-damaged utricles. Removing CHIR or TGF β i from the cocktail completely abolished proliferation throughout the utricle. While the absence of EGF or VPA from the cocktail significantly reduced proliferation in the extrastriola, removing bFGF, IGF-1, pVc had no significant effects, suggesting that these three factors are dispensable. Co-treatment with CHIR and TGF β i induced proliferation in the striola, whereas 4 factors (CHIR, EGF, VPA, and TGF β i) were needed to induce proliferation in the extrastriola, suggesting spatially distinct mitogenic response. While CHIR alone was insufficient to induce proliferation, there were many Edu+ SCs when CHIR was co-administered with EGF, VPA and TGF β i. Replacing CHIR with Wnt agonist or beta-catenin overexpression did not induce proliferation. Finally, β -catenin deletion did not prevent proliferation induced by 4F (CHIR EGF, VPA and TGF β i).

Conclusions: CHIR is necessary but insufficient to induce supporting cell proliferation in the neonatal mouse utricle. The mitogenic response differs between striolar and extrastriolar supporting cells: the former responds to CHIR and TGF β i, whereas the latter require the combination of CHIR, TGF β i, EGF, and VPA. Finally, CHIR induced proliferation in a Wnt/ β -catenin signaling independent manner.

SA204. Pharmacological Inhibition of TGF-B Signaling Impairs Supporting Cell Proliferation in the Injured Avian Basilar Papilla

Xiangyu Ma^{*1}, Stefan Heller¹, Nesrine Benkafadar²

¹*Stanford University School of Medicine, Institute for Stem Cell Biology and Regenerative Medicine*, ²*Stanford University School of Medicine, Institute for Neurosciences of Montpellier (INM) University Montpellier*

Background: Irreversible hearing loss in mammals stems from an inability to regenerate sensory hair cells. In contrast, birds robustly regenerate hair cells through the proliferation and subsequent differentiation of supporting cells, providing a model to discover pro-regenerative pathways. Our prior work identified a key signaling pathway that regulates supporting cell S-phase entry after hair cell injury. To further map the broader regulatory network, we mined our previously generated single-cell RNA-sequencing (scRNA-seq) datasets of the chicken basilar papilla (BP) across damage and regeneration time courses. This analysis identified TGF- β signaling as a candidate pathway with dynamic, time-ordered expression.

Methods: We analyzed scRNA-seq data from multiple post-injury time points to characterize expression changes in TGF- β pathway components and downstream targets. For functional validation in vivo, we performed lateral semicircular canal injections in post-hatch day 7 (P7) chickens. We co-administered the ototoxic antibiotic sisomicin with the pharmacological TGF- β inhibitor ITD-1 to suppress pathway activation in the damaged sensory epithelium. Supporting cell proliferation was assessed 48 hours post-injection by quantifying EdU incorporation, comparing ITD-1-treated BPs to vehicle controls subjected to identical ototoxic injury.

Results: Transcriptomic analysis revealed time-ordered modulation of TGF- β pathway genes during the transition from hair cell loss to the onset of regeneration. In situ, we observed a marked increase in expression of the ligand TGFB2 mRNA, coinciding with the onset of supporting cell proliferation. Pharmacological inhibition of TGF- β signaling in vivo significantly reduced EdU incorporation in supporting cells after ototoxic injury compared to controls.

Conclusions: Our findings implicate TGF- β signaling as a positive regulator of supporting cell proliferation in the avian auditory epithelium. The temporally distinct expression of TGF- β pathway components suggests a finely tuned regulatory role. Together with our prior work, these results support a model where precise timing and cooperation between TGF- β and other signaling pathways orchestrate cell cycle re-entry. Defining the temporal sequence and combinatorial interactions of these pathways is essential to elucidate the mechanisms of hair cell regeneration and to inform future therapies for human hearing loss.

Special Session 1: Restoring the Sixth Sense Through Vestibular Implantation - Clinical Trial Outcomes, Patient Perspectives and New Research Horizons

2:30 p.m. - 4:30 p.m.

Meeting Room 208ABC, Floor 2

Restoring the Sixth Sense Through Vestibular Implantation – Clinical Trial Outcomes, Patient Perspectives and New Research Horizons

First-In-Human Trial of the Labyrinth Devices Multichannel Vestibular Implant - Interim Results After 1-9 Years of Continuous Daily Use

Celia Fernandez Brillet¹, Margaret R Chow¹, Andrianna I. Ayiotis¹, Evan O. Vesper¹, Katherine N Mueller¹, Desi P. Schoo¹, Stephen Bowditch¹, Kelly E. Lane¹, Claudia N Lee¹, Lauren Trainer¹, Peter J. Boutros¹, Brian J. Morris¹, John P. Carey¹, Bryan K. Ward¹, Zubair Khan¹, Charles Della Santina*¹

¹*Johns Hopkins School of Medicine*

Individual Abstract: Purpose: Describe interim results for the first-in-human clinical trial of long-term, continuously motion-modulated prosthetic stimulation using the MVI™ Multichannel Vestibular Implant System developed by Labyrinth Devices LLC and MED-EL GmbH.

Methods: Twenty adults with bilateral vestibular hypofunction (11 ototoxic; 9 idiopathic/non-ototoxic/non-central) underwent unilateral implantation from August 2016 to May 2025. Duration from symptom onset to implantation ranged from 2-24 years. We assessed post-activation binocular 3-dimensional vestibulo-ocular reflex (3D VOR) responses to prosthetic stimulation and pre- to post-implantation changes in VOR responses to yaw, LARP and RALP head-on-body impulses and 0.1-2 Hz whole-body yaw rotation; pure tone and speech audiometry; dynamic visual acuity; clinical tests of posture and gait; and validated patient-reported outcome instruments for disability (Dizziness Handicap Inventory, Vestibular Activities of Daily Living) and health-related quality of life (SF36 and Health Utilities Index [HUI3]).

Results: Every implant recipient has used the system daily since device activation. Seven wear it 24 hr/day; others take it off while in bed. All but one have electrically-evoked VOR responses (typically ranging from ~5-100°/s and aligned approximately with the stimulated canal) for at least one electrode for each implanted canal. Rotary chair VOR responses are greater with motion-modulated stimulation than without. Motion perception thresholds are below VOR thresholds. Hearing sufficient for unaided telephone use was preserved in 11 of 19 implanted ears. Posture, gait, dizziness handicap, vestibular disability and health-related quality of life (quantified by SF36-derived SF6D utility) improved significantly compared to preop for the group. HUI3, which more heavily weights hearing, did not significantly change.

Conclusions: Vestibular implantation can be performed as an outpatient surgery while preserving useful hearing. Motion-modulated input generates motion percepts and 3DVOR responses consistent with semi-selective stimulation of each implanted canal, improving postural stability, gait, patient-reported disability and quality of life.

Rick Stephens, *none*

Individual Abstract: Mr. Stephens will relate his experiences as both an individual who suddenly lost vestibular function due to gentamicin ototoxicity and the first person to undergo vestibular implantation and continuous, long-term motion-modulated stimulation.

Constant “Baseline” Electrical Stimulation Can Improve Function in Patients Implanted With Vestibulo-Cochlear Implants

Gautier Grouvel¹, Julie Corre¹, Jean-Francois Cugnot¹, Samuel Cavuscens², Maurizio Ranieri², Anissa Boutabla², Raymond van de Berg³, Stephanie Armand², Nils Guinand¹, Angelica Perez Fornos*¹

¹*Geneva University Hospitals*, ²*University of Geneva*, ³*Maastricht University Medical Center+*

Individual Abstract: Prototypes of vestibular implants are under development to rehabilitate patients with bilateral vestibulopathy (BV), mimicking the physiology of the vestibular system. An alternative and simplified approach consists in delivering only constant electrical stimulation to restore a “baseline” activity in the vestibular system. This study aimed to quantify the benefits of such a “baseline” stimulation (BS) delivered to semicircular canal afferents during prolonged periods of activation.

Two female patients with BV received a modified cochlear implant providing 3 extra-cochlear electrodes implanted in the semicircular canals. The patients’ speech processor was programmed to deliver a BS to the posterior semicircular canal for a period of 2.5 months. Objective and subjective measurements (gait analyses, questionnaires) were acquired throughout the stimulation period and afterwards over 6 sessions. DHI scores and number of steps for the tandem walk task were also analysed.

For patient-1, DHI scores improved from 52 to 30 throughout the BS, reflecting clinically relevant changes. After BS deactivation, DHI score increased to 48, representing a decline of functional status. The number of steps in the tandem walk task increased from 2 to 10 steps. Results for patient-2 do not present any changes during the BS.

Results in at least one patient demonstrate that vestibular deficits were reduced during the BS, complemented by positive patient feedback: “the implant allows me to walk in a straight line”. Objective and subjective gains disappeared when BS was deactivated. While this stimulation shows promise, its effectiveness may vary among patients, highlighting the need for devices that employ stimulation methods closer to human physiology.

Cognitive Assessment in Human Patients Equipped With a Vestibulo-Cochlear Implant

Individual Abstract: Vestibular information improves navigation in rodents, but studies in human subjects with vestibular damage have been less conclusive. Herein, we investigated

the effects of short-term prosthetic vestibulo-cochlear implant (VCI) stimulation on navigation and neuropsychological function in patients with bilateral vestibulopathy. Specifically, two patients with severe bilateral vestibulopathy who underwent VCI surgery in 2021 completed a battery of neuropsychological tests, the Corsi Block Test (CBT), Digit Span Test (DST), and an egocentric mental transformation task (EMT), as well as a virtual reality-based spatial navigation task. This navigation task required subjects to perform a “return-to-home” challenge modeled on the triangle completion test under two distinct conditions: a dynamic condition involving yaw rotation and stepping in place, and a static condition in which navigation was performed via controller buttons while the head and body remained stationary. Testing was conducted at three time points: at least one month before stimulation, during active VCI stimulation, and at least one month after stimulation had ceased. During stimulation, both subjects demonstrated improved performance on the DST and EMT, while one also improved on the CBT. Furthermore, both subjects showed enhanced accuracy (angular error) and precision (standard deviation of angular error) in both dynamic and static conditions during VCI stimulation, with a subsequent decline in performance once stimulation was turned off. These preliminary findings suggest that VCI stimulation may positively influence higher-level cognitive and navigational functions in patients with bilateral vestibulopathy.

Optimization of Stimulation Parameters for a Vestibular Prosthesis: From Meniere’s Pacing to Bilateral Modulated Vestibular/Cochlear Stimulation

Leo Ling¹, Yoshiko Kojima², Christopher Phillips³, Shawn Newlands⁴, Jay Rubinstein⁵, James Phillips*¹

¹University of Washington, Oto-HNS Dept., ²University of Washington, ³University of California Davis, ⁴University of Rochester Medical Center, ⁵University of Washington

Individual Abstract: Introduction: Vestibular loss is highly debilitating. Limited options exist for restorative therapy. One therapeutic approach is to provide an implantable neuroprosthesis. This presentation will discuss the development of a vestibular/cochlear neuroprosthesis by the group at the University of Washington, with emphasis on the optimization of stimulation parameters.

Methods: Non-human primates and human subjects were implanted with one or two unilateral vestibular or combined vestibular/cochlear prostheses. These devices were controlled and powered via an IR link to an external processor which could command stimulation based on sound and rotational inputs. Stimulation parameters could be preprogrammed or controlled via an attached computer. Stimulation was performed in the dark, during en-bloc rotation, and/or while tracking point targets or while undergoing optokinetic stimulation. Eye movements were recorded with video eye tracking in humans and implanted scleral coils in non-human primates. Neural responses in animals were recorded with tungsten microelectrodes. We used charge balanced biphasic pulse stimuli that could be modulated in pulse rate or current amplitude. Since there were multiple stimulation sites on each of 3 electrode arrays implanted adjacent to the ampulla of each semicircular canal, and remote ball and case grounds, monopolar and multipolar stimulation could be performed at each ampulla, or across ampullae. In addition, in animals that were implanted bilaterally, simultaneous stimulation could be performed at each ear, with different modulation phase relationships between ears.

Results: Each stimulation approach had strengths and weaknesses. The most natural stimulation was produced by bilateral prosthetic stimulation. Pulse rate modulation presented challenges at low stimulation frequencies. Current amplitude modulation showed current spread at higher current amplitudes. Interaural phase modulation produced consistent eye velocity changes for both pulse rate and current amplitude modulation strategies. Modulation produced changes in both velocity and direction of eye movements. Vestibular nucleus neurons and vestibular afferent fibers showed complex relationships between pulse amplitude and rate and the resulting neural discharge. Multipolar stimulation reduced current spread but also significantly reduced the efficacy of stimulation in eliciting eye velocity. Cross canal stimulation produced enhanced responses at some electrode sites, with the directional response being dominated by the most effective electrode. Implementation of complex transfer functions between the stimulus and the output of the implanted stimulator only partially compensated for the inherent limitations of the device.

Conclusion: Vestibular neuroprostheses have significant limitations which are only partially overcome by novel stimulation strategies.

Probing Central Vestibular Processing of Prosthetic Input via High-Density Neural Recordings in Freely Moving Nonhuman Primates

Ruihan Wei^{*1}, Olivia M. E. Leavitt², Oliver Stanley², Kantapon P. Wiboonsaksakul², Bassil Ramadan², Akshit Chhabra², Charles C Della Santina², Kathleen E. Cullen²

¹*Johns Hopkins University*, ²*Johns Hopkins University School of Medicine*

Individual Abstract: Vestibular implants have shown promise in restoring function following bilateral vestibular loss (BVL), yet the central mechanisms by which artificial input is interpreted and integrated across sensorimotor pathways remain largely unexplored. To address this gap, we combine multichannel vestibular prosthesis (MVP) stimulation with high-density, single-unit population recordings in freely moving rhesus macaques. This platform enables us to investigate, with unprecedented resolution, how central vestibular and cerebellar circuits respond to prosthetic input across a broad repertoire of natural behaviors.

Monkeys with BVL were chronically implanted with MVPs targeting semicircular canal afferents. During experiments, animals engaged in naturalistic behaviors spanning multiple functional systems—including locomotion, voluntary gaze shifts, and postural stabilization—while receiving stimulation modulated in real time using inertial head velocity signals. To directly assess central processing, we used NHP high-density neural probes adapted for nonhuman primates to record from hundreds of simultaneously isolated units in vestibular nuclei and early cerebellar regions.

We found that MVP stimulation reduced head movement variability, stabilized gaze during locomotion, and partially restored short-latency postural responses to perturbations. Population-level recordings in the vestibular nuclei during naturalistic behaviors further revealed diverse single-neuron responses to prosthetic input. Standard stimulation protocols may induce maladaptive central adaptation, limiting long-term efficacy. Testing using novel waveform strategies—such as asymmetric pulses—evoked increased firing rates and reduced timing variability in some neurons, while others showed minimal modulation or phase-locked responses. Ongoing work is focused on how vestibular, cerebellar, and cortical circuits adapt over time to such prosthetic input, to inform stimulation strategies that avoid maladaptive plasticity and promote functional multisensory integration during self-motion.

This work establishes a unique translational platform to evaluate how the brain interprets artificial vestibular input in ecologically valid contexts. By linking neural activity across populations to behavior, we can identify key bottlenecks in central processing that may limit current prosthetic efficacy. Taken together, our findings underscore the need to refine stimulation strategies not only for reflexive responses but also for higher-order integration. Gaining a population-level understanding of how neural ensembles throughout the vestibular pathway—including cerebellar, thalamocortical, and cortical networks—encode prosthetic input will be essential for advancing stimulation design and improving clinical outcomes.

Prosthetic Stimulation of the Utricle and Saccule

Celia Fernandez Brillet^{*1}, Margaret R Chow², Kristin N Hageman², Gene Y Fridman², Charles C Della Santina²

¹*Johns Hopkins University*, ²*Johns Hopkins School of Medicine*

Individual Abstract: To date, electrical stimulation of the vestibular nerve has been mostly limited to targeting the three semicircular canals, which encode head angular velocity and acceleration. Stimulation of the two remaining vestibular end organs, the utricle and saccule, has been relatively unexplored because it is challenging to selectively target the densely packed, non-uniform, direction-encoding hair cells and nerve branches found in the otolith maculae. Our group characterized the normal otolith-ocular reflex (OOR) in chinchillas and showed the possibility of eliciting an OOR response using electrical stimulation, both in otherwise healthy and in diseased animals.

The microelectrode array (MEA) we used for that research comprised three shanks, each targeting specific regions: posterior canal, horizontal canal and saccule, and superior canal and utricle. Electrodes were inserted toward the maculae through ampullotomies on the horizontal and superior semicircular canals, precluding direct view of the targeted neuroepithelia. Although this method offered less visibility for electrode placement, it was chosen as a less-invasive approach with the goal of increasing the likelihood of hearing preservation. However, the planarity, stiffness and small dimensions of the array made insertion into the intended locations challenging and low yield.

Considering these challenges, we prioritized directly viewing the medial wall of the vestibule for precise and reliable identification of the utricle and saccule through a more invasive approach. We developed a new, custom-designed MEA based on skull prosections and a microMRI model of a chinchilla labyrinth and nerve anatomy. We designed the array to unfold and conform to the medial walls of the vestibule, fitting the anatomy and promoting consistent and successful MEA placement. It includes 45 pads targeting the utricle and saccule, plus two pads per semicircular canal. With this novel device, we intend to selectively and reliably stimulate the non-uniform branches innervating the otolith end organs.

Support:

The MEA described in this report was provided by the Polymer Implantable Electrode Foundry at the University of Southern California, which is funded under BRAIN Award U24NS113647. The project that gave rise to these results received the support of a fellowship from “la Caixa” Foundation (ID 100010434, fellowship code LCF/BQ/EU21/11890107) and Rafael del Pino Foundation.

Direct Current Stimulation of the Vestibular System Using Ionic Conduits in a Nonhuman Primate

Evan O. Vesper*¹, Katherine N. Mueller¹, Celia Fernandez Brillet¹, W. Mitchel Thomas¹, Brian J. Morris¹, Woo Seok Kang¹, Charles C. Della Santina¹, Gene Y. Fridman¹

¹*Johns Hopkins School of Medicine*

Individual Abstract: Modern neural implants use pulsatile, charge-balanced, biphasic stimulation to deliver information to nervous tissue. These electric pulses have a phase-locked excitatory effect on neurons that can be modulated by altering amplitude, frequency, phase duration, and interphase gap. While this approach avoids the generation of toxic byproducts at the electrode-tissue interface, pulsatile stimulation generally cannot inhibit neural activity—imposing limitations on its therapeutic effects. Ionic direct current stimulation (iDC) is a technique that can directly excite, inhibit, and sensitize neural tissue. This type of stimulation is delivered via ionic fluid conduits and can be paired with separated interface neural electrode systems to perform chronic experiments. Prior in-vivo rodent studies using iDC have noted its ability to suppress nociceptive fibers in peripheral nerves and broaden the dynamic range of the vestibulo-ocular reflex. However, long-term studies in larger animal models have not yet been conducted. In this paper, we present the first chronic implantation of iDC fluid conduits in the vestibular system of a nonhuman primate. We demonstrate the system's ability to deliver both conventional pulsatile and iDC stimulation and report on the implant's performance and stability over a six-month period.

The Future of Vestibular Implantation: Challenges, Opportunities and Controversies

Richard Lewis*¹

¹*Massachusetts Eye and Ear Infirmary, Harvard Medical School*

Individual Abstract: With Dr. Della Santina, Dr. Lewis will co-moderate a panel comprising all speakers in the session, with the group discussing open-ended questions about the future of vestibular implantation designed to elicit diverse opinions, spark convivial debate, and engage the audience.

Podium 1: Genetics of Hearing Loss: Screening, Sequencing and Outcomes

2:30 p.m. - 4:30 p.m.

Meeting Room 209ABC, Floor 2

Moderators: Paul Krumpoeck and Hela Azaiez

Preliminary Results From a Multicenter Evaluation of Hispanic Pediatric Genetic Hearing Loss

2:30 p.m. - 2:45 p.m.

Background: Pediatric hearing loss is a condition with diverse presentations and etiologies. Genetic evaluation is now considered the standard of care in this population. However, access to comprehensive genetic testing remains limited across Latin America for multiple reasons. The Latin American population has a wide range of genetic backgrounds, representing a unique ethnic group that, until now, has not been widely studied to determine genetic causes of hearing loss. Recent data show that Hispanic and Latino children with hearing loss have lower genetic testing diagnostic yields and significantly higher nondiagnostic or inconclusive results, despite similar prevalence rates of sensorineural hearing loss (SNHL) to their Asian and White counterparts. Few studies have evaluated genetic hearing loss in Latino populations using modern genomic technologies. In this study, we aimed to describe the results of genetic evaluations using comprehensive genomic testing in Hispanic children from Colombia, Mexico and the United States.

Methods: This multicenter study included hospitals in Colombia (Bogota and Cali), Mexico (Mexico City) and the United States (Boston). Data was collected from Hispanic children living in Colombia, Mexico and USA with SNHL who underwent hearing loss panels, commercial exome sequencing (ES) or custom targeted genomic enrichment and massively parallel sequencing (TGE+MPS). Variant pathogenicity was classified American College of Medical Genetics criteria.

Results: A total of 212 children (110 males) were evaluated; 66% were mestizos and 10% were white or white/caucasian. Congenital onset was present in 60% of cases and postlingual in 26% of the cases. Most patients (75%) underwent whole exome sequencing. Positive results were obtained in 111 probands (52%) and 51% of these cases were syndromic or syndromic mimic nonsyndromic hearing loss. Among probands with genetic etiology, 70 (66%) had an autosomal recessive inheritance. Bilateral hearing loss was present in 176 children; in this group, a genetic etiology was identified in 52%. Mutations in GJB2 accounted for 19 probands (20%), followed by, CDH7 (5%) SCL26A4 (5%), CDH23 (4%) and STRC (4%). Seventeen probands had unilateral hearing loss, with genetic etiology identified in only four cases (23%).

Conclusions: To our knowledge, this is the largest study to date describing the genetic etiology of hearing loss in Mexican, Colombian and Hispanic children. GJB2 mutations are the most common genetic cause of hearing loss in this population and syndromic diagnoses were higher than reported in other populations. Genetic evaluation in pediatric hearing loss is essential to personalize treatment and enable a multidisciplinary approach.

Continuous Updates to the Genomic Landscape of Deafness Associated Genes

2:45 p.m. - 3:00 p.m.

Brian Hong^{*1}, Hela Azaiez², Kevin T Booth², Terry Braun¹, Thomas Casavant¹, Genevieve Cox¹, Rose Gogal¹, Diana L. Kolbe³, Nathan Schaefer¹, Michael Schnieders¹, Richard J.H. Smith⁴

¹The University of Iowa, ²Indiana School of Medicine, ³University of Iowa Hospitals and Clinics, Molecular Otolaryngology and Renal Laboratories, ⁴Molecular Otolaryngology and Renal Research Labs, University of Iowa Carver College of Medicine

Background: Driven by the ever-increasing volume of exome and genome data, the classification of genetic variants remains a major challenge in providing precision medical care. The Deafness Variation Database (DVD) was developed to address this challenge in the domain of hearing loss by collating genetic, genomic, and phenotypic data with expert curation to provide Pathogenic/Likely Pathogenic/VUS/Likely Benign/Benign classifications for over millions of variants across 224 hearing-loss-associated genes.

Methods: The DVD v9.2 includes 224 genes known to cause hearing-loss related phenotypes. Based on human reference genome GRCh38 coordinates and uses GATK v4.2.6.1 Picard Liftover tool to include the GRCh37 coordinates, an internal computational pipeline, Kafeen, automates the classification of variants. The pipeline uses BCFtools to integrate information from gnomAD v4.1, ClinVar(2025-03-18 release), HGMD(2024.1 release) dbSNP(GCF_000001405.40). It implements VEP v111 plugins of computational tools: PhyloP, SIFT, LRT, MutationTaster, PolyPhen HDIV, GERP, REVEL v1.3, and CADD v1.7 to make predictions on the likelihood of variant pathogenicity. The front end web app provides a user friendly interface for the database and developed using the PHP Laravel framework.

Results: The DVD uses ACMG v3 guidelines to classify variants in 224 genes implicated in genetic hearing loss, using ClinVar and HGMD as published references and extracting minor allele frequencies for large scale populations from gnomAD v4.1. Computational tools assess conservation and deleteriousness to generate a composite pathogenicity score. The update to GRCh38 genomic coordinates allows for an increase in variant discovery. In aggregate, approximately 383,000 variants are classified as benign or likely benign, while 36,000 variants are classified as pathogenic or likely pathogenic.

Conclusions: The DVD provides a valuable resource for variant interpretation in the domain of genetic hearing loss. Ongoing efforts are focused on improving pathogenicity classification by integrating predictions of protein folding free energy differences with traditional sequence conservation based variant classifiers (e.g., CADD and REVEL) using a hearing-loss specific Bayesian framework. ACMG v4 guidelines will also be incorporated into the DVD.

An Ultra-Rapid Targeted Sequencing and Automated Bioinformatics Analysis for Genomic Newborn Hearing Screening to Reduce Time-To-Diagnosis for Hereditary Sensorineural Hearing Loss

3:00 p.m. - 3:15 p.m.

Shelby Redfield*¹, Charlotte Suh¹, Sierra Rios¹, Courtney French¹, Wanqing Shao¹, Cliff Li¹, Alexandra Loosli¹, Shira Rockowitz¹, Eliot Shearer²

¹*Boston Children's Hospital*, ²*Boston Children's Hospital, Harvard Medical School*

Background: The almost universal adoption of the newborn hearing screen (NBHS) in the United States has been instrumental in the early identification of infants with hearing loss. However, the NBHS is limited in which forms of sensorineural hearing loss it can detect, and it cannot identify genetic etiologies of hearing loss, which have important management implications. Prior studies have shown that the addition of limited genetic screening to the standard, physiologic NBHS improves screening sensitivity and decreases time to hearing habilitation. The purpose of this study is to develop a rapid, comprehensive, genomic NBHS that decreases time to diagnosis for children with hearing loss.

Methods: We obtained buccal swabs from newborns undergoing physiologic NBHS as standard-of-care. We performed rapid targeted genomic enrichment (Twist Biosciences) of definitive hearing loss genes (ClinGen Hearing Loss Gene Curation Expert Panel) followed by Illumina sequencing. To analyze the data, we developed an automated workflow integrating a standard bioinformatics analysis pipeline (Dragen, Illumina Inc) and a custom variant filtering process. The results of the genomic hearing screen (POSITIVE/NEGATIVE/INCONCLUSIVE) were provided to investigators in an emailed report. Positive results were reported when known or putative (likely) pathogenic variants that constitute a molecular diagnosis of nonsyndromic or syndromic hearing loss were identified. Variants of uncertain significance with congruous zygosity were called as inconclusive, as were heterozygous pathogenic variants in genes for which both autosomal dominant and recessive inheritance of hearing loss are possible. Secondary and incidental findings were excluded from analysis. The entire pipeline is automated with no human intervention required after sequencing is completed. Candidate variants were clinically confirmed prior to return of results with counseling.

Results: We have performed ultra-rapid comprehensive genomic NBHS for 50 controls and 69 subjects (119 in total). The total active time from sample collection to result was under 48 hours, with an average of 1 hour and 45 minutes for bioinformatic and variant analysis. There was complete concordance for 50 controls (28 gene-positive and 22 gene-negative) compared to standard-of-care genetic testing findings. Of the 69 subjects tested, 49 (71.0%) screened negative, 20 screened inconclusive (29.0%) and 1 screened positive (1.4%). The subject with a positive finding was diagnosed with mild-moderate sensorineural hearing loss on diagnostic auditory brainstem response testing. Clinical genetic confirmation testing of variants in OTOGL is pending. Inconclusive cases were reviewed by a genetic counselor and deemed nondiagnostic. Further enrollment of subjects and pipeline analysis is ongoing, including time-to-genetic-diagnosis comparison with a control group of newborns who did not undergo genomic NBHS.

Conclusions: Ultra-rapid genomic NBHS is a promising method to improve NBHS sensitivity and reduce time-to-diagnosis in newborns with hearing loss.

Comprehensive Whole Genome Sequencing Analysis of MYO15A and Genotype–Phenotype Correlations in Hearing Loss

3:15 p.m. - 3:30 p.m.

Yu Lu*¹, Jing Cheng¹

¹*West China Hospital, Sichuan University*

Background: In the Chinese population, MYO15A is the third most common deafness gene following GJB2 and SLC26A4. However, a substantial fraction of patients with hereditary hearing loss remain without a definitive molecular diagnosis, partly due to undetected pathogenic variants in MYO15A. These missed variants may reside in noncoding regions, poorly covered genomic segments, or represent structural variants (SVs). Addressing this diagnostic gap is essential for understanding the genetic architecture of MYO15A-related deafness.

Methods: We performed whole genome sequencing (WGS) on unsolved hearing loss cases, with a focus on individuals carrying single heterozygous pathogenic MYO15A variants identified in prior panel-based or exome testing. Comprehensive genomic interrogation included analysis of noncoding regions, low-coverage intervals, and structural variants. Candidate splice-altering and regulatory variants were validated through functional assays, including minigene splicing assays and transcript analysis. Genotype–phenotype correlations were explored with emphasis on recurrent mutational hotspots in the Chinese cohort.

Results: WGS significantly improved variant detection in MYO15A, especially in exon 2, which showed a markedly higher sensitivity compared to conventional methods. Fourteen distinct intronic variants were identified in 25 compound heterozygous hearing loss patients; splicing assays confirmed their disruption of canonical splicing, resulting in protein dysfunction. These discoveries increased the diagnostic yield for MYO15A-associated deafness by over 5%. Moreover, recurrent variants were enriched in exon 2, exon 64, and exon 65. Patients with mutations in these regions often presented with late-onset or moderate hearing loss, suggesting potential mechanistic differences compared to early-onset severe phenotypes.

Conclusions: This study demonstrates the power of whole genome sequencing in uncovering previously undetected pathogenic variants in MYO15A, including deep intronic and structural variants. By integrating functional validation, we establish the clinical relevance of these variants and refine genotype–phenotype correlations. Our findings highlight MYO15A as a major contributor to unsolved hereditary hearing loss in the Chinese population, expand its mutational spectrum, and suggest regional hotspots linked to variable clinical expressivity. Comprehensive WGS-based analysis thus represents an essential strategy to advance precision diagnostics and mechanistic understanding of MYO15A-related deafness.

Genetic Architecture of Tinnitus and its Relationship to Sensorineural Hearing Loss

3:30 p.m. - 3:45 p.m.

Caroline Nievergelt^{*1}, Adam X. Maihofer¹, Royce Clifford¹

¹*University of California - San Diego*

Background: Tinnitus is a highly prevalent multifactorial auditory disorder, whose pathophysiological mechanisms remain poorly known. Risk factors include hearing impairment, increasing age, and male sex, as well as environmental triggers such as noise exposure and stress. In addition, twin studies and recent large-scale genome-wide association studies (GWAS) have confirmed a heritable component to tinnitus. Further, tinnitus and sensorineural hearing loss (SNHL) are genetically highly correlated, with little indication of differentiating signals, and the divergent anatomic and genomic pathways for tinnitus from hearing damage remains unidentified. Here we dissect the genetic architecture of tinnitus from SNHL using the largest GWAS meta-analysis of tinnitus to date.

Methods: Genotype and phenotype data of over 750,000 individuals from the Million Veteran Program (MVP), the UK Biobanks (UKB), and the All of Us cohort were included. Tinnitus and SNHL were characterized by self-report and/or clinical diagnosis (ICD codes). GWAS was performed within each cohort in PLINK and inverse-variance weighted fixed effects meta-analysis was performed with METAL. Functional annotation was performed using FUMA, including MAGMA gene-based, pathway, and tissue expression analyses. Gene expression data of a human adult inner ear tissue (mostly from the vestibular system) was integrated to include disorder-relevant tissue for enrichment analyses. SNP based heritability and genetic correlation were estimated using LDSC. To estimate the genetic architecture of tinnitus and SNHL and the unique and shared polygenicity between the disorders, we performed univariate and bi-variate Gaussian mixer model analyses with MiXeR.

Results: A GWAS meta-analysis including 277,432 tinnitus cases and 475,916 controls identified 76 genome-wide significant loci, and gene-based analysis identified genes related to neuronal synapses and cochlear structural support. SNP-based heritability of tinnitus in individuals of European ancestry ranged from 6% (MVP, UKB) to 7% (All of Us). We found a large number of shared variants between tinnitus and SNHL, but also a distinct genetic architecture of tinnitus, with higher polygenicity and large proportion of variants not shared with hearing difficulty. Tissue expression analysis inferred broad enrichment across most brain tissues and the inner ear, in contrast to SNHL, which shows no enrichment in the brain, but enrichment in the inner ear, followed by nerve and pituitary tissues. Significant genetic correlations of tinnitus were found not only with SNHL, but also with psychiatric and health related traits.

Conclusions: We identified 76 tinnitus risk loci, almost doubling previous findings, and pointing to novel genes as well as known genes related to congenital and age-related hearing loss. Compared to SNHL, tinnitus has a higher polygenicity, and gene expression is enriched not only in the inner ear, but predominantly in the brain, establishing tinnitus as a distinct disorder separate from hearing loss. Finally, correlations of tinnitus with a spectrum of psychiatric disorders may provide potential new avenues for treatment.

Human Cochlear Cell-Specific Transcriptomes and Elevated Variants in Ménière's Disease and Hereditary Hearing Loss

3:45 p.m. - 4:00 p.m.

Samuel Adadey*¹, Shoujun Gu², Morag A Lewis³, Rafal Olszewski², Rabia Faridi⁴, Tyreek Jenkins⁵, Shelby Payne⁵, Kenechukwu Charles-Obi⁶, Robert J. Morell⁷, Thomas B. Friedman⁴, Bradley A. Schulte⁵, Karen P. Steel³, Judy R. Dubno⁵, Hainan Lang⁵, Michael Hoa²

¹National Institute on Deafness and Other Communication Disorders, ²Auditory Development and Restoration Program, National Institute on Deafness and Other Communication Disorders, National Institutes of Health, ³Wolfson Centre for Age-Related Diseases, King's College London, ⁴Laboratory of Molecular Genetics, National Institute on Deafness and Other Communication Disorders NIDCD, National Institutes of Health, ⁵Medical University of South Carolina, ⁶National Institute on Deafness and Other Communication Disorders, National Institutes of Health, ⁷Genomics and Computational Biology Core, NIDCD, National Institutes of Health

Background: The human cochlear transcriptome is crucial for identifying cell types and marker genes, and for understanding auditory function and inner ear disorders like Ménière's disease (MD) and hereditary hearing loss. MD is a debilitating chronic disease characterized by episodic vertigo, tinnitus, and fluctuating hearing loss, and is relatively understudied. We identified 34 distinct cell types in the human cochlea, uncovering its complex cellular diversity and novel marker genes.

Methods: We generated a comprehensive single-nucleus RNA-seq (snRNA-seq) reference transcriptome from human cochleae. Differential expression analyses combined with single-molecule fluorescence in situ hybridization were used to validate known markers and to identify new markers. To demonstrate the utility of our human snRNA-seq data, we mapped hereditary hearing loss genes across cochlear cell types and integrated variant data from the All of Us research program to identify genes associated with MD that show elevated variant loads in affected individuals. Leveraging genomic data involving 44,625 individuals from the All of Us Research Program, we conducted a case-control analysis to identify genetic variants significantly enriched in MD patients. Variant burden was assessed by comparing gene-level variant counts between MD and non-MD individuals.

Results: Based on our human snRNA-seq analysis, we annotated distinct cochlear cell types and identified novel cell type-specific marker genes. Cross-species comparison of these markers revealed strong conservation between humans and mice, supporting the continued use of mouse models in inner ear disease research. To explore the relevance of these findings to human hearing loss, we studied genetic variants linked to hereditary hearing loss and MD. Genes identified from this case-control analysis were then mapped onto our human cochlear snRNA-seq dataset to determine their expression across specific cochlear cell types. We identified candidate MD genes, including *BMPRI1B*, *FHOD3*, *LAMA2*, *RAB11FIP3*, and *SCN7A*, which showed cell type-specific expression within the cochlea, particularly in lateral wall structures. Expression of *Bmpr1b* in marginal cells was further validated in mouse cochlear tissue, highlighting the potential relevance of these genes to MD pathophysiology. Additionally, we used our transcriptomic resource to investigate the cellular expression patterns of genes implicated in hereditary hearing loss, providing a comprehensive framework for linking genetic risk to cochlear cell types.

Conclusions: Cross-species comparisons revealed strong conservation with mouse models, alongside key human-specific differences. Our dataset also enabled mapping of gene expression linked to Ménière's disease and hereditary hearing loss. This comprehensive human cochlear cellular transcriptome resource provides valuable translational insights, implicating specific cochlear cell types in the pathogenesis of MD and hereditary hearing loss.

Cochleovestibular Dysfunction in Patient With Primary Mitochondrial Disease Due to Pathogenic mtDNA Variants

4:00 p.m. - 4:15 p.m.

Johannes Ehinger*¹

¹*Lund University Hospital*

Background: Primary mitochondrial diseases (PMD) are a heterogeneous group of disorders, often with symptoms and findings from multiple organ systems, where pathogenic variants either in nuclear DNA (nDNA) or in mitochondrial DNA (mtDNA) affect mitochondrial function.

Methods: We have investigated how PMD affect hearing in one retrospective and one prospective cohort. Further, we have through video head impulse test (vHIT) and cervical vestibular evoked potentials (cVEMP) evaluated vestibular function in the prospective cohort of PMD patients.

Results: In the retrospective consecutive series of PMD patients seen at The Children's Hospital of Philadelphia, USA, SNHL was audiometrically confirmed in 20% of patients with pathogenic mtDNA variants, and in 58% of mtDNA deletions. In PMD due to pathogenic variants in mtDNA, onset of hearing loss was invariably post-lingual. In our ongoing prospective cohort of patients with PMD due to pathogenic mtDNA variants (primarily m.A3243A > G) at Skåne University Hospital, Sweden, to date 83% of subjects lack response to cVEMP on at least one side, while only 17 % had pathological vHIT.

Conclusions: That hearing loss due to mtDNA tend to have postlingual onset has important implications for the investigation of children and young adults with sensorineural hearing loss (SNHL). Genetic cause (mtDNA) of hearing loss has to be considered despite the child passing the newborn screen, and that whole genome sequencing also covering mtDNA should be considered the gold standard for investigation. SNHL is common in PMD, and vestibular dysfunction may be an underreported phenomena in this patient group, as imbalance and gait disorders in PMD is normally attributed to myopathy and fatigue. Here we show that vestibular dysfunction likely is an important contributor, and the inferior portion of the vestibular nerve seems to be affected earlier, as evident from the high proportion of pathogenic cVEMPs in this patient group.

FRMPD4 is Associated With X-Linked Non-Syndromic Hearing Loss

4:15 p.m. - 4:30 p.m.

Daniel Liedtke¹, Kristen Rak², Katrina M Schrode³, Philip Hehlert⁴, Niloofar Chamanrou⁵, Daniel Bengt¹, Radoslaw Katana⁴, Soganad Heydaran⁵, Julia Doll¹, Mei Han⁶, Indrajit Nanda¹, Pingkalai R Senthilan⁷, Linda Bieniussa², Johannes Voelker², Michaela AH Hofrichter¹, Jörg Schröder¹, Tobias Müller⁸, Marcus Dittrich¹, Oliver Bartsch⁹, Peter M Krawitz¹⁰, Eva Klopocki¹, Wafaa Shehata-Dieler², Reza Maroofian¹¹, Tao Wang⁶, Paul F Worley¹², Martin C Göpfert⁴, Hamid Galehdari⁵, Amanda M Lauer³, Thomas Haaf¹, Barbara Vona^{*13}

¹Institute of Human Genetics, Biocenter, Julius Maximilians University, ²University Hospital, ³Center for Hearing and Balance, Johns Hopkins University, ⁴University of Göttingen, ⁵Faculty of Science, Shahid Chamran University of Ahvaz, ⁶Institute of Genetic Medicine, Johns Hopkins University, ⁷Neurobiology and Genetics, Biocenter, Julius Maximilians University, ⁸Julius Maximilians University, ⁹Medical Care Centre Section Human Genetics and Institute of Human Genetics, University Medical Centre of the Johannes Gutenberg University Mainz, ¹⁰Institute for Genomic Statistics and Bioinformatics, University Bonn, ¹¹UCL Queen Square Institute of Neurology, University College London, ¹²Johns Hopkins University, ¹³Institute for Auditory Neuroscience, University Medical Center Göttingen

Background: Understanding the full clinical spectrum of disease-associated genes is critical for advancing genomic medicine for accurate diagnosis and therapy. FRMPD4 (FERM and PDZ Domain Containing 4) has previously been linked to intellectual disability and epilepsy,

but its role in auditory function has not been explored. We investigated the potential contribution of FRMPD4 variants to non-syndromic sensorineural hearing loss (NSHL) and examined conserved molecular mechanisms across species.

Methods: Exome sequencing was performed in two unrelated families with maternally inherited missense variants in FRMPD4. Clinical phenotyping included longitudinal audiological assessments. To assess evolutionary conservation and functional mechanisms, we analyzed FRMPD4 expression in mouse, zebrafish, and *Drosophila* auditory tissues. Functional assays included mouse auditory brainstem response (ABR) testing, zebrafish knockdown and mutant models with phenotypic evaluation of otic vesicle and posterior lateral line development, neuromast morphology, and acoustic startle responses, as well as behavioral assays of sound perception in *Drosophila* mutants.

Results: Three affected males presented with prelingual, bilateral, symmetric hearing loss, including congenital onset in one individual. No neurodevelopmental features were observed, and over 20 years of clinical follow-up in one family excluded syndromic involvement. Cross-species analyses showed conserved FRMPD4 expression in auditory structures. Zebrafish loss-of-function models demonstrated reduced neuronal populations in the otic vesicle and posterior lateral line, impaired neuromast development, and diminished acoustic startle responses, indicating impaired auditory processing. In mice, ABR testing revealed high-frequency hearing loss that paralleled the human phenotype. *Drosophila* mutants displayed quantifiable deficits in sound perception, supporting a conserved molecular role across vertebrates and invertebrates.

Conclusions: This study identifies FRMPD4 variants as a novel cause of non-syndromic sensorineural hearing loss, expanding its functional repertoire beyond neurodevelopmental disorders. The convergence of human genetics and cross-species functional evidence highlights a conserved auditory role for FRMPD4 and suggests that disruption of neuronal and synaptic pathways underlies hearing impairment. These findings broaden the phenotypic spectrum of FRMPD4, carry direct implications for genetic diagnosis and counseling in hearing loss, and establish new avenues for mechanistic and therapeutic research in auditory biology.

Podium 2: Neural Mechanisms of Speech Perception and Understanding

2:30 p.m. - 4:30 p.m.

Ballroom B, Floor 3

Moderators: Ciaran Stone and Jessica MacLean

Electroencephalographic Measurements of Speech Detection in Noise in the First Year of Life

2:30 p.m. - 2:45 p.m.

Laurianne Cabrera*¹, Clémence Basire²

¹CNRS, ²Université de Paris - CNRS

Background: Infants are known to have more difficulties detecting speech in the presence of a noisy background compared to adults. Most of the previous studies used behavioral methods to assess this capacity, whereas electroencephalography (EEG) may provide objective neural markers of the development of this ability. Our study aims to assess infants'

speech detection abilities in a noisy background by examining the auditory event related potentials (ERP) using a passive listening procedure.

Methods: We recruited a group of 25 three-month-old infants with normal hearing and typical development, who were following-up at 10 months of age. We also recruited a group of 31 adults for comparisons. All listeners were awake throughout the EEG recordings and were presented with the syllables "ba" or "da" in a continuous stationary speech-shaped noise played at 65 dB SPL via two speakers in front of the listeners. The syllables were randomly played at four different signal-to-noise ratios (SNR = +3, -4, -8, -15 dB). A total of 52 trials per SNR was played while measuring ERPs for about 20 min. The ERP amplitude after syllable onset was averaged over five frontal electrodes and in the time window 400:600 ms, corresponding to the P300-like ERP response.

Results: A first analysis showed that for both infant groups and the adult group, only ERP amplitude obtained at the SNR -15 dB were not significantly different from the neural responses obtained during the noise inter-trial presentation (considered as the baseline response when no speech was presented). A second analysis using a linear-mixed model was run on the mean [400-600ms] ERP amplitude and revealed a significant effect of Age ($p = .008$), SNR level ($p < .001$) and interaction between these two factors ($p = .020$). Post-hoc analyses indicated that at 3 months of age, decreasing the SNR significantly decreased the ERP amplitude, while at 10 months of age the ERP amplitude differed significantly between the -15 and +3, -15 and -4, and -8 and +3 conditions, but not between any other pairs.

Conclusions: These findings revealed, at both 3 and 10 months of age, an effect of SNR on the P300-like amplitude related to syllable detection in noise: the greater SNRs, the greater the ERP amplitude. This result is in line with adult studies showing that the P300 amplitude decreases as the difficulty of discriminating stimuli increases. Importantly, at 3 and 10 months, ERP responses were significantly different from neural noise, starting at SNR equal to -8 dB. This finding suggests that as for the adults, the infants' brain is able to detect syllable at this SNR level by 3 months of age. Our results are promising for objective clinical measures of speech-in-noise development during infancy.

Speech-In-Noise as a Biomarker of Peripheral Auditory Neuropathy in Metabolic Disorders: Proof of Concept in Patients With Uncontrolled Type 2 Diabetes

2:45 p.m. - 3:00 p.m.

Jerome Nevoux^{*1}, Fabrice Giraudet², Camille Rochmann³, Kaier-Green Zoe³, Blandine Duval³, Laullier Hugo³, Laura Breda³, Mathieu Schué³

¹CHU Bicêtre, ²UMR INSERM 1107, University Clermont Auvergne, Institute of Hearing, University Hospital of Clermont-Ferrand, SoluSons, Clermont-Ferrand, ³CILcare

Background: Sensorineural hearing loss (SNHL) is an underrecognized comorbidity of type 2 diabetes (T2D).

Peripheral auditory neuropathies, including cochlear synaptopathy and cochlear microangiopathy, and chronic systemic inflammation affecting central auditory pathways are potential mechanisms.

These factors may contribute to early auditory dysfunction, specifically speech-in-noise (SIN) comprehension difficulties with standard hearing thresholds within normal limits, often reported as "hidden hearing loss".

Methods: DIAMANT was a French, multicenter, cross-sectional, prospective study conducted at three diabetology centers. It aimed to evaluate the prevalence of different auditory dysfunctions among an uncontrolled population with T2D, especially SNHL and identify effective tools to distinguish them.

Participants who consented (aged 25–70, T2D > 2 years, HbA1c > 7%) underwent a comprehensive battery of tests : standard (0.25-8 kHz) and extended high frequency (8–16 kHz) pure-tone audiometry, SIN testing with the French Matrix test (Framatrix), Distortion Product OtoAcoustic Emissions (DPOAE), electrocochleography (EcochG), and cognitive screening via the Montreal Cognitive Assessment (MoCA).

Participants with abnormal otoscopy, tympanometry, conductive / asymmetrical hearing loss were excluded.

Results: Among 241 participants (61% women, median age 60 [IQR:53.0-64.0]), three hearing profiles emerged:

- Normal hearing (NH, standard pure-tone average at 0.5,1, 2, 4 kHz (PTAv) < 25 dB and Framatrix < −3 dB): 45.6%

- SIN-Deficit (SIN-D, PTAv < 25 dB and Framatrix $\geq$ −3 dB): 37.4%

- Hearing loss (HL, PTAv $\geq$ 25 dB): 17%

After excluding those with cognitive impairment (MoCA < 26), 137 participants remained: 59.8% NH, 26.3% SIN-D, and 13.9% HL.

In NH and SIN-D, DPOAE were present (90.7%), or partially present (5.6%).

Audiometry revealed significant differences in hearing thresholds between NH and HL across all frequencies. NH and SIN-D had similar thresholds at low frequencies (0.25–1 kHz), but SIN-D diverged at mid-to-high frequencies ($\geq$ 2 kHz), no longer resembling HL at 8-16 kHz.

Framatrix scores were significantly correlated with PTAv low, PTAv mid, PTAv high, indicating SIN performance deteriorates as pure-tone sensitivity declines.

SIN testing effectively distinguished SIN-D and NH per the median 2 dB signal-to-noise ratio difference observed.

At the group level, EcochG revealed significantly reduced auditory nerve response in SIN-D compared to NH, reflecting a decrease or degeneration of synapses and/or spiral ganglion cells. At the individual level, EcochG correlated with Framatrix scores and PTAv at mid-to-high frequencies, but not at low frequencies. This reinforces the concept that EcochG and SIN testing can identify emerging deficits, specifically at mid-high frequencies.

Conclusions: Although SNHL prevalence in T2D was not higher than in the general population, SIN deficit with normal hearing was more frequent.

For SIN-D, outer hair cell dysfunction can be excluded and peripheral auditory neuropathy suspected when controlling for cognitive factors.

SIN testing offers a practical, non-invasive alternative to electrophysiology and should be integrated into routine auditory testing.

More work should confirm SIN testing as a biomarker of peripheral auditory neuropathy.

A Cortical Hierarchy of Temporal Integration Windows During Naturalistic Speech Processing in Children

3:00 p.m. - 3:15 p.m.

Tong Shan*¹, Dawlat El-said¹, Kelly Eggen¹, Mia Obermueller¹, Carlo de los Angeles¹, Montana Wilson¹, Joshua Medor¹, Warsan Ali¹, Daniel Abrams¹

¹*Stanford University*

Background: Real-life verbal communication depends on the brain's ability to dynamically integrate speech over time, allowing listeners to derive meaning. Recent neuroimaging methods enable investigation of comprehension during naturalistic communication. Prior studies in adults have demonstrated a hierarchy of temporal receptive windows, with auditory cortices processing short timescales and the default mode network (DMN) and lateral frontoparietal network (LFPN) supporting integration over longer timescales. However, the neurodevelopmental trajectories of these systems in children, and their relationship to narrative comprehension and social communication abilities, remain largely unknown. The present study investigates the developmental mechanisms underlying comprehension during naturalistic speech in typically developing children.

Methods: Twelve neurotypical children (ages 9–12 years; 3 female), all native English speakers, participated in an fMRI study. Scanning was performed on a 3T MRI scanner (48-channel coil, TR = 800 ms). During scanning, participants listened to (1) natural narratives read by a female speaker, (2) a word-scrambled version of the narrative, and (3) a sentence-scrambled version. Compositional and pragmatic comprehension of the narrative were assessed following each narrative. For each condition, inter-subject synchronization (ISS) analysis was performed. Voxel-wise correlation coefficients were computed across listeners to assess the reliability of BOLD response time courses to each stimulus. ISS differences between intact and scrambled narratives were computed.

Results: Neurotypical children showed high comprehension accuracy (> 90%) for both compositional and pragmatic content across narratives, indicating that the children heard and understood the narratives during fMRI data collection. Consistent with findings in adults (Lerner et al., 2011), robust ISS was observed in auditory cortex, including Heschl's Gyrus, Planum temporale and Superior Temporal Gyrus, across all conditions, indicating short-timescale integration in superior temporal regions. However, only the intact narrative elicited significant ISS in the precuneus and angular gyrus of the DMN, as well as in the superior parietal lobule and dorsolateral prefrontal cortex of the LFPN. In contrast, the word- and sentence-scrambled narratives failed to elicit ISS in DMN or LFPN regions, except for the precuneus in the sentence-scrambled condition. Results are consistent with the hypothesis that DMN and LFPN support long-timescale integration.

Conclusions: Preliminary findings suggest that, in children, DMN and LFPN support long-timescale integration of naturalistic narratives, whereas auditory cortices reliably encode shorter timescales associated with word-level processing. Findings suggest that a cortical hierarchy for temporal analysis of naturalistic speech is intact in school-aged children. Future analyses will examine relationships between individual differences in temporal integration of speech and neuropsychological measures of language and social communication abilities as well as brain network connectivity underlying temporal integration.

Central Auditory Function is Related to Earlier Reading Development in Childhood

3:15 p.m. - 3:30 p.m.

⁴Creare LLC, ⁵Muhimbili University of Health and Allied Sciences

Background: Central auditory tests assess the brain, which is crucial for reading development in children. Therefore, testing central auditory function in early childhood (< age 5) may provide a marker for reading ability in later childhood. This may be particularly useful in low- middle-income countries where testing resources are limited.

Methods: We studied 169 children from an ongoing longitudinal study in Tanzania that entered the study by age 5 and were followed for at least 4 visits (follow-up between 1.5 and 6 years). For all children, a polynomial curve was fit to triple digit test (TDT – speech perception in noise) performance across age to provide a normal age trajectory of the test in the cohort. High-performers were identified as those who consistently performed better than the age-appropriate mean value.

We assessed subsequent oral reading fluency in high-performers and the comparison group on the early grade reading assessment (EGRA).

We treated performance on the oral fluency task in 5 point increments (from 0 to 60, the maximum score) on the EGRA as discrete Performance Levels (PL). We treated “age at first attainment of PL” as a time-to-event outcome and constructed interval-censored event times from longitudinal scores on the reading assessment. We fit log-logistic accelerated failure time (AFT) models with group (high-performers vs. comparison) as the only predictor to estimate median ages for reaching each PL for our two groups.

Results: Plotting performance on the oral fluency task against age showed that on average, the high-performer group had better reading ability compared to same-age children in the comparison group from 5-11 years of age.

Across PLs 10–60, the estimated difference in median age to reach the threshold ranged from 0.95 to 1.72 years, exhibiting an increasing lag between groups at higher PLs. The corresponding time ratios comparing high-performers to the comparison group were consistently between 0.85 and 0.90, indicating that high-performers progressed in oral fluency approximately 10–15% earlier than the comparison group across the entire range of PLs.

Specifically, high-performers reached the PL of 50 (out of 60 words) at a median age of 9.4 years, whereas the comparison group reached it at 10.7 years, with an estimated time lag of 1.3 years (95% CI: 0.61, 2.04 years).

Conclusions: Using interval-censored AFT models, we found that children who are consistently high-performers on TDT in early years show a stable 10%-15% acceleration (earlier attainment) of oral fluency skills compared to those performing at average or below-average on the TDT for their age.

Elliptical Speech Reveals the Use of Broad Phonetic Categories Aids Noise-Degraded Speech Perception

3:30 p.m. - 3:45 p.m.

Gavin Bidelman*¹, Zara Eisenhut¹, Lucy Borowski¹, Rose Rizzi¹, David Pisoni¹

¹*Indiana University*

Background: Speech perception requires that listeners both classify sensory information into smaller groupings while also coping with noise that often corrupts the speech signal. The strength of categorization and speech-in-noise (SIN) abilities show stark individual differences. Some listeners perceive speech sounds in a gradient fashion, while others categorize in a discrete/binary manner, favoring fine acoustic details vs. a more abstract phonetic code, respectively. Prior work suggests SIN processing is (i) related to more gradient phonetic perception and (ii) varies with musical training.

Methods: To further probe relations between perceptual gradiency and noise-degraded listening, we measured phoneme categorization (identification labeling), SIN recognition (QuickSIN), and sentence recognition in listeners with varying musical background. Categorization was measured for vowels and stops using standard labeling tasks. Sentence-level speech recognition and discrimination were assessed using “elliptical speech” [Miller and Nicely. (1955). *J. Acoust. Soc. Am.*, 27, 338–352], which use featural substitutions that renders them meaningless under normal (clean) conditions but surprisingly improves their recognition under noise degradation. We hypothesized listeners who use broader perceptual equivalency classes in hearing elliptical speech would show better SIN perception, indicative of a more gradient listening strategy.

Results: Listeners perceived elliptical sentences as different than their intact counterparts in the clear (as expected) but, surprisingly, as sounding the same under noise degradation. However, this elliptical noise-related benefit varied with music background. Nonmusicians showed larger “susceptibility” to ellipses than musicians, consistent with the notion they used broader phonetic categories (i.e., more gradient listening) than their musician peers. Relatedly, more gradient listeners had larger elliptical noise benefit, indicative of broader category use. Elliptical speech perception was also associated with QuickSIN performance in both groups but in opposite ways. Use of broader categories was related to better SIN processing in nonmusicians but poorer SIN processing in musicians.

Conclusions: Collectively, our findings suggest listeners can use broader perceptual equivalence classes to deal with degraded listening situations but this depends critically on their prior auditory experience. Nonmusicians might use broader phonetic categories to assist SIN perception while musicians might use narrower categories in otherwise similar speech contexts.

Interpretable Embeddings of Speech Explain and Enhance Brain Encoding Performance of Audio Models

3:45 p.m. - 4:00 p.m.

Riki Shimizu*¹, Richard Antonello¹, Chandan Singh², Nima Mesgarani¹

¹*Columbia University*, ²*Microsoft Research*

Background: Self-supervised speech models (SSMs), such as HuBERT, are increasingly hailed as powerful computational models of human speech perception, as their embeddings are shown to be highly effective in predicting brain responses to speech. However, since their representations are inherently black-box, it remains unclear what drives their alignment with brain responses. Although representational similarity analysis or linear probing of their representations provides insight into what these models encode, they do not reveal which representational components are responsible for alignment with neural activity. To establish a stronger neuroscientific basis for the alignment between SSMs and neural responses for

speech perception, it is essential to directly test which features of SSM representations account for their predictive power.

Methods: In this study, we analyzed open-source electrocorticography (ECoG) recordings collected from nine neurosurgical patients as they listened to naturalistic speech stimuli. To investigate the representational basis of SSM-brain alignment, we constructed linear encoding models of neural responses using banded ridge regression. These models incorporated hand-crafted, interpretable features—spanning acoustic to lexical domains—and contextualized embeddings from three state-of-the-art speech models: Whisper, HuBERT, and WavLM. By applying a variance partitioning approach, we quantified the extent to which ECoG response variance was shared between two feature classes, directly testing the representational basis of SSM–brain alignment.

Results: We first demonstrate that the SSMs' alignment with the brain can be mostly explained by their ability to learn and encode simple interpretable speech features. Additionally, SSMs exhibit a systematic trade-off between encoding of brain-relevant low-level and high-level features across layers. Finally, our results show compellingly that SSMs learn brain-relevant semantics that cannot be explained by lower-level speech features, with this capacity increasing with model size and context length. Together, these findings suggest a principled approach to building better and more efficient encoding models of the brain by augmenting SSM embeddings with interpretable features.

Conclusions: By applying the variance-partitioning approach to a diverse set of interpretable features and SSM representations, we identify which representational features are responsible for SSM's ability to predict brain responses for speech perception. Our results further demonstrated that augmenting SSM embeddings with interpretable features yields more accurate and efficient encoding models, highlighting the value of refined interpretable feature sets. Importantly, although our interpretable features account for most of the neural variance captured by SSM representations, a statistically significant portion remains unexplained. Identifying the nature of this residual variance is an important direction for future research.

Linking EEG Evoked Potentials to Dimensions of Lexical Competition in Cochlear Implant Users

4:00 p.m. - 4:15 p.m.

Francis Smith^{*1}, Sarah Colby², Nour Alsabbagh¹, Joel Berger¹, Phillip Gander¹, Timothy Griffiths³, Bob McMurray¹, Inyong Choi¹

¹University of Iowa, ²University of Ottawa, ³Newcastle University

Background: One key challenge in spoken word recognition is the temporary ambiguity that results from speech unfolding over time. Models of speech perception which are based on research with normal hearing (NH) listeners resolve this ambiguity through incremental processing and competition among lexical candidates. Multiple studies have found that these patterns of competition differ in cochlear implant (CI) users (Farris-Trimble et al., 2014; McMurray et al., 2017) and recent work has revealed that this basic mechanism of competition varies along three principal dimensions across both CI users and NH listeners: delayed lexical access (“wait-and-see”), resolution of competition (“sustained-activation”), and overall rate of activation (McMurray et al., 2024). The neural substrates underlying these dimensions of lexical access and the sources of individual variability remain unclear. We examined a subset of CI participants from McMurray et al. (2024) to investigate the neural correlates of these three dimensions of word recognition in CI users.

Methods: We tested 63 experienced (> 1 year of device use) CI users (mean age = 60.5 years) from McMurray et al. (2024) who also participated in a speech recognition task (the Iowa Test of Consonant Perception: ITCP; Geller et al., 2020, 2021; Smith et al., 2025) while 64-channel EEG data were collected. The ITCP is a four-alternative forced choice speech perception task. Monosyllabic words were presented in multi-talker babble in both high (+15 dB) and low (+7.5 dB) signal-to-noise ratio trials. We used data from Cz to analyze early and late evoked activity to the onset of babble and the onset of the target word and correlated these measures with each of the three dimensions of word recognition described above. This yielded eight EEG measures (early/late $\times$ noise/target $\times$ amplitude/latency), which we correlated with competition dimensions.

Results: Participants who showed lower EEG amplitudes in response to the target word onset (both early and late peaks) were more likely to be more “wait-and-see” in their eye movement patterns ($r = -.22$, $r = -.20$). Participants who showed delayed latency in their late activity in response to the target were more likely to show “sustained activation” eye movement patterns ($r = .31$). Participants who showed delayed latency in their early activity in response to the initial noise were more likely to show “slow activation rate” eye movement patterns ($r = .29$).

Conclusions: Within this large cohort of CI users, we found significant correlations between EEG evoked potentials collected in a speech perception task and patterns of word recognition collected in a separate visual world paradigm task. There was substantial variability in both EEG measures and word recognition dimension measures among the CI population measured in this study, which matches the large variability in lexical competition profiles shown by this group.

Neural Encoding of Acoustic and Linguistic Speech Features Reveals Correlates of Understanding

4:15 p.m. - 4:30 p.m.

Alexis MacIntyre^{*1}, Tobias Goehring², Matt Davis³

¹*University of Cambridge*, ²*Cambridge Hearing Group, University of Cambridge*,

³*Cambridge Hearing Group, MRC Cognition and Brain Sciences Unit, University of Cambridge*

Background: How listeners parse a variable and continuous acoustic speech signal into meaningful, abstracted representations—language—is a question central to auditory neuroscience. Moreover, the resilience of this process to multiple forms of signal degradation is not fully understood. Theory suggests that listeners benefit from simultaneous and redundant cues that situationally differ in their availability and utility. These cues can range from higher-level information, such as semantic context, to low-level acoustic properties, such as spectral contrasts; however, previous studies investigating low-level speech cues tend to examine short, discrete stimuli in the context of behavioural paradigms. Hence, it is unclear how low-level spectral properties are neurally encoded and whether this can be detected using non-invasive electrophysiology during continuous speech listening.

Methods: The current study consists of a listening task wherein $n = 38$ young, typically hearing adults were presented with a naturalistic story whilst undergoing continuous electroencephalography (EEG). Critically, access to speech cues was manipulated over two dimensions: Acoustic spectral clarity and linguistic familiarity, with the latter contrast consisting of a familiar language paired against an unfamiliar but closely related language,

both produced by the same bilingual speaker. Using banded regression, we modelled neural responses to a set of spectro-temporal and linguistically derived features, including lexical surprisal scores obtained from large language models. To disentangle correlated predictors and ensure robustness of results, we subjected encoder weights to a random permutation analysis. We performed comparisons across listening conditions at the group level as well as a data-driven analysis of individual differences in self-reported understanding.

Results: The results reveal unique contributions from four acoustic properties: The amplitude envelope; peaks in the envelope first derivative; spectral variation, an intensity-invariant measure of spectral change; and spectral flux, which reflects both spectral and signal energy change. When introducing higher-level features to the acoustic encoding model, we found substantive word onset encoding that was specific to intelligible speech, but minimal additional variance explained by phoneme and syllable onsets or surprisal. We identified features, time windows, and channel clusters in which the neural response was mediated by language, acoustic clarity, or their interaction. Finally, differences in the neural response across listening conditions could be summarised as a composite score that strongly predicted subjective individual comprehension of the most spectrally degraded but moderately intelligible speech ($\text{Rho} = 0.90$, $p < .001$).

Conclusions: These findings underscore the complex interplay between low- and high-level features during naturalistic speech perception and illustrate inter-listener as well as inter-condition differences in the neural encoding of such features. Syllable and phoneme onset encoding may be driven by correlated acoustic properties; however, word onset encoding persists after controlling for low-level acoustics. The observed brain-behavioural link between feature encoding and intelligibility may hold promise for future interventions.

1. Hearing Loss and Vocalization Deficits in Two Mouse Models of Alzheimer's Disease

Sevda Abdavinejad^{*1}, Bridget Crandall¹, Emma Ogilvie¹, Amanda Lauer², Micheal Dent¹

¹*The University at Buffalo - SUNY*, ²*Johns Hopkins University*

Background: Alzheimer's disease (AD) is the most common cause of dementia, affecting millions of people worldwide. In addition to memory decline, AD is also often associated with early-onset hearing loss and vocal communication impairments. While hearing loss has been identified as the most modifiable risk factor for dementia, the mechanisms linking it to AD remain poorly understood. Transgenic mouse models carrying human genes connected to familial AD can be a powerful tool to examine these associations. APP/PS1 mice capture the deposition of extracellular amyloid plaque pathology seen in AD patients, while 3xTg-AD mice display both amyloid plaques and intracellular neurofibrillary tangles (NFTs). The present study investigated hearing thresholds and ultrasonic vocalizations (USVs), a measure of mouse social communication, across the lifespan in these widely used AD models. Hearing was assessed using behavioral and psychoacoustic techniques that engage attention, memory, and participation, providing greater sensitivity than physiological measures.

Methods: Behavioral hearing thresholds were collected daily in male and female 3xTg-AD, APP/PS1, and wild-type (WT) control mice (n = 5 per sex per strain) across the lifespan using operant conditioning and psychophysical techniques. The same mice were recorded for USV assessment at four time points (11, 24, 52, and 68 weeks of age) across three social conditions: isolation, same-sex, and opposite-sex pairs. Calls were analyzed for number, type, bandwidth, and duration. Analyses compared outcomes across age, strain, sex, and social condition.

Results: Behavioral thresholds revealed progressive, age-related hearing loss in both sexes across all strains, which was positively correlated with a reduced number and diversity of USVs. 3xTg-AD mice exhibited significantly earlier-onset hearing loss than both WT and APP/PS1 mice, suggesting a role for NFT-specific pathology or the combination of plaques and tangles in auditory and vocal communication declines. In contrast, APP/PS1 mice showed only age-related hearing loss comparable to their WT controls. USV analysis revealed age-related reductions in call number and repertoire diversity in both models, with 3xTg-AD mice showing the most severe impairments. A sex effect was observed in the

3xTg-AD model, with males exhibiting more severe hearing and vocalization decline than females.

Conclusions: Hearing loss was positively correlated with reduced vocalization output, indicating that auditory decline contributes directly to impaired social communication in AD models. Findings demonstrate that hearing and communication deficits are early, progressive features of familial AD mouse models. The 3xTg-AD line more closely recapitulates human patterns of hearing loss and vocal communication decline, underscoring the significant role of NFTs or combined plaque and tangle pathology in familial AD. These results support USVs and auditory thresholds as promising biomarkers for early AD-related cognitive impairment and highlight the need for further studies on the mechanistic links between AD pathology, auditory processing, and communication deficits.

2. From Sound to Movement: The Neural Backbone of the Acoustic Startle Reflex

Jan Frederik Ahrend*¹, Jana Erlmoser¹, Kathrin Deborah Wicke², Felix Felmy², Christian Vogl¹

¹*Auditory Neuroscience Group, Institute of Physiology, Medical University Innsbruck,*

²*Institute of Zoology, University of Veterinary Medicine Hannover Foundation,*

Background: The acoustic startle reflex (ASR) is a fast bodily reaction to a loud and unexpected auditory stimulus – a protective mechanism inherent to most mammalian species. On cellular level, large cochlear root neurons (CRNs), located between the auditory periphery and cochlear nucleus, have been identified as the first neural substrate of the underlying reflex circuitry. CRNs receive glutamatergic input from primary afferent spiral ganglion neuron (SGN) collaterals and were shown to be subject to various efferent modulatory pathways. Their large axons mainly target neurons of the contralateral pontine reticular nucleus (PnC) formation, which project onto cranial and spinal motor neurons and are in turn subject to extensive modulatory inputs from various brain areas. Despite their fundamental role in a survival reflex circuit, CRNs are still remarkably poorly characterized in regard to their cellular excitability and activity patterns as well as their molecular composition and morphology in situ. Despite behaviorally apparent acoustic startle reflexes in humans, the taxonomic equivalent of rodent CRNs has yet to be identified. However, ASR measurements are of major clinical relevance, as altered startle behavior is linked to neuropsychiatric or neurodevelopmental disorders – such as autism spectrum disorders.

Methods: Here, we prepared fixed vibratome-sectioned tissue slice preparations of the cochlear root nucleus as well as whole-mount preparations of the intact peripheral auditory pathway of mice (*Mus musculus*) for immunohistochemical stainings and ethyl cinnamate based tissue clearing. For fiber input tracing experiments, we utilized various genetic reporter mouse models alongside lipophilic tracer dyes. Data were acquired using confocal and lightsheet fluorescence microscopy and analyzed using Imaris software. To probe evolutionary conservation and the functional role of CRNs in various animal models with distinct hearing frequency ranges, we additionally analyzed Mongolian gerbils (*Meriones unguiculatus*), Etruscan shrews (*Suncus etruscus*) and common fruit bats (*Carollia perspicillata*).

Results: In this work, we were able to develop a novel tissue preparation technique that preserves the cochlear root nucleus within its native context in the intact peripheral auditory pathway. Lightsheet images of such chemically-cleared preparations allowed us to

characterize the exact 3D localization, morphology, size and count of the CRN population. Furthermore, we analyzed the afferent and efferent synaptic connectome of CRNs to establish excitatory and inhibitory neurotransmitter identities as well as their respective innervation densities and further plan to probe their role on cellular excitability measures.

Conclusions: In this project, we aimed for a holistic in situ characterization of the CRN population by performing detailed anatomical, morphological and functional analyses regarding cellular location and neuronal connectivity. Our current findings yield strong evidence for distinct CRN subpopulations that may serve differential functions in the ASR pathway – thereby highlighting the surprising complexity of a supposedly simple and rapid reflex circuit.

3. Transient Unilateral Hearing Loss Induces Bilateral but Reversible Central Gain Plasticity

Megan Arnold*¹, Aravindakshan Parthasarathy²

¹*University of Pittsburgh School of Medicine*, ²*University of Pittsburgh*

Background: Unilateral hearing loss (UHL) presents a paradox: despite preserved hearing in one ear, affected individuals often experience disproportionate difficulty with speech perception in noise (SPIN). Standard audiometric assessments do not capture these deficits, suggesting abnormalities in central auditory processing contribute to these impaired outcomes. One proposed mechanism driving SPIN deficits is maladaptive central gain, in which reduced input from one ear drives a compensatory increase in the responsiveness of central auditory pathways. While such plasticity may partially compensate for reduced audibility in quiet, it can impair SPIN by indiscriminately amplifying both target and background signals. Central gain following bilateral hearing loss is well documented in both humans and animal models, but its dynamics in UHL remain poorly understood. Moreover, whether these changes reverse to baseline after hearing restoration has not been systematically examined.

Methods: To address this gap, we developed a reversible model of UHL using unilateral earplugging in Mongolian gerbils, a rodent model with human-like hearing at speech-relevant frequencies. Animals (n=16) were recorded longitudinally at baseline, during earplugging, and after earplug removal. Envelope following responses (EFRs) were measured non-invasively with stimulus parameters emphasizing cortical versus peripheral neural generators. A central gain index was derived as the ratio of cortical to peripheral EFR amplitudes, enabling assessment of level dependence, ear-specific effects, and recovery trajectories.

Results: Earplugging for 14 days produced a stable conductive hearing loss of ~40 dB that resolved upon earplug removal. Peripheral EFR amplitudes were reduced in the plugged ear and unchanged in the unplugged ear. In contrast, cortical EFRs were enhanced relative to peripheral responses, yielding a bilateral increase in central gain: approximately five-fold in the plugged ear and 2.5-fold in the unplugged ear. Central gain enhancement was level dependent, peaking at moderate intensities (40–60 dB SPL). Critically, longitudinal recordings after earplug removal revealed that central gain returned to baseline within two weeks. These findings demonstrate that restoring hearing within this time window enables compensatory gain changes (likely hindering SPIN) to normalize, informing the therapeutic window for intervention in UHL.

Conclusions: These findings demonstrate that UHL drives robust but reversible increases in central auditory gain. The bilateral and time-limited nature of these effects suggests a window

of plasticity during which maladaptive gain can normalize, highlighting the value of early intervention. This gerbil model provides a tractable platform for probing neural mechanisms underlying SPIN deficits and for testing interventions to accelerate recovery of maladaptive plasticity following hearing restoration. Ongoing work examines how central gain dynamics shape neural coding of speech-relevant cues and behavioral outcomes in a tone-in-noise detection task. Together, this work has direct implications for understanding perceptual consequences of enhanced central gain and for optimizing timing and effectiveness of clinical rehabilitation in otolaryngology.

4. Predicting Auditory Midbrain Responses to Natural Sounds With Integrate-And-Fire Gabor Receptive Field Models

Jenna Blain^{*1}, James Dion¹, Ruotong Li¹, Ian Stevenson¹, Monty Escabí¹

¹*University of Connecticut*

Background: Spectro-temporal receptive fields (STRFs) are widely used to model the time-frequency sensitivity of auditory neurons. Often, STRFs are derived using unbiased synthetic stimuli, such as dynamic ripples or random chords, which can easily be estimated using spike-triggered averaging. However, with natural sounds, decorrelation and regularization techniques are needed to remove embedded stimulus correlations that distort the estimated STRFs. Furthermore, nonlinearities and non-stationarities make it difficult to predict spiking neural responses to natural sounds at millisecond timescales.

Methods: Neural recordings were obtained from the inferior colliculus (IC) of unanesthetized rabbits in response to an ensemble of 50 natural sounds as well as dynamic moving ripples (DMR). We developed a model-based approach for deriving auditory STRFs and predicting single trial spike trains to these sounds. The model consists of a first and second-order nine parameter Gabor STRF (gSTRF; Qiu et al. 2003), accounting for the neuron's linear and non-linear spectro-temporal integration. A four-parameter nonlinear integrate-and-fire (IF) compartment incorporates intrinsic noise, cell membrane integration, and nonlinear thresholding to generate simulated spikes, and a six-parameter adaptive context receptive field that dynamically adjusts the intracellular current to account for slow fluctuations in firing rate in response to naturalistic stimuli. Simulated annealing optimization was used to fit neural data and derive optimal model parameters by minimizing the log-likelihood.

Results: We compared optimal gSTRFs to other approaches such as a generalized linear model and regression. STRFs derived via regression were spectrally smeared, indicating that stimulus correlations were not effectively removed. In comparison, the gSTRF was compact and provided biologically feasible parameter estimates, including best frequency and temporal modulation. The adaptive context receptive field improves predictions of firing changes across sounds not captured by the gSTRF alone. Furthermore, unlike conventional receptive field models, which generate continuous outputs, the model produces and predicts spiking activity with spike timing precision comparable to IC neurons (between ~0.5 -5 ms).

Conclusions: This new approach allows one to derive auditory STRFs and predict neural spiking activity to natural sounds in IC using functionally interpretable basis functions. The small number of functionally interpretable parameters makes exploration of nonlinear and nonstationary effects due to natural sound statistics more feasible.

NIH (R01DC020097)

5. Layer 6 Corticothalamic Neurons Show Attentional-Gain Responses During a Tone-In-Noise Detection Task

Marina Cardoso de Oliveira*¹, Patrick O. Kanold¹

¹*Johns Hopkins University*

Background: Neuronal activity adapts to behavioral context, optimizing performance. Although previous studies have shown that layers (L) 2/3 in the auditory cortex show attentional gain when mice are engaged in a detection task, how this modulation is achieved is unknown. Previous studies have reported the presence of noise-invariant neurons in upper cortical layers, and that the amplitude of responses and bandwidth decrease as SNR decreases. Since L6 corticothalamic (CT) neurons play an important role in modulating cortico-thalamo-cortical activity, we hypothesize that this modulation could sharpen the tuning curves and increase the gain of neurons in L2/3 and thalamic nuclei, thereby improving the perception of sound in environments with high background noise, for example. However, it remains unclear whether L6 CT neurons contribute to the mechanisms that improve performance in such conditions. Here, we aim to investigate how L6 CT neurons respond during behavior and whether L6 CT neurons could enhance the perception of target tones embedded in a noisy background.

Methods: We trained adult mice of the Ntsr1-Cre (B6.FVB(Cg)-Tg(Ntsr1-cre)GN220Gsat/Mmucd) line on a fixed hearing background (B6.CAST-Cdh23Ahl+/Kjn) crossed with a reporter line expressing (B6.Cg-Igs7tm162.1(tetO-GCaMP6s,CAG-tTA2)Hze/J) on a tone-in-noise detection task. Constant broadband white noise (50 dB SPL) was presented together with a one-second duration tone of 11.5 kHz (30 to 70 dB SPL), to obtain signal-to-noise ratios (SNRs) of -20 to +20 dB SPL. The mouse had to turn a wheel 25° degrees in either direction to receive a water reward. Mice were then imaged under 2-photon microscopy while performing the task. The pupil diameter was also recorded to assess the animal's attentional state during the task. Passive imaging sessions were conducted after the behavioral sessions to obtain frequency response areas for each neuron.

Results: Our preliminary findings indicate that pure-tone-responsive L6 CT neurons increase their response gain when mice successfully detect a tone embedded in a noisy background, compared to when they do not. This enhancement in response gain appears to become stronger as the SNR decreases.

Conclusions: Our preliminary results are consistent with our hypothesis for a role of L6 CT neurons in hearing in noisy environments. The observed increase in gain of L6 CT neurons at lower SNRs for hit trials in comparison to miss trials suggests that task difficulty and possibly the state of attention may be driving their responses when hearing target tones becomes more challenging.

6. Developing Optimization Strategies to Compensate for Losses Due to Auditory Nerve Synaptopathy

Ahsan Cheema*¹, Sunil Puria²

¹*Harvard Medical School, Massachusetts General Hospital*, ²*Harvard Medical School*

Background: Difficulty understanding speech in noise is the most common complaint of patients with sensorineural hearing loss. Cochlear neural degeneration (CND)—the loss of peripheral auditory nerve fibers (ANF)—has been hypothesized as a major contributor to these deficits, yet it remains sub clinical in audiometry measurements. In the absence of

noninvasive methods to probe for neural deficits, current hearing-aid (HA) fitting algorithms, such as NAL/NL2, which are based solely on audiometric thresholds, ignore the neural component of hearing loss. The first question we address in this study is how to effectively design speech stimuli that can probe deficits resulting from CND. The second question that we address in this study is how to explore the Hearing Aids parameter space to specifically address neural deficits.

Methods: We used a phenomenological model of auditory periphery (Bruce et. al 2018), to simulate the auditory nerve fiber responses to input sound stimulus. (1) To address the 1st question i.e. the effectiveness of speech materials to detect CND, we developed a Mutual information based framework that uses loss of information between inner hair cells receptor potential and ANFs to quantify the loss of encoding and reduction in information carrying capacity of ANF due to CND. (2) For the second question i.e. Hearing aids fitting, we developed a Simulation-Based Inference (SBI) pipeline to optimize HA level compression algorithms with a focus on compensating for CND. We simulated speech processing under varying degrees of sensory loss and CND. The HA parameter space, including compression threshold, slope, and attack/release times, were systematically explored within the SBI framework to identify parameter sets that minimize neural deficits. Our approach aims to identify alternative parameter combinations that could, in theory, provide better neural compensation and improve speech-in-noise performance.

Results: (1) Our mutual information framework suggests that time-compressed speech (40% and 65% dilatation) produces the greatest sensitivity to CND-related information loss, making it an effective speech probe for evaluating neural deficits. (2) Preliminary results indicate that hearing aid parameters can be explored using SBI to address CND deficits as a framework to reveal parameter-space not captured by the standard NAL/NL2 prescription, particularly for challenging listening conditions.

Conclusions: This project establishes an SBI-based approach to systematically evaluate and optimize HA parameter settings in the context of CND. By highlighting where current gain prescriptions fail, we will re-evaluate compensation strategies to better address the hidden neural deficits underlying speech-in-noise difficulties. Moreover, by exploring the larger parameter space of HA algorithms, this work could uncover fitting strategies that provide more effective compensation for CND-related deficits. [Work supported by MEE SharkTank award and grant R01 DC07910 from the NIDCD of NIH.]

7. Central Auditory Synapse Alterations in Mice With Modified Medial Olivocochlear Efferent Activity

Daniela Chequer Charan^{*1}, Fangfang Wang², María Eugenia Gómez-Casati³, Haoyu Wang⁴, Yumeng Qi⁴, Carolina Wedemeyer¹, Yunfeng Hua⁴, Ana Belén Elgoyhen¹, Mariano Nicolas Di Guilmi¹

¹*Instituto de Investigaciones en Ingeniería Genética y Biología Molecular, INGEBI-CONICET*, ²*Shanghai Ninth People's Hospital*, ³*Instituto de Farmacología, Facultad de Medicina, Universidad de Buenos Aires*, ⁴*Shanghai Institute of Precision Medicine, Shanghai Ninth People's Hospital, Shanghai Jiao Tong University School of Medicine*

Background: In many mammals, the auditory system is functionally immature at birth and undergoes postnatal refinement to achieve precise connectivity in adulthood. Spontaneous activity in the immature cochlea drives the organization of auditory brainstem circuits, a process modulated by the medial olivocochlear (MOC) efferent system. While the MOC

pathway is known to protect against noise-induced hearing loss in adulthood, its developmental role remains less understood. We investigated how altered MOC activity during the critical period impacts the synaptic and morphological maturation of the calyx of Held (CH) synapse in the medial nucleus of the trapezoid body (MNTB)

Methods: We combined whole-cell patch-clamp recordings from MNTB principal neurons with 3D reconstructions from serial block-face electron microscopy (SBEM) at P12–14. Three mice genotypes were analyzed: wild type (WT), $\alpha 9$ KI (enhanced MOC activity), and $\alpha 9$ KO (absence of MOC activity). Morphological complexity of CH terminals was quantified using a custom Python pipeline based on graph theory, which enabled classification into distinct morphotypes.

Results: Electrophysiological recordings revealed that $\alpha 9$ KO mice showed electrophysiological responses comparable to WT. However $\alpha 9$ KI mice displayed reduced synaptic strength compared to WT, including smaller excitatory postsynaptic current (WT: 5.01 ± 1.58 nA, $n=28$; $\alpha 9$ KI: 3.61 ± 1.23 nA, $n=25$; $\alpha 9$ KO: 4.23 ± 1.34 nA, $n=20$; ANOVA: $p=0.0013$; Tukey WT- $\alpha 9$ KI, $p=0.0008$), stronger short-term depression during repetitive stimulation (100Hz: WT: $33.59 \pm 1.62\%$, $n=12$; $\alpha 9$ KI: $22.52 \pm 2.99\%$, $n=10$; $\alpha 9$ KO: $33.92 \pm 4.16\%$, $n=11$; ANOVA: $p=0.0224$; Tukey WT- $\alpha 9$ KI: $p=0.0403$) and a decreased readily releasable pool size (WT: 374.02 ± 29.11 , $n=10$; $\alpha 9$ KI: 253.01 ± 21.78 , $n=12$; $\alpha 9$ KO: 323.21 ± 21.39 , $n=9$; ANOVA, $p=0.0057$, Tukey WT- $\alpha 9$ KI, $p=0.005$). Morphological analysis indicated that $\alpha 9$ KI animals exhibited a lower proportion of structurally complex CH terminals and evidence of loss in synaptic pruning, both in pre- and post-hearing stages. The $\alpha 9$ KO mice displayed reduced morphological complexity but neither pruning nor electrophysiological performance were significantly altered (poly-innervation rate: WT/ $\alpha 9$ KO~10%; $\alpha 9$ KI~30%).

Conclusions: Synaptic depression pattern in $\alpha 9$ KI matches well with a higher proportion of simple CHs, according to literature linking structure and function at this synapse. Although previous studies in other auditory centers show both synaptic and morphological alterations when MOC efferent activity is lost, these results suggest that there may be some type of compensation at the level of the MNTB. Our findings demonstrate that enhanced MOC efferent activity during early development triggers profound modifications in both synaptic physiology and morphology at the CH–MNTB synapse. These results highlight the critical role of efferent pathways in shaping auditory brainstem maturation and suggest that altered efferent activity may contribute to long-term deficits in auditory processing.

8. Meclizine, an H1 Antihistamine, Disrupts Roll-Axis Postural Control

Samantha Davis*¹, David Schoppik²

¹New York University, ²NYU School of Medicine, Neuroscience Institute

Background: Antihistamines are the largest class of pharmaceutical compounds used to treat and prevent vestibular disorders. Despite their efficacy, we do not know how their ability to suppress vestibular perception affects balance circuits.

Methods: Using a simple vertebrate model, the zebrafish, we show that a commonly-prescribed H1 antagonist, meclizine, modulates balance behavior.

Results: Strikingly, we observed that larval zebrafish swim upside-down during treatment with meclizine, implicating suppression of gravity-driven roll stabilizing postural reflexes. In contrast, H1 agonist exposure caused no change in posture, suggesting a ceiling effect on postural stability. Next, to understand changes to central vestibular processing after

antihistamine administration, we imaged neural responses to body tilts in central vestibular circuits before, during, and after exposure to meclizine. While hindbrain neurons increased their response to roll-axis (leaning left and right) body tilts, preliminary data from downstream midbrain neurons showed changes in stimulus-evoked and spontaneous activity.

Conclusions: These results suggest that antihistamines act directly on central roll-stabilizing circuits. Future work using other drugs will reveal shared and/or divergent mechanisms of antihistamines. We anticipate that our model will generate new hypotheses for clinical studies with the long-term goal of shaping vestibular intervention strategies.

9. Glucocorticoid Receptor Beta Expression as a Marker of Steroid Resistance in Autoimmune Inner Ear Disease

Vijay Deopersaud^{*1}, Shresh Pathak², Andrea Vambutas²

¹Donald and Barbara Zucker School of Medicine at Hofstra/Northwell, ²Northwell Health

Background: Autoimmune inner ear disease (AIED) is a form of sensorineural hearing loss that is characterized by either fluctuation or worsening hearing loss in either one or both ears. The first line of treatment for AIED is high-dose corticosteroids. While 70% of initially respond, many lose responsiveness over time. Steroids are the mainstay of treatments as previous trials of other immunosuppressants, such as methotrexate and TNF-alpha inhibitors, have not shown significant benefit. Patients who fail to respond to corticosteroids express high levels of IL-1 β (Pathak et al 2011), and an early-stage clinical trial shows that anakinra, a recombinant IL-1 receptor antagonist, improves hearing capabilities in 46-70% of corticosteroid-resistant AIED patients (Vambutas et al 2014, Vambutas et al, 2025). The mechanism(s) underlying this steroid resistance remain poorly understood. Evidence from other steroid-resistant inflammatory diseases such as asthma and ulcerative colitis suggests the involvement of glucocorticoid receptor beta (GR- β). Glucocorticoid receptor alpha (GR- α) is the active glucocorticoid receptor isoform that mediates anti-inflammatory effects, while GR- β is a splice variant that does not bind glucocorticoids and inhibits GR- α 's transcriptional activity, contributing to steroid resistance. The role of GR- β has not been studied in AIED.

Methods: We examined the relative mRNA expression and protein levels of GR- β and GR- α in peripheral blood mononuclear cells (PBMCs) of patients with AIED using qRT-PCR and Western blot, and investigated how these levels change following treatment with dexamethasone and anakinra under inflammatory conditions.

Results: In PBMCs from corticosteroid-resistant AIED patients, the relative expression of GR- β appears to increase with dexamethasone treatment when co-stimulated with LPS, while treating with anakinra and LPS reduces GR- β expression. Furthermore, this change was also reflected when assessing intracellular GR- β protein with Western blotting.

Conclusions: Characterizing the role of GR- β expression can deepen our understanding of steroid resistance in AIED patients and better predict who may respond to steroids. Further studies are underway to characterize the effect of interleukin-1 expression on GR- β .

10. The Influence of Spectrum and Modulation Statistics on the Neural Representation of Speech in Natural Background Sounds

James Dion^{*1}, Jenna Blain¹, Ruotong Li¹, Ian Stevenson¹, Monty Escabí¹

¹University of Connecticut

Background: Separating target sounds from background noise is challenging for people with normal hearing, and especially challenging for people with hearing impairments as well as artificial speech recognition systems. Why different natural backgrounds mask the perception of speech to varying degrees, and how the brain separates speech from background noise is not yet fully understood.

Methods: Here, we recorded multi-unit activity from the inferior colliculus of head-fixed unanesthetized rabbits passively listening to speech mixed with eleven natural backgrounds (speech babble, bird babble, water, fire, city noise, etc.). Speech was mixed with each original (OR) background at multiple acoustic signal-to-noise ratios (aSNRs). We also presented speech mixed with spectrum-matched (SM) backgrounds that retain the original spectra but have whitened modulations, or modulation-matched (MM) variants that retain the original modulations but have whitened spectra. Using a cross-spectrum shuffling procedure, we separated the foreground- from the background-driven neural responses. The neural signal-to-noise ratio (nSNR) was then estimated and used as a metric of speech coding fidelity.

Results: We find that nSNR depends on background category and statistics. Compared to OR backgrounds, nSNR can increase or decrease for SM and MM backgrounds in a category-dependent manner. This suggests that the original spectra (OR vs. MM) or modulations (OR vs. SM) improve or worsen the neural representation of speech. Interestingly, the impact of background category and statistics was largely independent of aSNR, since increasing aSNR amplified nSNR approximately linearly. We also demonstrate how the background spectrum and modulation statistics affect neural encoding of speech at temporal modulations below 10 Hz, which overlap and potentially mask temporal fluctuations for phonemes, words, and syllables. Spectrum and modulation masking effects were segregated by background category, and a model of the cochlea and auditory midbrain showed similar segregation. Finally, human perceptual tasks using the same backgrounds suggest that nSNR correlates with speech recognition accuracy.

Conclusions: Collectively, the results posit that spectrum and modulation statistics critical to speech masking are reflected in the population activity of the inferior colliculus. These neural response statistics reflect the coding fidelity for speech and likely contribute to downstream signaling underlying speech perception in real-world noise.

11. A Model of Speech Recognition Reproduces Signatures of Human Speech Perception and Reveals Mechanisms of Contextual Integration

Gasser Elbanna^{*1}, Arnav Aggarwal², Josh McDermott²

¹*Harvard University*, ²*MIT*

Background: Humans rapidly and dexterously transform acoustic waveforms into linguistic representations despite the inherent variability of the speech signal. The mechanisms that enable such robustness remain poorly understood, in part due to the lack of stimulus-computable models that both approach human performance and can test theoretical principles and mechanistic hypotheses.

Methods: We built an artificial neural network model of continuous speech recognition optimized to produce sequences of sublexical units (phonemes or characters) from simulated cochlear representations. The front end simulated outer, middle, and inner ear filtering, followed by half-wave rectification and low-pass filtering at 4 kHz to approximate the upper

limit of mammalian auditory-nerve phase-locking, yielding cochleagrams that served as input to stacked convolutional and recurrent layers trained to predict sublexical sequences. The model was trained on 15,000 hours of speech data superimposed on naturalistic noisy backgrounds, with varied SNRs and sound levels.

We compared the model to humans using a new large-scale benchmark of nonword transcription and discrimination along with a battery of previously documented signatures of speech perception, including categorical perception, neighbourhood density effects, phonotactic probability effects, formant-based vowel space, and benefits of talker familiarity. We tested the role and importance of contextual integration by ablating contextual integration mechanisms (recurrent processing), and by manipulating the directionality of contextual processing in the model.

Results: Human nonword transcription and discrimination exhibited highly reliable phoneme confusion structure (split-half $r=0.98$). The model closely matched human performance, reproducing human-like patterns of phoneme recognizability ($r=0.96$) and confusions ($r=0.95$). It also recapitulated classic human perceptual signatures: categorical perception of consonants, sensitivity to neighborhood density and corpus statistics, formant-based vowel encoding, and improved recognition with talker consistency.

Removing contextual processing substantially reduced human–model similarity, suggesting that human recognition depends critically on integrating surrounding speech information.

Conclusions: We built a biologically grounded stimulus-computable model of speech perception, and developed a suite of evaluations with which to compare it to humans and probe the basis of recognition. The model aligns closely with human behavior on speech perception tasks, but only if allowed to integrate information from the surrounding speech signal, implicating contextual processing in human speech perception. By providing both a working model and an evaluation suite, this work supports systematic assessment of existing and future theories of speech perception.

12. Is There a Stream Nearby? Auditory Detection of Water in a Natural Environment

Matthieu Fraticelli^{*1}, Christian Lorenzi²

¹*Laboratoire des systèmes perceptifs, UMR CNRS 824, Ecole normale supérieure, Université Paris Sciences and Lettres*, ²*Laboratoire des Systèmes Perceptifs, École Normale Supérieure, PSL University*

Background: Water is an essential nutrient for living organisms. Surprisingly, knowledge is lacking about the way human beings process acoustic information conveyed by water in natural settings with their ears and their auditory brain. Our research aims to better understand how humans perceive liquid sounds within natural soundscapes, hypothesizing that water holds a particular perceptual role for human observers due to its ecological importance. To achieve this, we sought to address various objectives: (i) understanding which auditory cues and mechanisms humans use for the detection of water sounds in natural environments, (ii) determining if these cues vary as a function of distance, moments of the day and seasons.

Methods: To address this issue, a Mediterranean stream was recorded at varying distances from a stream segment (hereafter called ‘the source’), times of day (morning, noon, evening), and seasons (spring, summer) in a nature reserve (a forest). Human participants tested online under headphones performed a two-interval forced-choice task in which they had to

determine presence of water. On a typical trial, target and standard stimuli corresponded to acoustic samples recorded over a range of 0-100m distances to the source on a given transect, and samples recorded at 150 or 200m from the source on a different transect, respectively. To eliminate memory effects, a single-trial procedure was used where each participant was tested on a single trial only.

Results: The results confirmed that auditory detection of water depends strongly on distance to the source, consistent with expectations from spherical spreading and masking effects produced by the ambient-noise field. Seasonal changes associated with variations in sound-propagation conditions and masking effects produced by geophysical events and animal vocalizations also influenced water detection, whereas diel variations had no significant effect on auditory judgments. The empirical psychometric functions were compared to simulated psychometric functions obtained by running the same task with the same stimuli with a computational model of the auditory system. This model implemented a cochlear filterbank followed by a modulation filterbank and a decision stage based on a template-matching strategy. The best fit to the human data was obtained when the auditory model based its decisions upon skewness and kurtosis of envelope fluctuations at the output of cochlear filters, and cross-channel correlation patterns at the output of modulation filters.

Conclusions: These results suggest that human listener detect presence of water in natural settings by analysing the sparsity and coordination of amplitude-modulation cues conveyed by natural soundscapes, consistent with previous work demonstrating a role of these texture statistics in water identification (McDermott and Simoncelli, 2011).

13. Processing of Salient Vocalizations in Auditory Cortical Regions Cell Types

Zahra Ghasemahmad*¹, Elliot Chin², Maryse Thomas¹, Carolyn Sweeney¹, Jeffrey Wenstrup³, Anne Takesian¹

¹*Mass Eye and Ear; Harvard Medical School*, ²*Harvard College*, ³*Northeast Ohio Medical University*

Background: Mice produce a rich repertoire of complex vocalizations across diverse behavioral contexts, such as mating and stress. Playback of these calls elicits distinct behavioral responses and neuromodulator release patterns that vary with the listener's state and the context in which the calls occur. The auditory cortex is thought to relay information about these vocalizations to motor and limbic centers, thereby shaping context-appropriate reactions. However, how such salient vocalizations are represented across cortical subpopulations, and how this representation depends on behavioral state, remain unclear.

Methods: We measured vocalization responses in multiple auditory cortical cell types, including pyramidal excitatory neurons and a subset of inhibitory interneurons expressing Neuron-Derived Neurotrophic Factor (NDNF). These interneurons receive strong neuromodulatory inputs and are thought to modulate cortical activity in a state-dependent manner. Using transgenic mice expressing GCaMP in either pyramidal neurons or NDNF interneurons, we performed widefield and two-photon calcium imaging across auditory cortical regions in awake, head-fixed mice. Mice listened to playback of vocalization syllables recorded during negative (stress), positive (mating), or neutral (isolation) contexts, while we simultaneously monitored pupil dynamics and locomotion.

Results: Vocalizations evoked robust, widespread responses across primary auditory cortex (A1) and multiple higher-order regions. Two-photon recordings revealed region- and cell

type-specific response patterns, with subsets of L2/3 and L4 pyramidal neurons, and NDNF interneurons displaying strong selectivity for specific vocalizations or call classes (e.g., mating versus stress). Notably, many neurons responded robustly to natural vocalizations but not to synthetic sounds with matched spectral content, and small ensembles of vocalization-selective neurons could reliably decode call identity. Ongoing analyses are evaluating how behavioral state modulates the selectivity of these responses.

Conclusions: Together, these findings suggest that auditory cortical circuits encode behaviorally relevant vocalizations in a region- and cell-type-specific manner, and highlight a role for NDNF interneurons in shaping state-dependent processing. By identifying circuit mechanisms for encoding natural communication sounds, this work advances our understanding of auditory perception and lays a foundation for future studies of how internal state and experience shape communication.

14. Effects of Cochlear Synaptopathy on Single-Unit Cochlear Nucleus Responses in the Budgerigar

Leslie Gonzales*¹, Margaret R. Youngman¹, Kenneth Henry¹

¹*University of Rochester Medical Center*

Background: Cochlear synaptopathy (CS) is a commonly occurring pathology in aging humans, defined as the loss of synapses between hair cells and auditory-nerve fibers (ANFs). CS is hypothesized to impair perception of sounds in noise, but underlying neural mechanisms are unknown. Recent studies suggest that CS can amplify auditory-nerve onset responses and alter temporal dynamics. However, effects of CS on brainstem encoding remain less explored. The current study quantified effects of CS on neural encoding in the nucleus angularis (NA) of the budgerigar, a parakeet species. NA is one of two avian brainstem cochlear nuclei receiving direct input from the auditory nerve. Budgerigars were selected based on recent studies of kainate-induced CS in this species and previous behavioral research demonstrating performance comparable to humans for various complex auditory discrimination tasks.

Methods: The current experiment compared basic NA response properties including frequency tuning curves, post-stimulus time histograms (PSTHs), and rate-level functions between control and CS-induced budgerigars. In CS animals, substantial (60-70%) ANF loss was induced via intracochlear infusions of 1-2 mM kainic acid. Distortion-product otoacoustic emissions were used to confirm normal hair-cell function. For in-vivo recordings of NA units, a craniotomy was made above the anterior, vertical semicircular canal. A glass electrode with 40 to 80 M Ω impedance was placed in the flocculus of the cerebellum and driven into NA to record single-unit responses. PSTHs were obtained with a characteristic-frequency (CF) tone presented 30 dB above threshold. Rate-level functions were created by randomly presenting CF tones of varying sound levels (0 to 80 dB SPL).

Results: NA neurons in control budgerigars had primary-like, onset, and chopping PSTHs in response to CF tones. Tuning curves were V-shaped, with characteristic frequencies within the range of the budgerigar's behavioral sensitivity (i.e., up to 5-6 kHz). Strength of synchrony was calculated from PSTHs using vector strength (VS). VS was greatest below 1 kHz and generally insignificant above 2 kHz, in contrast to budgerigar ANFs which show significant VS up to 4-5 kHz. From rate-level functions, we found that some NA units monotonically increased firing rate as sound levels increase, while others had nonmonotonic rate-level functions. NA units in CS-induced animals showed the same PSTH response categories and had broadly similar tuning curves, VS of phase-locking, and rate-level

functions to control units. Population results are compared between groups to quantify changes in NA encoding with CS.

Conclusions: Preliminary results suggest that NA units in the CS-induced budgerigars have similar characteristics to control units. Further analyses will test population differences and characterize potential changes in onset activity, adaptation, and envelope encoding in CS-induced animals. Research in this species can provide important insight into the neural bases of normal and hidden hearing loss.

15. Neural Correlates of Decreased Sound Tolerance Disorders: Insights From Task-Based fMRI Study

Namitha Jain*¹, Shagun Ajmera¹, Somayeh Shahsavarani², Rafay Khan¹, Gibbeum Kim¹, Howard Berenbaum¹, Fatima Husain¹

¹*University of Illinois Urbana Champaign*, ²*San Jose State University*

Background: Sounds that do not bother most people—a neighbor chewing, a pen clicking, or the hum of machinery—can be intolerable for individuals with decreased sound tolerance (DST) disorders. DST includes clinically distinct but often co-occurring disorders, most notably hyperacusis and misophonia. Hyperacusis involves increased sensitivity to sounds above a certain loudness threshold, causing discomfort or pain. By contrast, misophonia is characterized by intense negative emotional reactions to specific “trigger” sounds (e.g., chewing or sniffing), regardless of their volume. Despite growing clinical recognition, the neural mechanisms underlying these disorders remain poorly understood. Prior neuroimaging studies have typically examined hyperacusis and misophonia in isolation and without accounting for comorbidity. To address these gaps, the present study aims to delineate the neural correlates of hyperacusis, misophonia, and their co-occurrence using task-based fMRI with emotionally valent sounds.

Methods: Ninety-two young adults were recruited and categorized into four groups: misophonia only (MISO; n = 29), hyperacusis only (HY; n = 14), comorbid misophonia and hyperacusis (MiHy; n = 24), and age- and sex-matched healthy controls (CTR; n = 25). Participants completed a task-based fMRI experiment during which they listened to 90 emotionally valent sounds (30 unpleasant, 30 neutral, and 30 pleasant) from the International Affective Digitized Sounds-2 database. Participants rated each sound as pleasant, neutral, or unpleasant using button presses. Whole-brain and region-of-interest functional activation, as well as seed-to-voxel functional connectivity analyses, were conducted with a primary threshold of $p < 0.001$ and cluster-level family-wise error correction at $p < 0.05$.

Results: Behaviorally, the comorbid group (MiHy) rated more sounds as unpleasant than both MISO and CTR groups, suggesting heightened aversive perception. fMRI analyses revealed both distinct and overlapping neural patterns. MISO and MiHy (relative to CTR) showed increased engagement of visual processing regions and altered salience–visual network connectivity during unpleasant (versus neutral) sound processing, suggesting atypical cross-modal sensory involvement. The HY and MiHy (relative to MISO and CTR) groups exhibited reduced connectivity between salience hubs and frontal control regions, indicating impaired top-down regulation. Notably, in MISO, this connectivity was preserved for non-trigger unpleasant sounds, suggesting intact regulation in that context. The comorbid group (MiHy) combined both neural signatures: altered visual engagement and reduced

regulatory control. Finally, both MISO and HY (relative to CTR) groups showed increased dlPFC–SMA connectivity, pointing to a shared mechanism of motor readiness.

Conclusions: Misophonia was linked to atypical cross-modal visual processing, hyperacusis to reduced top-down control, and comorbidity combined features of both, revealing distinct and overlapping neural correlates of DST. Future research should integrate neural and behavioral measures to refine mechanistic models and guide targeted interventions.

16. Aging Masks Auditory Dysfunction Associated With the Autism Spectrum Disorder Gene *Mef2c*

Tyreek Jenkins^{*1}, Jiaying Wu¹, Shelby Payne¹, Emily Fabrizio-Stover¹, Jeremy Barth¹, Dariusz Pytel¹, Rachel D. Penrod¹, Christopher Cowan¹, Hainan Lang¹

¹*Medical University of South Carolina*

Background: Autism spectrum disorders (ASDs) are associated with sensory deficits. Specifically, difficulties in hearing and sound processing are often reported in both children and adults with ASD. Mutations or deletions in the *MEF2C* gene results in a syndromic form of ASD known as *MEF2C* haploinsufficiency syndrome (MCHS). Global *Mef2c* heterozygosity is sufficient to elicit MCHS-like phenotypes in mice, including sensory deficits. Young-adult *Mef2c*-heterozygous mice exhibit auditory nerve functional impairment and a moderate reduction in hearing sensitivity. To date, most studies of auditory dysfunction in ASD preclinical models have focused on early development and young adulthood. The long-term trajectory of these deficits with advanced age is largely unknown, highlighting a critical gap in understanding the intersection of aging and auditory function in ASD.

Methods: Global *Mef2c*-heterozygous mice were backcrossed to B6.CAST mice to eliminate the *Cdh23Ahl* mutation present in the C57BL/6J background, which causes early-onset hearing loss, for auditory functional assessments. Auditory brainstem responses were used to assess hearing sensitivity and auditory nerve activity in aging *Mef2c*-heterozygous and wildtype mice. Bulk RNA-sequencing of cochlear tissue and Simoa (Quanterix) analysis of peripheral blood were performed to assess differential gene expression and circulating neurodegenerative biomarkers, respectively. Cognitive and behavioral phenotypes relevant to MCHS were evaluated using open field, vertical locomotor, social interaction, and acoustic startle tests.

Results: Aging *Mef2c*-heterozygous mice displayed similar auditory thresholds to wildtype controls, suggesting similar age-related hearing decline. Analysis of suprathreshold auditory brainstem responses revealed no significant differences in wave I amplitude or latency between groups, indicating that both genotypes experience similar age-related reductions in peripheral auditory nerve function. However, aging *Mef2c*-heterozygous mice exhibited a reduced acoustic startle response compared to wildtype controls, suggesting enhanced age-dependent declines in central auditory processing. Behavioral testing revealed increased hyperactivity in aging *Mef2c*-heterozygous mice compared to wildtype controls during the open field and locomotor activity assays, similar to changes reported in young-adult mice. Social interaction with social novelty test showed no significant differences between genotypes, indicating similar social behavior with aging. Bulk RNA-seq analysis of cochlear tissue identified a small number of differentially expressed genes between aging *Mef2c*-heterozygous and wildtype mice. Finally, biomarker analysis using Simoa (Quanterix) technology revealed evidence of increased age-related neurodegeneration in *Mef2c*-

heterozygous mice compared to wildtype controls, including increased levels of neurofilament light chain (NFL).

Conclusions: While young-adult Mef2c-heterozygous mice exhibit auditory nerve impairment and mild hearing loss, age-related declines seem to mask auditory sensitivity, peripheral auditory nerve activity, and cochlear gene expression changes between Mef2c-heterozygous mice and wildtype controls. Persistent hyperactivity and reduced acoustic startle responses, however, highlight central auditory processing effects and underscore the need to investigate how ASD risk genes influence cognitive behavioral outcomes across the lifespan.

17. A Comparison of Auditory Brainstem Responses to Diverse Stimulus Conditions in Rhesus Macaques

Alireza Karimi^{*1}, Reagan Whitaker², Aneesh Batchu¹, Swarat Kulkarni¹, Sarah Burkey², Colleen Le Prell³, Troy A Hackett², Ramnarayan Ramachandran²

¹Vanderbilt University, ²Vanderbilt University Medical Center, ³University of Texas at Dallas

Background: Nonhuman primates (NHPs) are a critical translational model for human hearing, with cochlear mechanics, brainstem and cortical organization similar to those of humans. Crucially, macaques have similar noise exposure susceptibility to humans, and support human-like perceptual and behavioral paradigms, enhancing the translation of both physiological and functional outcomes. In addition, NHPs permit controlled acoustic exposures and post-exposure intervals prior to histology. Together, these features make NHPs uniquely suited for auditory-system studies, particularly of noise injury and its brainstem correlates. However, normative non-invasive physiological measures spanning multiple stimulus classes are scarce in this species. To remedy this, we measured physiological responses to a wide range of stimuli.

Methods: Anesthetized young adult rhesus macaques (*Macaca mulatta*, age 4-7 years, n=16, 8 female, 8 males), were tested using non-invasive physiological assays, including auditory brainstem responses (ABRs) and Distortion Product Otoacoustic Emissions (DPOAEs) in a sound-treated

RF-shielded booth. Anesthesia was induced with ketamine and midazolam and maintained with isoflurane. Eight physiological tests are reported: DPOAEs (1-32 kHz), tones (0.5–32 kHz), chirps and clicks presented at various rates (27.7-200 /s), click and chirp pairs with varying inter-stimulus intervals (1-10 ms). For each, we extracted standard wave metrics (Waves I/II/IV amplitudes and latencies) and quantified ear-wise asymmetries.

Results: Thresholds to tones showed the expected U-shaped frequency dependence, with no sex-related differences. Click and chirp thresholds also showed no sex related differences. Inter-ear threshold differences were ≤ 10 dB SPL for most subjects, with no significant sex- or frequency-related bias. Paired-stimuli conditions exhibited canonical temporal-recovery signatures: reduced response amplitudes and prolonged latencies compared to the first stimulus response at short inter-stimulus intervals, with responses more similar to the first stimulus at longer intervals. Rate-manipulation experiments produced rate-dependent reductions in amplitude and latency increases at higher stimulus rates. Across ears, per-wave response amplitude correlations were stronger for closer tone frequencies and for chirp–click comparisons. Latency correlations were weaker and sparser than amplitude correlations.

Conclusions: Together, these results provide a comparative reference for macaque ABRs across complementary stimulus classes—covering thresholds, ear asymmetries, and temporal-recovery functions—and furnish benchmarks to support longitudinal studies of auditory brainstem physiology in a translational primate model. These data form pre-exposure baselines for chronic noise exposure in the same cohort. By spanning complementary stimulus classes and including DPOAE, this baseline enables sensitive detection of exposure-related changes, including subtle synaptic / neural deficits that may precede threshold shifts, through shifts in wave-I/II/IV amplitudes and latencies, altered temporal recovery functions, and rate-dependent modulation.

18. Probing Invariances in Auditory Event Categorization Using Model Metamers

Hee So Kim^{*1}, Malinda McPherson-McNato², Abigail Noyce¹, Jenelle Feather¹

¹*Carnegie Mellon University*, ²*Purdue University*

Background: Real-world acoustic inputs contain rich sensory information that we parse into discrete auditory objects and categories. However, the transformation from acoustic waveforms to neural representations is complex and poorly understood, especially as neural representations are invariant across some feature changes, such as variation in the exact pitches or timing. Further, previous investigations of auditory category representations have largely explored speech, music, or tone structures, with very few studies exploring categorical representations of non-speech stimuli. Computational modeling allows researchers to explicitly probe the transformation from input waveforms into higher-level representations, with recent work suggesting that deep neural networks (DNNs) are well-suited to model human auditory processing. Here, we test whether the invariances of DNNs trained to categorize non-speech sound stimuli are aligned with the invariances of human observers.

Methods: We developed an experimental paradigm to compare humans and DNNs using forced-choice classification across 25 non-speech sound categories using sounds obtained from the FSD50K dataset. For the tested models, we generated ‘model metamers’—stimuli whose activation produces the same response as the natural stimulus at a given model stage. We then tested whether humans (n=4) could recognize the model metamers as well as they could recognize the original audio. Recognizable model metamers imply that invariances of the model are shared with those of human observers. We tested DNNs pretrained on three different tasks: (1) word recognition only, (2) auditory event recognition only, and (3) a multi-task model for word recognition, speaker recognition, and auditory event recognition. These models were trained to be robust to small “adversarial” perturbations in the input cochleagram, a technique that was previously shown to help align the invariances of models with the invariances of human observers in the speech domain. For comparison of including this type of training, we also tested a multi-task model without adversarial training.

Results: First, humans and models can reliably categorize the natural sounds, demonstrating that our novel behavioral paradigm is well suited for testing invariances in auditory categories. For all models, we found that recognition accuracy for model metamers dropped significantly, but there was variability across models. Metamers generated for the adversarially trained auditory event recognition model were the most recognizable among the four models. This result indicates that task-specific optimization plays a significant role in creating human-like invariances. Among the multi-task models, metamers from the

adversarially trained model had significantly higher accuracy, confirming that training with adversarial perturbations helps align model invariances more closely with those of humans.

Conclusions: The results indicate that model metamers provide a powerful tool for probing human auditory perception in the domain of categorical representations of auditory events. These findings provide additional evidence that adversarial training and task-specific optimization can improve model alignment with human perception.

19. Detecting Individual Auditory Brainstem Responses (ABRs)

Malcolm Slaney¹, Emily Kuo^{*1}, Daibhid O Maoileidigh¹

¹*Stanford University*

Background: The Auditory Brainstem Response (ABR) is a measure of neural activity in response to sound stimuli. It is widely used for diagnosing hearing loss in humans and other animals. Current practice estimates hearing thresholds by identifying peaks in the mean ABR over hundreds of trials. However, thresholds based on the mean ABR alone decrease without bound as the number of trials used to estimate the mean increases.

We propose to score the similarity of each ABR trial with the population of ABR trials using covariance. By comparing the score distributions of stimulus-present and stimulus-absent trials, we define an ABR threshold based on the discriminability index d' . We show this measure converges as the number of trials increases.

Methods: We build a model to assess our new method, compare our new method with conventional methods, and confirm the theoretical basis for our method with a simple model and simulations.

We simulate ABR trials by generating deterministic waveforms with added Gaussian white noise. Increasing the amplitude of the deterministic waveform mimics responses to sounds of increasing stimulus level.

We then filter the simulated trials and calculate their mean for each stimulus level. At a given level, each individual trial is assigned a score equal to its covariance with the mean. The score distribution quantifies similarity between the trials.

Lastly, we compute the discriminability index d' value between the score distributions of a stimulus-present condition (non-zero waveform amplitude) with that of a stimulus-absent condition (no deterministic waveform). Because d' is the distance between the distributions, a stimulus is detected when d' is sufficiently large (for example, $d' > 1$). The stimulus level at which stimulus is detected is defined as the ABR threshold.

Results: We show that d' converges to a constant value as the number of trials increases. Consequently, ABR thresholds based on d' no longer decrease without bound as the number of trials increases. Using our simple model, we show how d' is related to the signal-to-noise ratio.

Conclusions: Previous ABR methods use the mean ABR waveform alone, causing the ABR threshold to depend on the number of stimulus trials. In this study, we introduce an alternative approach that uses covariance and d' to detect ABRs. This method defines an ABR threshold that becomes independent of the number of trials as the number increases. Future work will assess the utility of this approach using human and animal ABR data.

20. Effects of the Vestibulocochlear Implant on Balance and Gait in Bilateral Vestibulopathy

Meichan Zhu*¹, Rik Marcellis², Paul Willems³, Jona Beckers², Bernd Vermorken¹, Benjamin Volpe¹, Stan van Boxel¹, Joost Stultiens¹, Elke Devocht¹, Angélica Pérez Fornos⁴, Nils Guinand⁴, Kenneth Meijer³, Raymond van de Berg¹, Christopher McCrum³

¹*Division of Balance Disorders, Maastricht University Medical Center, School for Mental Health and Neuroscience*, ²*Maastricht University Medical Center*, ³*NUTRIM Institute of Nutrition and Translational Research in Metabolism, Maastricht University*, ⁴*Geneva University Hospitals and University of Geneva*

Background: Bilateral vestibulopathy (BVP) often causes a range of debilitating symptoms. The resulting gait and balance problems significantly increase the risk of falls. The vestibulocochlear implant (VCI) is a neuroprosthesis that may offer a promising treatment for patients with severe BVP. This study aimed to explore the impact of different vestibular stimulation modes on gait and balance outcomes.

Methods: The VertiGo! trial is a prospective, nonrandomized, single-center cohort study. The trial includes nine patients with severe BVP who demonstrated inadequate compensation despite conventional treatment. Nine patients received the VCI and were extensively tested in four testing weeks, the first providing reference data (no VCI stimulation) followed by three weeks each with different stimulation modes: (A) baseline stimulation combined with head motion-modulated stimulation, (B) reduced baseline stimulation combined with head motion-modulated stimulation, and (C) only baseline stimulation, without modulation. For the gait and balance assessments, patients walked at 0.6m/s, 0.8m/s, and 1.0m/s on an instrumented treadmill integrated in a 6-DoF motion platform (CAREN; Motek). Five walking conditions were evaluated: unperturbed walking in both lit and dark environments, along with three sizes of pseudorandom mediolateral platform sway perturbations. Coefficients of variation (CoV) were analyzed using 3D motion capture data for step time, step length, double support time and step width. Patients also completed the Mini-BESTest each week.

Results: Step time, length and double support time CoV consistently reduced with increasing walking speeds across all walking conditions whereas step width CoV increased with increasing walking speeds across all walking conditions. Larger perturbations increased CoV consistently. The CoV in the reference mode and stimulation modes A, B and C varied across patients for all gait parameters with no consistent effect for any one stimulation mode (e.g., 5 of 9 patients had lower step time CoV and step length CoV for one stimulation mode but these did not always align with the modes with lower CoVs in the other parameters and the stimulation mode that benefited one patient was often not the mode that benefited another patient). Darkness usually increased CoV but no clear effect of a specific stimulation mode in darkness was found. In the Mini-BESTest, at least one stimulation condition total score was higher than the reference total score for 6 of 9 patients but these were distributed across the different stimulation modes.

Conclusions: Walking speed, perturbations and stimulation modes can influence gait variability and balance performance. While specific stimulation modes may provide slight advantages during acute stimulation, individual responses exhibit considerable variability. The findings emphasize the importance of further investigating tailored stimulation. Investigation into potential differences between acute stimulation and ongoing stimulation is needed.

Poster Blitz Session II

4:45 p.m. - 5:45 p.m.

Meeting Room 209ABC, Floor 2

21. Single-Cell Proteomics and AP-MS to Elucidate Auditory Mechanotransduction in Mammalian Cochlea

Ruxandra Bighiu^{*1}, Andrea Lelli², Elise Pepermans¹, Christine Petit³, Geert Baggerman¹, Vincent Van Rompaey¹

¹University of Antwerp, ²Institut Pasteur, ³Institut de l'Audition/ Institut Pasteur

Background: The mammalian cochlea contains two mechanosensitive receptor cell types, inner hair cells (IHCs) and outer hair cells (OHCs), essential for hearing. Despite their importance, the molecular mechanisms driving their distinct function, particularly those underpinning mechano-electrical transduction (MET), remain incompletely understood. This study is the first effort to generate distinct proteomic profiles for IHCs and OHCs, using postnatal day 7–9 (P7–P9) murine cochleae, to uncover key proteins involved in auditory signalling, including novel components of the MET complex.

Methods: Due to the limited number and fragility of cochlear hair cells (~3,500 IHCs and ~12,000 OHCs per cochlea), we employed a suction pipette technique to isolate individual OHCs from enzymatically treated, mechanically dissociated tissue. Isolated cells were cryopreserved and processed using a streamlined one-pot protocol that combines lysis, sonication, denaturation, and tryptic digestion in a minimal volume. We applied TimsTOF SCP with Evosep One for mass spectrometry, identifying up to 500 protein groups per single OHC and 2,200 from pooled five-cell samples. Further analysis will use the higher-sensitivity TimsTOF Ultra 2 system.

Results: Initial work focused on OHCs due to their accessibility. Hair cell-specific proteins were successfully identified in OHCs. We now aim to compare them with recently isolated IHCs. To specifically study the MET complex, we integrate single-cell proteomic data with affinity-purification mass spectrometry (AP-MS) targeting the known MET component protocadherin 15 (Pcdh15). As Pcdh15 is an intrinsically disordered protein (IDP), we apply crosslinking strategies and optimized buffers to capture weak or transient interactions. Potentially interesting protein-protein interactions will be validated using AlphaFold3 and AlphaPulldown.

Conclusions: This study provides new molecular insights into cochlear mechanosensation by profiling key proteins and identifying components of the MET complex. Our approach advances single-cell proteomics in fragile cell types and contributes foundational knowledge for therapeutic strategies in auditory disorders.

22. Towards Precision Medicine in Hearing Loss: Genetic Diagnosis and Functional Studies in Zebrafish

⁷Pharmacology Institute, Faculty of Medicine, University of Buenos Aires, ⁸Institute for Research in Genetic Engineering

Background: Hearing loss (HL) is a highly prevalent condition, affecting nearly 10% of the global population, and genetic factors account for more than half of the cases. Congenital HL occurs in approximately 1 in every 500–1000 births, predominantly as non-syndromic forms (70%), usually with autosomal recessive inheritance (80%). While GJB2 and GJB6 variants represent the most frequent causes, more than 100 genes have been implicated in HL. Whole-exome sequencing (WES) has become a valuable diagnostic approach, allowing simultaneous interrogation of all candidate genes. Nonetheless, the interpretation of novel missense variants remains a major challenge for establishing robust genotype–phenotype correlations. In this study, we investigated the genetic etiology of HL in an Argentine cohort and functionally evaluated novel variants.

Methods: An initial genetic screening of 1,200 HL patients was performed using Sanger sequencing and GAP-PCR for GJB2 and GJB6 genes. In a subset of 100 unresolved cases with moderate HL, STRC deletions were tested using multiplex ligation-dependent probe amplification. Subsequently, WES was applied to 100 families (82 non-syndromic and 18 with additional clinical features, presumably syndromic). In one non-syndromic family, we identified a novel MYO6 missense variant, which was further characterized by AlphaFold2 protein modelling, followed by in vivo functional validation through zebrafish knockdown phenotype rescue assay.

Results: The GJB2/GJB6 analysis yielded a diagnostic rate of 15.5% in sporadic cases and 36% in familial cases. Screening for STRC deletions accounted for 6% of moderate HL cases. WES provided a molecular diagnosis in 45% of families, with nearly half of the pathogenic variants being novel. Among these, a MYO6 variant segregating with postlingual HL was identified. Structural modeling predicted that this variant markedly altered the protein’s surface electrostatic potential, suggesting a disruptive effect on its function. Functional validation in zebrafish experiments provided further support, as mutant mRNA failed to rescue the knockdown phenotype, confirming its pathogenicity.

Conclusions: This work highlights the power of combining comprehensive genetic testing with in-silico modeling and zebrafish functional assays to strengthen variant interpretation. The diagnostic algorithm applied in this cohort proved highly effective and supports the integration of preclinical models into routine pipelines for hereditary HL, ultimately advancing precision medicine and therapeutic perspectives in the field.

23. Determining Tropism of AAV Serotypes in the Neonatal Mouse Cochlea

Tracy Cheng^{*1}, Alan G. Cheng¹

¹Stanford University

Background: Over 170 genetic mutations have been identified to cause hearing loss, with many amenable to replacement via gene therapy in preclinical models. More recently, clinical trials in gene therapy have revealed promising results for otoferlin-related hearing loss.

Adeno-associated viruses (AAVs) have become increasingly popular as a vehicle to deliver gene replacement for genetic hearing loss because of their high tropism and low immunoreactivity. Currently, there are multiple AAVs reported with different tropisms when injected through the posterior semicircular canal (PSCC). We set out to characterize the tropism of 5 AAVs in neonatal mice after PSCC injection, with the goal of determining one that is most efficient in gene therapy for *Tmprss3* KO mice.

Methods: C57Bl/6 postnatal 3-day-old (P3) mice were injected with 1 μ l of each virus at 5 nl/s through PSCC injections. 5 different viruses were tested: AAV2/8-CMV.EGFP (5.32×10^{13} GC/mL), AAV2/9-CMV.EGFP (7.55×10^{12} GC/mL), AAV2/Anc80L65.CMV.EGFP (1.89×10^{13} GC/mL), AAV2.7m8-CAG-GFP (5×10^{12} GC/mL), AAV-ieK558R-CAG-mCherry-3xFLAG -WPRES (1.33E+13 GC/mL). Each virus was mixed with 1:25 trypan blue (1:25 v:v) to facilitate visualization during injection. Mice were sacrificed 7 days after injection, and immunohistochemistry of whole mounts was performed to determine expression of mCherry or GFP using an anti-GFP antibody. Tissues were also immunostained for inner and outer hair cells (IHCs and OHCs, Myo7a) and support cells (SCs, Sox2). Cell counts of hair cells and support cells were performed in each cochlear turn in whole mounts to compare the transduction efficacy of the different AAVs. Saline injection and the contralateral ear were used as controls.

Results: For AAV2/8-CMV.EGFP and AAV2/9-CMV.EGFP, IHC transduction was most efficient in the apical turn ($60.4 \pm 7.5\%$ and $61.4 \pm 10.4\%$, respectively) with a decreasing gradient towards the basal turn ($35.9 \pm 2.6\%$; $17.6 \pm 3.0\%$). AAV2/8-CMV.EGFP had overall higher transduction of the IHCs, OHCs, and SCs ($46.0\% \pm 4.3\%$, $7.2\% \pm 2.7\%$, $11.7\% \pm 2.4\%$) compared to AAV2/9-CMV.EGFP ($31.2\% \pm 4.3\%$, $6.8\% \pm 3.7\%$ and $5.6\% \pm 4.0\%$). While AAV2/8-CMV.EGFP had minimal transduction efficacy in the contralateral, uninjected ear only in the basal turn ($2.5\% \pm 0.7\%$), AAV2/9-CMV.EGFP had no transduction in the contralateral, uninjected ear. There was minimal toxicity of the AAVs with little to no degeneration of the native IHCs, OHCs, or SCs after injection. Ongoing experiments aim to characterize the transduction efficacy of AAV2/Anc80L65.CMV.EGFP, AAV2.7m8-CAG-GFP, and AAV-ieK558R-CAG-mCherry-3xFLAG -WPRES.

Conclusions: There are significant differences in the transduction efficacy of different AAVs in the IHCs, OHCs, and SCs. The results of this study can guide selection of AAV to deliver gene replacement for *Tmprss3* mutant mice.

24. Responses to Prosthetic Stimulation Remain Robust After Two Weeks of Continuous Ionic Direct Current Stimulation

Celia Fernandez Brillet¹, W Mitchel Thomas¹, Katherine Mueller¹, Dale Roberts¹, Catherine Graham¹, Woo Seok Kang¹, Mohamed Lehar¹, Charles Della Santina¹, Gene Fridman¹

¹*Johns Hopkins University*

Background: The vestibular system in the inner ear detects head motion to maintain balance through reflexes like the vestibulo-ocular and vestibulo-colic reflexes (VOR and VCR). Previous work has shown the advantages of ionic direct current (iDC) over pulsatile stimulation due to its ability to excite, inhibit, and modulate vestibular pathways' sensitivity. Those acute experiments lasted up to 4 hours and used a separated interface nerve electrode (SINE) configuration. Without periodic replacement, that setup would be unsafe for chronic stimulation due to the production of chemical by-products that could alter pH levels at the

tissue beyond safety limits. The effects of continuous iDC delivery to neural tissue have not yet been evaluated for safety. We developed a SINE device to continuously deliver iDC through replaceable gel-filled reservoirs via silicone tubing to fine microcapillary tips in the inner ear.

Methods: We injected both ears in adult chinchillas with the ototoxic drug gentamicin, then implanted microcapillary tips in the anterior semicircular canal of the inner ear's vestibular labyrinth. We used video-oculography (VOG) to measure electrically-evoked VOR (eeVOR) eye movements before and after animals received two weeks of 10-20 μ A continuous iDC using our head-mounted stimulator. The stimulator's electrolytic gel chambers were replaced daily for 2 weeks. During the two weeks of stimulation, VCR head tilt responses to 1-2 second step changes in current amplitude were measured hourly in free-roaming animals.

Results: Sensitivity to iDC stimulation varied across animals, as shown by both eeVOR and eeVCR measurements. Throughout the two weeks of constant iDC stimulation, animals consistently responded with head tilts to hourly changes in current amplitude. Head tilts were roughly aligned with the axis of the implanted semicircular canal and in phase with current changes. eeVOR responses after 2 weeks of stimulation varied but remained robust, with peak velocities exceeding 50 deg/s.

Conclusions: This study demonstrates that delivering ionic direct current to the inner ear over a prolonged period is possible without disrupting physiological function.

25. Identification of Genes That Regulate Development and Maturation of Cochlear Supporting Cells

Sofia Gallino*¹, Matthew Kelley¹

¹*National Institute on Deafness and Other Communication Disorders, National Institutes of Health*

Background: The sensory epithelium of the cochlea, the organ of Corti, is a highly derived and rigorously patterned structure that acts to convert auditory stimuli into electrical impulses. This structure consists of a highly diverse cellular mosaic that includes two different types of mechanosensory hair cells, and at least six different types of associated supporting cells. While there has been considerable research conducted on the development of hair cells, the maturation of supporting cells, which are equally necessary for normal hearing, has not been sufficiently examined. Therefore, this project aims to improve our understanding of supporting cell (SC) development by characterizing the maturation of pillar cells, Deiters' cells and Hensen's cells during the early post-natal period.

Methods: Cochlear duct cells were dissociated at postnatal day (P) 1, P3, P5, and P7 to obtain individual cells for analysis using single-cell RNA sequencing (scRNAseq) techniques. Bioinformatic approaches, including PySCENIC analysis, were employed to identify potential transcription factors that may modulate the development of different supporting cell types. To validate some of the cell-type-specific genes identified in the data set, we employed in situ immunofluorescent labelling of mRNAs to visualize the localization of candidate transcripts within supporting cell types in cross-sections from postnatal cochlea.

Results: PySCENIC analysis of supporting cell scRNAseq data suggests that *Etv1* and *Etv4* regulons are highly active in inner pillar cells (IPCs) and outer pillar cells (OPCs) during the first postnatal week. This hypothesis is supported by localization of *Etv1/4/5* in inner and outer pillar cells at P1, P5 and P21. Furthermore, the PySCENIC analysis identified

additional transcription factor candidates, such as Gata2, that may play crucial roles in SC development during the same time period.

Conclusions: This study presents a scRNAseq atlas for the development of supporting cells during early postnatal time points. The validation of these results indicates that these data will serve as a valuable resource for the examination of multiple developmental events that occur during the formation of the mammalian cochlea. As a first step in utilizing this resource, I plan to generate a conditional mouse line to disrupt the expression of Etv genes exclusively in postnatal SCs (Sox2CreERT/+; Etv1fl/fl; Etv4^{-/-}; Etv5fl/fl). This approach was designed to ascertain the significance of these transcription factors in the postnatal survival and maintenance of IPC and OPCs. Similarly, a Sox2CreERT/+; Gata2fl/fl model will be established to examine the role of Gata2 in the differentiation and maturation of lateral supporting cell subtypes.

26. Neurotrophin Therapy for Cochlear Synapse Regeneration After Excitotoxic Trauma

Mardi Gammon^{*1}, Patrick Lam², Ella Trang², Catherine Mathew², Yingjie Hu³, Andrew Wise²

¹*The University of Melbourne*, ²*Bionics Institute*, ³*The University of Melbourne; Bionics Institute*

Background: The cochlear synapses between sensory inner hair cells and auditory neurons in the inner ear are vulnerable to noise-induced excitotoxic damage (cochlear synaptopathy). For patients, this is thought to manifest as difficulty interpreting speech in background noise, despite normal hearing thresholds. Although there is growing concern amongst health experts regarding damaging occupational and recreational noise exposure for current and future generations, there are no pharmaceutical treatment options available to patients who experience milder forms of hearing loss. Brain Derived Neurotrophic Factor (BDNF) and Neurotrophic Factor 3 (NT3) are two neurotrophins that target Trk receptors on the auditory nerves, in turn promoting their development, survival, and repair. These two neurotrophins have shown therapeutic potential in cochlear synapse repair in preclinical models of hearing loss. A key challenge to overcome before clinical implementation of neurotrophin therapy is their complicated and costly manufacturing process. We propose the use of novel, Fc fusion variants of these neurotrophins (NT3.Fc and BDNF.Fc), which are produced in mammalian cell lines. This project aimed to assess the bioactivity of our novel BDNF.Fc and NT3.Fc neurotrophins to activate their target Trk receptors and repair cochlear synapses after excitotoxic damage using in vitro assays.

Methods: Trk-NFAT-Bla CHO-K1 cell lines that express high-affinity human Trk receptors for either NT3 or BDNF were used to characterise the dose-response relationship and EC50s (dose that produces half-maximal response) of BDNF.Fc and NT3.Fc for Trk receptor activation. These EC50s were benchmarked to those of commercially available native BDNF and NT3 variants, respectively. Postnatal day 2-5 C57BL/6 mouse cochleae were explanted and cultured in kainic acid to simulate excitotoxic damage seen at the glutamatergic cochlear synapse upon excessive noise exposure. The cochleae were treated with NT3.Fc or BDNF.Fc across a range of concentrations. Cochlear synapses were immunostained and imaged, then synapse density quantified for control and treated explants.

Results: Trk receptor assay results demonstrate that BDNF.Fc and NT3.Fc activate their specific Trk receptors and have a lower EC50 (higher potency) than BDNF and NT3,

respectively (analyses ongoing). Preliminary cochlear explant results suggest that explants treated with BDNF.Fc or NT3.Fc had higher synapse density relative to damaged, untreated control explants (analyses ongoing).

Conclusions: These results show promise for the therapeutic potential of the novel BDNF.Fc and NT3.Fc neurotrophin variants to activate their target receptors and repair cochlear synapses. If the current trend in the data continues, this project could support further preclinical testing using in vivo animal deafness models and first in human clinical trials. Further research is required to understand whether cochlear synapse repair corresponds to improvements in hearing function following excessive noise exposure.

27. Experimental Programming for Cochlear Implants: Dynamically Focused Stimulation Combined With Monopolar Edge Electrodes

Charles Hem*¹, Julie Arenberg²

¹Harvard University, ²Massachusetts Eye and Ear Infirmary, Eaton Peabody Laboratory

Background: Channel interaction, or activation of overlapping neural populations, is one likely contributing factor to cochlear implant (CI) users' difficulties in understanding speech in noise and music. Clinical strategies in CIs use monopolar (MP) stimulation, which results in broad current spread that contributes to channel interaction. Current focusing with adjacent electrodes is one potential solution to reduce spread. Experimental programs using current focusing to reduce channel interaction have shown potential benefit; however, these programs have only been tested using 14 of 16 electrodes, as the electrodes at the edge of the array have no flanking electrodes to use for focusing and are therefore deactivated. Using these edge electrodes with monopolar stimulation may provide better spectral resolution by reducing channel filter size and fuller sound quality by stimulating spiral ganglion neurons at the edges of the electrode array that were previously un-stimulated in focused programs. In this study, participants were tested on speech in noise and timbre instrument recognition using three programs: a 14-channel monopolar program (MP14), a 14-channel dynamic tripolar program (DT14), and a 16-channel dynamic tripolar program with electrodes 1 and 16 active as monopolar electrodes (DT16).

Methods: At this point, data have been collected from 11 ears in 9 adult participants (mean age = 50.9 years, SD = 19.4 years). All participants used Advanced Bionics devices and were tested across two sessions. In session one, three experimental programs were created: auditory detection thresholds and max comfort levels were first measured across all electrodes to be used as the programming levels, which were further fine-tuned using live speech. Participants finished session one by completing the test battery using their clinical device as training. The test battery consisted of the instrument timbre recognition task from the UW CAMP test, closed-set /hVd/ vowel identification in noise, and the closed-set American English Matrix Test (AMT) in adaptive noise. In session two, participants completed the test battery for each program, with program order block-randomized across participants. Data was analyzed using linear-mixed effects models to determine the effect of program.

Results: Planned comparisons showed no significant mean difference between MP14 and DT14 (testing the effect of focusing) and DT14 and DT16 (testing the effect of MP edge electrodes), with high variability across subjects. Despite incorporating additional training during session one and increased practice trials for each program during session two, the timbre task shows significant learning with test order ($\beta = 5.81\%$ /test block, $p = .028$). AMT and vowels were stable across test order.

Conclusions: Reincorporating electrodes 1 and 16 as monopolar electrodes in a dynamically focusing program show no clear benefit in this interim analysis, but data collection is still underway. It is possible that the added interaction from these electrodes contributed to this lack of benefit.

28. Transcriptomic Analysis of Newly Regenerated Avian Auditory Hair Cells

Austin Huang^{*1}, Xiangyu Ma¹, Lyn Miranda Portillo¹, Stefan Heller¹, Nesrine Benkafadar¹

¹*Stanford University School of Medicine*

Background: Inner ear sensory hair cells (HCs) are essential for transducing auditory and vestibular stimuli. In mammals, lost HCs do not regenerate, resulting in permanent sensory deficits. In contrast, non-mammalian vertebrates, such as birds, can regenerate HCs through activation of adjacent supporting cells (SCs). Newly regenerated HCs in the avian hearing organ, the basilar papilla, differ from fully mature HCs by lacking hair bundles and innervation. We hypothesize that the transcriptomic profiles of these nascent HCs are distinct and reflect an intermediate phase of HC identity that precedes full cytomorphological and functional maturation.

Methods: Chicken basilar papilla hair cells were ablated with an injection of sisomicin into the inner ear at post-hatch day 7. We utilized single-cell RNA sequencing to profile the undamaged chicken basilar papilla as well as at 5- and 10-days post-sisomicin treatment (PST). A list of the top marker genes of nascent HCs at different time points was curated. The duration of marker gene expression was determined through qPCR and in situ mRNA detection at various days after the first appearance of nascent HCs at 4 days PST. Ingenuity Pathway Analysis was used to identify signaling pathways activated during nascent HC maturation. To investigate the functional requirement of these pathways, pharmacological inhibitors were infused into sisomicin-treated inner ears during the period of nascent HC maturation.

Results: Single-cell RNA sequencing revealed notable differences in gene expression profiles among undamaged HCs, nascent HCs at 5d PST, and 10d PST. Validation of these distinct marker genes showed that nascent HCs, although formed over several days, exhibit a coordinated onset of a nascent gene expression pattern, followed by a transition toward a gene expression profile indicative of HC maturation. Initial results from signaling pathway inhibition experiments will be presented.

Conclusions: Our findings reveal a unique transcriptomic signature in nascent HCs in the chicken basilar papilla, characterized by the presence of genes not usually expressed by mature HCs. These genes may be required for replacement HC fate commitment and differentiation, and their expression may be specific to regeneration versus normal development during embryonic stages. Understanding the molecular mechanisms of HC regeneration in birds could provide valuable insights for developing reprogramming strategies aimed at inducing HC regeneration in mammals.

29. Characteristics of Dexamethasone Palmitate Lipid Nanoparticle in Protecting Against Kanamycin-Induced Ototoxicity: In Vitro and in Vivo Models

Hyun Su Lee^{*1}, Eun Soo Lee¹, Temuulen Batsaikhan¹, Hyo Kyung Yang¹, Daun Jeong¹, Tae Hoon Kong¹, Young Joon Seo¹

¹*Yonsei University Wonju College of Medicine*

Background: Drug delivery to the inner ear (IE) remains challenge. Dexamethasone (DEX) is widely used to protect against ototoxicity, but its conventional formulation, dexamethasone sodium phosphate (DSP), shows limited penetration after intratympanic (IT) injection. Nanoparticle-based formulations, such as dexamethasone palmitate lipid nanoparticle (DPLN), may enhance delivery and efficacy. DPLN, a liposomal formulation incorporating dexamethasone palmitate, has shown potent anti-inflammatory effects in chronic inflammation models and is clinically used for rheumatoid arthritis and osteoarthritis. This study compared the protective effects of DPLN with DSP in in vitro and in vivo ototoxicity models.

Methods: HEI-OC1 cells were cultured under permissive conditions and seeded in 96-well plates. After 3 h of serum starvation, cells were treated with kanamycin (5-20 mM) for 1-24 h to induce toxicity. Steroid pretreatment (1-200 μ M, 6 h) was performed prior to kanamycin exposure. Cell viability and ROS levels were evaluated at multiple time points.

For in vivo experiments, adult C57BL/6 mice received subcutaneous kanamycin combined with intraperitoneal furosemide for two consecutive days to induce ototoxicity. IT-DPLN or DSP were administered every other day for a total of four injections. Auditory brainstem response (ABR) thresholds were measured at baseline and 7, 14, and 21 days after insult. Hearing gain was defined as the interaural threshold difference between the IT-injected and contralateral ears.

Results: In vitro, 24-h kanamycin exposure caused dose-dependent cell death, with 20 mM reducing viability by ~70%. With 20 mM kanamycin, steroid pretreatment improved viability, with the maximal protection at 10 μ M DPLN (89.1%) and 100 μ M DSP (90.7%). Notably, DPLN reduced early ROS spikes within 3 h post-kanamycin, reaching a maximum of 1.8-fold of control at 10 μ M and 0.6-fold at 100 μ M, suggesting rapid and sustained antioxidant action. In contrast, DSP-treated cells showed elevated ROS, up to 2.6-fold at 10 μ M and 3.0-fold at 100 μ M in 3 h.

In the in vivo experiments, 400 mg/kg kanamycin with 170 mg/kg furosemide induced complete ototoxicity, producing a hearing loss of 82.5 dB SPL. IT-DPLN demonstrated greater auditory protection than IT-DSP, with hearing gains of 10 dB at 1 week and 16.7 dB at 3 weeks, compared with 6.7 dB at both time points for IT-DSP. Control ear showed minimal recovery.

Conclusions: DPLN exhibits stable antioxidant effects, mitigating ROS elevation and improving cells survival in vitro. Sustained release of active DEX likely underlies enhanced auditory protection in vivo, resulting in greater and longer-lasting hearing gains compared with DSP. The pronounced suppression of ROS by DPLN indicates its potential as alternative for IT-steroid therapy, effectively overcoming the limited penetration and viability efficacy of conventional DSP in the IE.

30. The Role of a Conserved Extracellular Loop in TMC1 Gating

Nurunisa Akyuz¹, Trey Scott², Corena Loeb^{*1}, Bifeng Pan¹, Charles Phillips¹, Yaqiao Li¹, David Corey¹

¹*Harvard Medical School*, ²*Harvard University*

Background: The transmembrane channel-like (TMC) family is an ancient group of proteins conserved across eukaryotes. During evolution, the mechanosensory channels TMC1 and TMC2 first appeared in the vertebrate lineage; they are expressed perhaps exclusively in vertebrate hair cells and seem to be highly specialized to mediate hearing and balance. In mammals, TMC1 appears to have undergone further specialization to function in its primary role in adult auditory transduction. Yet the molecular mechanism by which force opens TMC1 channels is not well understood. Here, we investigate the role of a conserved extracellular loop between transmembrane helices 1 and 2 (the 1-2 loop) that may contribute to channel gating.

Methods: We first used evolutionary analysis to find residues in TMC1 that were positively selected for and may underly its functional adaptations. We then used structural modeling to predict how these regions may affect overall structure and transduction complex binding partners. To assess functional consequences, we then selectively mutated individual amino acids in TMC1, constructed AAV vectors carrying the mutant sequence, injected AAVs into the cochleas of *Tmc1/2* null mice at P1, and recorded transduction currents from cochlear hair cells in vitro at P8-15.

Results: Evolutionary analyses revealed residues in the TMC1 1-2 loop that were positively selected in mammals. Structural modeling suggested that this loop arches over the extracellular side of the pore, approaching both the auxiliary subunit TMIE and the pore-lining helices TM4 and TM6. Mutating two conserved aromatic residues shifted channel activation towards the closed state without affecting slope, suggesting that these residues participate in biasing the channel to be open part of the time at rest.

Conclusions: A combination of evolutionary probing, structure analysis, and electrophysiology suggest the 1-2 loop has a specialized role in mammalian hearing. Targeted mutagenesis influences channel activation and in following, this loop contains several residues linked to hereditary deafness. Integration of evolutionary, structural and physiological studies provides a holistic platform for investigating residues of functional importance in sensory transduction channels.

31. Mechanisms for Generation and Control of EMREOs (Eye Movement-Related Eardrum Oscillations)

Stephanie Lovich^{*1}, Steven Eliades², David Kaylie¹, Cynthia King¹, Christopher Shera³, Jennifer Groh¹

¹Duke University, ²Duke University School of Medicine, ³University of Southern California

Background: Accurate information about eye movements is necessary for audiovisual integration because such movements shift the positions of the eyes with respect to the head/ears. We have recently reported an eardrum oscillation, time-locked with eye movement onset and occurring in the absence of outside auditory stimuli, that suggests eye movement information is sent by the brain to the ears (Eye movement-related eardrum oscillation, EMREO; Gruters et al. PNAS 2018; Lovich et al. PNAS 2023). But what is the proximal and neural mechanism producing such eardrum oscillations? The chief suspects are the middle ear muscles (MEMs) and the outer hair cells (OHCs).

Methods: We recorded eye movements and associated eardrum oscillations in rhesus monkeys before and after surgical intervention involving the MEMs -- specifically, stapedotomy and tensor tympani tenotomy. Such transections of the tendons connecting the MEMs to the ossicles are typically done in human patients suffering from otosclerosis or

MEM myoclonus, and the procedures were adapted here for the monkey. The procedures served to eliminate the contribution of the particular MEM in question to the EMREO.

Results: Sectioning MEM tendons did not eliminate the EMREO. Following stapedotomy, the EMREO was reduced in amplitude but still occurred. Following tensor tympani tenotomy, the EMREO was actually increased in amplitude. When stapedotomy and tensor tympani tenotomy were combined, the EMREO still occurred, and was again increased in amplitude. Together these findings suggest the MEMs are not the sole cause of the EMREO, but rather regulate its amplitude likely in a push-pull fashion. These results from animals are largely consistent with related preliminary data in human clinical patients who have undergone similar procedures.

A general caveat to the interpretation of the MEM surgical interventions is that the procedure may change the mechanical load on the eardrum such that interpretations of changes in amplitude of the EMREO signal should be confirmed by additional research. However, that the EMREO continued to exist even after both MEMs were disconnected from the ossicles indicates that there must be an additional source of force contributing to the signal. The most likely such source is the OHC, which could potentially generate this signal by oscillating in concert throughout the cochlea. It is also possible that in the event of OHC dysfunction, the signal can be generated by MEMs acting alone, a possibility not tested here.

Conclusions: We interpret these findings in the context of how eye movements may alter sound localization cues. Recent work has shown that forces applied by the MEMs to the eardrum in a cadaver model could alter both interaural timing and level difference cues in an eye movement-dependent way (Cho et al., Hearing Research 2023).

32. Cellular Control of Functional Tonotopic Gradients in Cochlear Bone

Christoforos Meliadis^{*1}, Yoshihiro Obata², Joanna Bons³, Laura Müller⁴, Charles Schurman³, Michael Sieverts⁵, Barat Q. Achinuq⁶, Dilworth Y. Parkinson⁶, Edoardo Pedrinazzi⁴, Stéphane Blouin⁷, Dylan Chan¹, Peggi Angel⁸, Birgit Schilling³, Davide Ruffoni⁴, Claire Acevedo², Tamara Alliston⁹, Pupa U.P.A. Gilbert¹⁰

¹University of California, San Francisco, ²University of California, San Diego, ³Buck Institute for Research on Aging, ⁴University of Liège, ⁵University of Utah, ⁶Lawrence Berkeley National Laboratory, ⁷Ludwig Boltzmann Institute of Osteology, ⁸Medical University of South Carolina, ⁹National Institute of Arthritis and Musculoskeletal and Skin Diseases, ¹⁰University of Wisconsin, Madison

Background: Tonotopy of the basilar membrane arises from an EMILIN-2–dependent stiffness gradient. The surrounding cochlear bone—the stiffest bone in mammals—is essential for hearing, yet how its material properties are set is unclear. Because classic osteoblast/osteoclast remodeling is suppressed in the otic capsule, we hypothesized that osteocytes regulate cochlear bone quality along the cochlea’s established hearing axes. This builds on evidence that TGF- β /Runx2–dependent matrix calibration is required for normal hearing and that TGF- β inhibition can rescue hearing in Runx2 haploinsufficiency.

Methods: Cochlear bones from 4-month-old female C57BL/6J mice were profiled with a co-registered, multi-scale pipeline: quantitative backscattered electron imaging (calcium content), synchrotron μ CT (tissue mineral density and lacunar morphometry), second harmonic generation (collagen organization), polarization-dependent imaging contrast mapping (hydroxyapatite nanocrystal orientation), and nanoindentation (stiffness). Spatial

proteomics by MALDI-QTOF MSI mapped extracellular-matrix peptides; immunofluorescence localized osteocyte/ECM markers. Bulk RNA-seq compared apical vs. basal halves. Notably, PIC-mapping and MSI were applied for the first time to bone to resolve nanoscale crystal orientation and spatial proteomic gradients.

Results: Cochlear bone properties varied coherently across radial and tonotopic axes. Radially, inner cortex was more mineralized than outer cortex at apex, middle, and base. Tonotopically, the basal turn showed higher mean mineral density than the middle. At the nanoscale, adjacent nanocrystal misorientation increased from apex to base, while collagen alignment decreased basally; stiffness tracked mineral content most strongly in lamellar regions. Lacunae were larger and more elongated apically and smaller/rounder basally and inwardly, consistent with heightened apical perilacunar/canalicular remodeling (PLR). Immunofluorescence confirmed inner-layer enrichment of DMP1, osteopontin, and MMP13. Spatial proteomics identified basal enrichment of TGF- β antagonists (Asporin, EMILIN-1). RNA-seq revealed apical TGF- β pathway enrichment with basal up-regulation of antagonists (e.g., *Aspn*, *Dcn*, *Ltbp4*, *Fmod*, *Cilp*). Together, these datasets define a spatially patterned TGF- β program that directs osteocyte PLR and ECM composition, establishing axis-registered gradients in cochlear bone material properties that mirror functional hearing axes.

Conclusions: Cochlear bone behaves as a patterned, functionally graded material that likely co-tunes with sensorineural tissues to support frequency selectivity and gain. An osteocyte- and TGF- β -based program appears to sculpt these gradients, and a shared toolkit—EMILIN-1 in bone mirroring EMILIN-2 in the basilar membrane—may coordinate tuning across hard and soft tissues, supporting integrated cochlear function. In light of prior evidence that TGF- β /Runx2-dependent matrix calibration is necessary for hearing and pharmacologically adjustable, our findings suggest a working causal model linking bone material quality to auditory function and point to osteocyte PLR and local TGF- β tone as testable, potentially modifiable levers in sensorineural/mixed losses (e.g., cleidocranial dysplasia, otosclerosis).

33. cAMP and PKA Signaling is Essential for Mitotic Hair Cell Regeneration in the Basilar Papilla in Vivo

Lyn Miranda Portillo^{*1}, Stefan Heller¹, Nesrine Benkafadar²

¹*Stanford University School of Medicine, Institute for Stem Cell Biology and Regenerative Medicine*, ²*Stanford University School of Medicine, Institute for Neurosciences of Montpellier (INM) University Montpellier*

Background: Hearing loss is a global health issue with a profound impact on quality of life and currently has no restorative treatments. Mammals suffer from permanent hearing loss due to an inability to regenerate sensory hair cells. In contrast, non-mammalian vertebrates, like birds, regenerate hair cells and restore hearing throughout life, a process driven by supporting cell proliferation. Our prior work identified an essential signaling pathway for supporting cell S-phase entry and hair cell regeneration in vivo after hair cell damage induced by an ototoxic drug, sisomicin. To deepen our understanding, we now explore additional pathways that regulate mitotic quiescence in the undamaged basilar papilla and promote supporting cell proliferation after hair cell ablation. Previous in vitro studies found that cyclic AMP (cAMP) activators stimulate proliferation in undamaged auditory sensory epithelium, a response blocked by cAMP-regulated protein kinase A (PKA) inhibitors. Our study uses a robust in vivo model to validate these findings.

Methods: In post-hatch day 7 (P7) chickens, cAMP levels were pharmacologically elevated in the damaged basilar papilla by co-infusing cAMP activators with the ototoxic sisomicin into the lateral semicircular canal. cAMP activators were also infused into the undamaged basilar papilla. Supporting cell proliferation was quantified via EdU incorporation 48 hours post-infusion. To assess the role of PKA, we infused PKA inhibitors with sisomicin and measured their effect on supporting cell proliferation.

Results: Elevating cAMP levels with 8-Bromo-cAMP and 3-isobutyl-1-methylxanthine (IBMX) in the damaged basilar papilla resulted in a significant increase in supporting cell proliferation compared to sisomicin treatment alone. Conversely, PKA inhibitors blocked the typical proliferative response in supporting cells observed after sisomicin treatment. Surprisingly, in the undamaged basilar papilla, co-administration of cAMP activators caused only a minimal increase in supporting cell proliferation, as indicated by sparse EdU incorporation.

Conclusions: Our results reveal that the cAMP/PKA signaling pathway is essential for triggering supporting cell proliferation in vivo after damage. Furthermore, while this pathway can modestly promote S-phase entry in the absence of damage, it is primarily an essential component of the proliferative response to injury. Together with our previous work, these findings demonstrate that multiple intracellular signaling pathways are necessary for S-phase entry of basilar papilla supporting cells in response to hair cell loss. Future research must investigate how these distinct pathways interact to coordinate a precise regenerative response that effectively restores auditory function in the avian inner ear. These insights enhance our understanding of sensory hair cell regeneration in birds and lay the groundwork for future translational studies for hearing loss in mammals that utilize signal transduction pathways as potential therapeutic targets.

34. Oto coherence: Interspecies Analysis of Phase Self-Consistency in Spontaneous Otoacoustic Emission

Seth Peacock^{*1}, Václav Vencovský², Rebecca Whaley¹, Natasha Mhatre³, Christopher Bergevin¹

¹York University, ²Czech Technical University in Prague, ³Western University

Background: Spontaneous otoacoustic emission (SOAE) provides compelling evidence of active force generation inside the inner ear, although significant debate exists about the underlying generation mechanisms. SOAE is commonly characterized by peaks in the spectral magnitudes, which occur at frequencies unique to a given ear. This measure is typically computed as an averaged magnitude spectrum that discards phase information. Here, we explore the hypothesis that this phase information reveals pertinent features of SOAE generation beyond what can be extracted from magnitudes alone.

Methods: Our method characterizes the self-coherence of oscillations over time. This “otocoherence” uses a short-time Fourier transform to provide a set of phase estimates as a function of both frequency and time. For each frequency, we calculate the phase accumulation over time periods of some fixed length. The consistency of these phase accumulations is then quantified, providing an otocoherence spectrum: a function of frequency analogous to the magnitude spectrum, but calculated using only phase information from a single SOAE signal. For a fixed frequency, otocoherence is a function of the length of the accumulation time period, typically falling off roughly exponentially as this time increases. Fitting an exponential to this decay allows us to extract a time constant, a process

we repeat for a handful of SOAE frequency centers per subject. These data allow us to characterize the self-coherence of spontaneous emission as a function of frequency across species. Finally, we introduce a class of dynamic windowing methods to address issues associated with the fundamental time-frequency tradeoff.

Results: We analyzed SOAEs recorded from humans, barn owls, and lizards, and found striking interspecies differences in otochherence. Our comparison of the otochherence decay constants with measures of tuning extracted from auditory nerve fibers (barn owl and Tokay gecko) indicated that the method can predict the upper bound of frequency selectivity encoded in the central nervous system. Since our approach does not involve presenting any external stimuli, our results indicate that measures of the spontaneous emissions on their own allow for a noninvasive and stimulus-independent way to infer the degree of cochlear tuning possible.

Conclusions: We report that SOAE phase information provides data that extend beyond spectrally averaged magnitudes alone. A key finding is that the decay in otochherence at a fixed SOAE frequency appears to allow for estimates in peripheral auditory tuning. These methods can readily be employed to re-analyze previously collected SOAE waveforms from a variety of species, making them of broader comparative utility. Further, we suggest how these methods can be extended to reveal new information about SOAE generation. For example, otochherence-based methods can provide a complementary tool to improve the detection of small-magnitude SOAE peaks near the noise floor.

35. Time-Series Transcriptome Analysis of the Older Adult Mouse Cochlea After Noise-Induced Hearing Loss Reveals an Acute Immune Response and Recovery-Associated Pathways

Lize Sels^{*1}, Fien Aben¹, Krystyna Szewczyk¹, Carole Faghel¹, Esther Bartholomeus¹, Eva Lion¹, Erik Fransen¹, Ligia Monica Mateiu¹, Guy Van Camp¹, Vincent Van Rompaey², Peter Ponsaerts¹, Dorien Verdoodt¹

¹University of Antwerp, ²Universitair Ziekenhuis Antwerpen

Background: Noise-induced hearing loss (NIHL) affects approximately 5% of the global population, significantly impairing health-related quality of life, and is of particular interest in the aging population due to its association with an increased risk of cognitive decline. The pathophysiology of NIHL involves a complex interplay of damage to multiple cellular structures within the cochlea. While the pathophysiology of NIHL has been extensively studied in young mice, limited research exists on the molecular mechanisms underlying NIHL in older adult populations. This study provides the first insights into temporal differences in gene expression following noise exposure in older mice with an average age of 17 months.

Methods: We exposed mice to broadband noise of 115 dB sound pressure level (SPL) for 2h and conducted auditory testing before and after noise exposure to confirm the presence of NIHL. Cochleae were collected at 24h, 72h and 1 week post exposure for RNA sequencing (RNA-seq).

Results: Pathway enrichment analysis using the Ingenuity Pathway Analysis (IPA) tool revealed distinct temporal patterns in the cochlear transcriptome. Acute inflammatory pathways were prominently activated at 24h following noise exposure, while pathways associated with collagen degradation, hormone signaling, potassium channel activity and GABA receptor activation peaked at 72h or 1 week after noise exposure.

Conclusions: These findings shed light on the age-specific molecular responses to acoustic trauma, largely consistent with previous experiments in younger mice, and highlight critical windows for cochlear damage and repair. Understanding these temporal patterns in older adults provides information for the development of targeted treatment strategies to mitigate NIHL and its associated risks.

36. Extending the Therapeutic Window: Ndp Overexpression Improves Hearing in an Adult Norrie Disease Mouse Model

Ilkem Sevgili*¹, Yutaka Koizumi², Yushi Hayashi³, Albert Edge⁴

¹Harvard Medical School, Mass Eye and Ear, ²Massachusetts Eye and Ear, Harvard Medical School, Yamagata University, ³Nippon Medical School, ⁴Harvard Medical School

Background: Norrin, or Norrie disease protein (Ndp), is a secreted protein that functions as a Wnt pathway agonist, playing a critical role in cochlear vascularization, hair cell survival, and maintenance of the sensory epithelium. Mutations in Ndp cause Norrie disease, a rare, X-linked recessive genetic disorder characterized by congenital blindness, progressive hearing loss and cognitive decline. Our Ndp-KO mouse model recapitulates key features of human mutations, since it is not a complete null but reflects reported loss-of-function variants observed in patients. Previous studies have shown that Ndp overexpression can rescue hearing in neonatal Ndp knockout (Ndp-KO) mice, but whether this approach is effective beyond the early postnatal period remains unknown and is essential for defining the therapeutic window for intervention.

Methods: We used a conditional mouse model in which Sox2Cre drives tamoxifen-inducible Ndp overexpression (Ndp-OE) in an Ndp-KO background, enabling temporal control of gene activation in Sox2+ cochlear supporting cells. Sox2Cre; Ndp-KO; Ndp-OE mice were divided into treated (tamoxifen injection at postnatal day 30–35) and untreated groups; a control group consisted of Sox2Cre; Ndp-KO mice lacking the Ndp-OE construct. Cochlear function was assessed by auditory brainstem responses (ABR) and distortion product otoacoustic emissions (DPOAE) performed 1 and 2 months of age to assess baseline hearing, progression, and post-treatment effects. Cell morphology, Ndp expression, hair cell integrity and vascularization were evaluated by immunohistochemistry on whole-mount cochleae and cochlear cryosections. Comparisons were made across wild-type mice, Ndp-KO mice, Sox2Cre; Ndp-KO mice and untreated and treated Sox2Cre; Ndp-KO; Ndp-OE mice.

Results: Through comparative review of published human NDP mutations, we determined that the Ndp-KO model reflects clinically reported loss-of-function variants rather than a complete null, establishing its relevance as a model for Norrie disease. ABR testing showed progressive threshold shifts across all frequencies in untreated controls between 1 and 2 months of age. In contrast, tamoxifen-induced Ndp overexpression significantly reduced threshold shifts at the basal-to-mid cochlear regions, where treated mice maintained stable or improved responses while untreated animals declined. Immunohistochemistry verified successful induction of Ndp in Sox2+ supporting cells and revealed improved cellular organization in the organ of Corti, including preserved hair cells. Vascular analyses compared differences between treated and untreated groups. Comparison with a viral-mediated Ndp delivery model demonstrated differences in expression patterns relative to the genetic overexpression approach.

Conclusions: These findings establish the Ndp-KO model as a clinically relevant representation of human NDP mutations and provide the first evidence that inducible Ndp

overexpression at the young adult stage mitigates progressive threshold shifts. Together, these results support the feasibility of Ndp-targeted strategies for delaying or mitigating progressive hearing loss in Norrie disease.

37. Expanding the Genetic and Phenotypic Landscape of Auditory Nerve Deficiency: Results From Analysis of Whole-Exome Sequencing in a Chinese Cohort of 53 Patients

Haojie Sun^{*1}, Yanmei Wang², Dongdong Ren¹

¹E and ENT Hospital affiliated to Fudan University, ²Fudan University

Background: Cochlear nerve deficiency (CND) is an important etiology of sensorineural hearing loss. While audiological interventions including hearing aid fitting and cochlear implantation are the first-line treatment for these children, outcomes are variable. Therefore, it is particularly important to define the etiology of CND. However, the pathogenesis of CND in humans remains largely unclear, and no known large-scale genetic study has been conducted on CND yet. Among all genetic testing methods, the trio-WES has the unique advantages in the sensitivity of detecting de novo variants (DNM).

Methods: We recruited 53 trio families with SNHL and CND confirmed by MRI findings from the Eye and ENT Hospital, Fudan University between June 2016 and August 2023. Demographic, clinical, and audiological data were collected from electronic medical record, Blood samples from the affected individual and unaffected biological parents were obtained. Whole-Exome Sequencing and variant calling was conducted. De novo variants were filtered out and the deleterious effect of variants was predicted by SIFT scores, REVEL, and CADD scores. Statistical Analysis was performed to investigate the associations between multiple clinical characteristics of patients.

Results: Among 53 CND nuclear families, 68 de novo variants were identified, among which 26 DNMs were considered possibly pathogenic according to several predicting models, including SMARCE1, ITGB1, TRPM8, MCM4, TUBB3, etc. Functional analysis showed that several genes might be linked to the etiology of CND, including developmental process, synapse, regulation of postsynaptic neurotransmitter receptor activity and regulation of synapse pruning. In addition, the phenotypic associations between damaging DNMs and multiple clinical traits were explored. Damaging DNM had a higher ratio in bilateral, inner ear anomaly cases and slightly lower ratio in systemic anomaly patients.

Conclusions: In this study, we identified a large fraction of genes and their potential pathogenic mutations that may be associated with the development of CND in this largest sequencing study of families with cochlear nerve dysplasia to date. Collectively, our results delineate the genomic landscape of Chinese CNDs and identify several potential pathogenic DNMs of CND.

38. Three-Dimensional Analysis of the Effects of Chronic Implantation and Stimulation on Hearing

Ella Trang^{*1}, Gabriela Segal², Ellie Cho³, Andrew Wise¹, James Fallon¹

¹Bionics Institute, ²Garvan Institute of Medical Research, ³Biological Optical Microscopy Platform, University of Melbourne

Background: Chronic cochlear implantation and stimulation is known to produce a fibrotic tissue response within the cochlea. This fibrosis would be expected to impact residual hearing; however, previous studies have failed to produce a conclusive correlation between the two. We hypothesise this lack of correlation may be due to limitations in conventional histological techniques – analysis from two-dimensional microtome sections, being unrepresentative of the complex response that occurs following chronic implantation and stimulation. We have leveraged recent developments in tissue clearing – a process whereby normally opaque tissue is rendered transparent - and developed a method to allow for three-dimensional characterisation of the cochlear structures and fibrotic response to chronic implantation and stimulation within an intact cochlea.

Methods: Normal hearing guinea pigs (n=4) were bilaterally noise deafened (10kHz 120dB SPL free-field for 1 hour). After 14 days the left cochlea was implanted with an 8-contact intracochlear electrode array and received stimulation (50 μ C/cm²) for 4 weeks from a clinical stimulator and speech processor. Right cochlea served as deafened, unimplanted controls. Hearing assessments (acoustically evoked compound action potentials, aCAPs, 8 – 32kHz) were performed at implantation and at the conclusion of the chronic stimulation period. Cochleae were collected (with implant left in-situ); immunofluorescently stained with markers for cochlear structures (hair cells and spiral ganglion neurons, SGN) and fibrosis (e.g. fibroblasts and macrophages); and cleared in ethyl cinnamate. The whole cochlea was imaged on a light-sheet fluorescence microscope, and images volumetrically rendered and analysed using Imaris software.

Results: Noise deafening resulted in a significant increase of 58dB (SEM=2.3) at 8-32kHz (n=8 ears). In two animals, chronic implantation and stimulation resulted in a 1.5dB increase in hearing thresholds at 1-32kHz. Histological analysis is ongoing; preliminary analysis indicates chronic implantation and stimulation resulted in fibrotic growth, although this did not appear to affect hair cell or SGN survival.

Conclusions: Three-dimensional visualisation of the cochlea offers unprecedented insight into how the fibrotic tissue response to chronic implantation and stimulation can affect hair cell and spiral ganglion neuron survival. In addition, imaging the cochlea with the implant left in-situ allowed for the identification of the fibrosis and cochlear structures in relation to specific electrodes. Using a range of pathophysiological markers, this study demonstrates a novel method that provides an accurate assessment of the cochlea following chronic implantation and stimulation. This improved validation tool will be used in developing treatments to reverse or prevent cochlea damage.

39. Comparative Analysis of Rna Versus Protein Splicing in Dual Aav-Mediated Gene Therapy in a Mouse Model of DFNB9 Deafness

Mengzhao Xun^{*1}, Xintai Fan¹, Wang Hui², Jingjing Zhao¹, Jianping Liu¹, Tang Honghai³, Geng-Lin Li¹, Bing Chen¹, Yilai Shu³

¹Eye and ENT Hospital, Fudan University, ²ENT Institute, Eye and ENT Hospital, State Key Laboratory of Medical Neurobiology and MOE Frontiers Center for Brain Science, Fudan University, ³Eye and ENT Hospital, State Key Laboratory of Medical Neurobiology and MOE Frontiers Center for Brain Science, Fudan University

Background: Pathological mutations in the OTOF gene cause autosomal recessive deafness 9 (DFNB9). Although dual-AAV gene replacement therapy has been shown to partially

rescue the hearing of patients with DFNB9, the therapeutic effects still need further exploration.

Methods: To investigate the impact of different recombination strategies on the efficacy of OTOF gene therapy, we constructed five dual-AAV1 therapeutic agents using RNA or protein splicing principles.

Results: Based on the recombination strategy using RNA splicing, the AAV1-AK system rescued the hearing of *Otof* ^{-/-} mice to 55–70 dB, which outperformed the AAV1-AP and AAV1-TS systems. Based on protein splicing, the AAV1-intein system rescued the hearing of *Otof* ^{-/-} mice to 35–70 dB, which outperformed that of AAV1-AK, and the effects lasted up to 12 months after injection in both newborn and adult mice. The efficacy of otoferlin re-expression and the number and functional restoration of ribbon synapses in the AAV1-intein system were also better than the AAV1-AK system.

Conclusions: These results show that protein recombination is more efficient than nucleic acid recombination for gene therapy in DFNB9. Therefore, this work not only provides data for optimization of DFNB9 gene therapy, but also provides a reference for the delivery of other large genes.

40. Musical Context Influences the Impact of Vocal Boost Manipulations for Cochlear Implant Users

Stephanie Younan¹, Arjun Kurup¹, Patpong Jiradejvong¹, Jonathan Mo², Charles J. Limb¹, Nicole Jiam¹, Stephanie Younan*¹

¹UCSF, ²University of California, Davis School of Medicine

Background: Music perception and enjoyment remain a persistent challenge for post-lingually deafened adults with cochlear implants (CIs), largely due to the degraded spectral cues essential for melodic processing. Vocal boosting - enhancing the levels of vocals relative to background – has been proposed as a means of improving sound quality and enjoyment in this population. Yet, whether the benefit of vocal boosting derives from greater access to lyrical content within a coherent musical scene, as opposed to increased audibility over a non-musical masker, remains unclear. This study investigates how the perceptual gains from vocal boosting depend on the acoustic nature of the background.

Methods: Fourteen CI users rated the sound quality of stimuli on a 100-point scale. Vocals from ten popular songs were extracted and paired with three types of backgrounds: original instrumentals, off-key instrumentals (+4 semitones), and multi-talker babble. Each vocal-background pair was normalized to have an equal signal-to-noise ratio (SNR), forming the +0 dB SNR condition. Stimuli were then manipulated to create +9 dB (boosted) and -9 dB (attenuated) SNR conditions. An anchor stimulus (1,000 Hz low-pass filter with white noise) was included. Participants rated stimuli relative to the +0 dB SNR condition for each background. A subsequent forced-choice test assessed recognition of the original song from the three background types.

Results: Background type had a dominant impact on sound quality ratings ($\eta^2=0.68$), exceeding the vocal level effect ($\eta^2=0.35$). Vocals over both original and off-key instrumental backgrounds were rated similarly (58.2 vs. 56.9; $p=0.774$) and significantly higher than vocals over babble noise (22.9-point difference, $p < 0.001$). Thus, CI users reliably differentiated musical from non-musical backgrounds, but were insensitive to large pitch distortions. Vocal boost (+9 dB) increased ratings modestly (+ 7.2 points; $p < 0.05$), while attenuation (-9 dB) produced a more pronounced decline (-14.7 points; $p < 0.001$). Results

revealed a significant interaction between background type and vocal level ($F(2,39)=11.31$, $p < 0.01$), with vocal boost effects varying by background type: babble showed the largest improvement (+16.6 points, $p < 0.001$), followed by original instrumental (+7.2 points, $p=0.001$) and off-key instrumental (+4.1 points, $p=0.122$). Overall song recognition accuracy was 68%. Participants with a history of musical training showed a significant advantage in recognition (75% vs. 61%, Cohen's $d=0.31$) and derived greater benefit from vocal manipulations.

Conclusions: While vocal boosting provides benefit across all background types, the highest absolute sound quality ratings emerge when vocals are embedded within a coherent musical structure, highlighting the importance of preserving contextual cues rather than simply amplifying speech. The ability to distinguish musical from non-musical content, coupled with insensitivity to pitch inaccuracy, underscores a reliance on structural over spectral fidelity. These findings suggest that future CI musical processing strategies should retain musical scaffolding, while selectively boosting vocal prominence to meaningfully improve musical enjoyment.

41. Connexin30-Deficient Mice Increase Susceptibility to Noise via Redox and Lactate Imbalances

Jifang Zhang^{*1}, Jun Yang¹, MaoLi Duan²

¹Shanghai Jiao Tong University School of Medicine, ²Karolinska University Hospital

Background: Noise significantly contributes to one-third of the global burden of hearing loss. The intricate interplay of genetic and environmental factors impacts various molecular and cellular processes that lead to noise-induced hearing loss (NIHL). Defective connexin 26 (Cx26) and connexin 30 (Cx30), encoded by Gjb2/Cx26 and Gjb6/Cx30, respectively, are prevalent causes of hereditary deafness. However, the role of Cx30 in the pathogenesis of NIHL remains unclear.

Methods: Cx30-deficient mouse models related to NIHL were established and subjected to audiological follow-up using auditory brainstem response (ABR) measurements. Cochlear morphology was analyzed via immunofluorescence, transmission electron microscopy, and toluidine blue staining. Changes in oxidative stress were observed and compared using dihydroethidium (DHE), 4-hydroxynonenal (4HNE), and western blot assays. Cochlear glucose transport and energy metabolism were assessed via 2-NBDG glucose uptake and ATP release assays. Metabolomic analysis was employed to investigate mechanisms underlying cochlear energy alterations.

Results: We observed that homozygous Cx30 knockout (Cx30 KO) mice exhibited poorer hearing recovery after noise exposure (97 dB mean sound pressure level for 2 h) and increased susceptibility to noise. In addition to the exacerbation of noise-induced damage to hair cells and synapses, Cx30 KO mice exposed to noise exhibited increased oxidative stress. The 2-NBDG assay showed a reduction in glucose levels associated with a decrease in gap junctions as well as a reduction in adenosine triphosphate release. Glucose metabolomics analysis further revealed that Cx30 KO mice had elevated lactate and NAD⁺ levels after noise exposure, thus worsening anaerobic oxidation from glycolysis.

Conclusions: Our study emphasizes that Cx30-deficient mice increase susceptibility to noise via redox and lactate imbalances in the cochlea.

NIDCD Workshop: Navigating NIDCD Funding for Early Stage and New Investigators

7:00 p.m. - 8:30 p.m.

Meeting Room 209ABC, Floor 2

Kelly King, *NIDCD, National Institutes of Health*

The *Early Stage/New Investigator* workshop will provide practical information on how grant applications are processed within NIH/NIDCD. Specific information will be presented regarding funding opportunities for early-stage investigators, including the NIDCD Career Development Award (R21) and recent changes in NIH policy, providing information to early-stage investigators to facilitate their successful transition from trainee to independent investigator.

NIDCD Workshop: NIDCD Extramural Clinical Trial Workshop

7:00 p.m. - 8:30 p.m.

Ballroom B, Floor 3

Trinh Ly, *NIDCD/NIH*

Castilla McNamara

This workshop will provide investigators an overview of how NIDCD approaches extramural clinical trials. The goal of this session is to help investigators determine clinical trials risks, select the most appropriate funding opportunity as well as highlight important application requirements and points to consider when planning an NIDCD clinical trial. Investigators will also gain an understanding of how NIDCD manages clinical trials and expectations for the implementation of NIDCD funded high-risk clinical trials.

Biomarkers of Neuroplasticity in the Perilymph in Prelingual Deafness

8:00 a.m. - 8:15 a.m.

Monika Matusiak^{*1}, Anna Konopka², Monika Ołdak¹, Dominika Oziębło¹, Henryk Skarżyński¹

¹*Institute of Physiology and Pathology of Hearing*, ²*PORT Łukasiewicz Research Network*,

Background: Congenital deafness treatment with cochlear implantation (CI) is a standard therapy with, in overall, very good results, however, in some cases implanted children do not reach the age norm in verbal communication. Molecular biomarkers would facilitate the clinical management of deaf born children, helping in predicting the level of linguistic proficiency a child would achieve after CI. Having known, from our previous studies, that the serum level of matrix metalloprotease 9 (MMP-9) has been identified as a biomarker of neuroplasticity in prelingual deafness it is of great interest to investigate the MMP-9 also in the perilymph, as well as look for another biomarkers in the perilymph. Inner ear liquid biopsy would also help in understanding the molecular environment of the diseased organ in congenital deafness cases.

The objective of the study is to investigate the perilymph proteome, including MMP-9, and blood serum proteome, and to see their relation to auditory development after CI.

We have collected 6 pairs of samples perilymph/blood during the surgical procedure of CI from prelingually deaf children in Institute of Physiology and Pathology of Hearing, Warsaw. The perilymph was sampled by using glass capillary via the round window just before the array insertion.

Methods: Using Mass Spectrometry (MS) protein quality analysis was performed in each perilymph/blood sample. MMP-9 was assessed by Enzyme-Linked Immunosorbent Assay (ELISA). Auditory development of implanted children was assessed by using LittleEARs Questionnaire (LEAQ).

Results: We have detected 1471 perilymph proteins, including MMP-9, out of which 441 were detected only in perilymph and 43 were detected only in blood plasma. Preliminary analyses of correlations between perilymph proteomic profiles, blood plasma and auditory development were performed.

Conclusions: There are correlations between proteome content of the perilymph and auditory development outcomes of cochlear implantation in prelingual cases.

Can Impedance Predict Intracochlear Neo-Ossification and Fibrosis in Cochlear Implant Recipients?

8:15 a.m. - 8:30 a.m.

Nicole E. Tomassi*¹, Abbie Hall¹, Caylin McCallick¹, Alexander Geerardyn¹, Julie G. Arenberg¹, Alicia M. Quesnel¹

¹*Mass. Eye and Ear, Harvard Medical School*

Background: Foreign body responses are a common result of cochlear implantation. Although surgical techniques have changed over the years in attempts to reduce insertion trauma, neo-ossification and fibrosis around the electrode array is still commonly observed. Historically, neo-ossification and fibrosis have been thought to affect the resistivity of electrodes, measured clinically as the level of impedance. Since neo-ossification and fibrosis cannot be easily visualized and quantified in living humans, the relationship between these foreign body responses and cochlear implant impedance levels has been limited to animal and tissue-engineered models. However, post-mortem temporal bone specimens enable high resolution 3-dimensional mapping and quantification of intracochlear fibrosis and neo-ossification, allowing the investigation of these relationships in human cochlear implant recipients. The purpose of this study was to relate neo-ossification and fibrosis volume adjacent to individual electrodes in human implanted cochleae to impedance levels measured during life.

Methods: Human temporal bones from cochlear implant users were histologically processed, sectioned, and digitized. 3D reconstructions of the cochleae and electrodes were generated. The anatomical regions of the cochlea including the scala tympani, scala vestibuli, and scala media (when applicable), as well as the electrode array and areas of neo-ossification and fibrosis, were digitally segmented. The individual electrode locations were mapped using the 3D electrode reconstruction and manufacturer reported intra-electrode distances. The last measured impedance before death was extracted from the clinical records of each temporal bone donor. The amount of neo-ossification and fibrosis was compared to impedance levels using Pearson's correlation coefficient.

Results: We expect a total of 16 donors to be represented in this study. Within these clinical records, impedance levels were higher at the base of the array (likely due to insertional trauma) in 14 donors. Preliminary results in seven completely analyzed temporal bone specimens indicate a direct relationship between neo-ossification and impedance at the group level such that more bone deposition was positively correlated with higher impedance levels ($p < 0.001$, $r = 0.484$). The relationship between neo-ossification and impedance at the individual level varies. In the preliminary dataset, no significant relationship was observed between fibrosis and impedance.

Conclusions: Thus far, a positive relationship has been observed between neo-ossification and impedance at the group level. This approach bridges otopathology and clinical outcomes in humans by quantifying these foreign body responses with high precision and relating them to impedance levels of each electrode.

Distribution Patterns of Cochlear Endosteal Invasion in Otosclerosis

8:30 a.m. - 8:45 a.m.

Tomotaka Shimura¹, Nevra Keskin Yilmaz¹, Sebahattin Cureoglu¹, Meredith Adams¹, Rafael da Costa Monsanto*¹

¹*The University of Minnesota*

Background: Most cases of otosclerosis involve bone remodeling localized to the fissula ante fenestram. In a subset of cases, however, the pathological process extends to the cochlear endosteum, resulting in fibrosis, atrophy, or ossification of the cochlear lateral wall. Owing to the limited resolution of current imaging modalities in delineating intracochlear alterations and the precise interactions between osseous and membranous structures, the spatial distribution and morphological patterns of these lesions remain insufficiently defined. The objective of the study was to characterize the frequency, severity, and site-specific distribution of cochlear endosteal invasion in otosclerosis from a pathological perspective.

Methods: Archival histological slides of human temporal bones from donors with otosclerosis from the Paparella Otopathology and Ear Pathogenesis Laboratory collection (University of Minnesota) were examined. Endosteal invasion was defined as direct disruption of the cochlear endosteum and classified into three grades. Grade I was defined as partial contact with the endosteum accompanied by mild surface irregularity, without spiral ligament hyalinization or stria vascularis atrophy. Grade II was characterized by mild pathological changes of the lateral cochlear wall, whereas Grade III encompassed moderate to severe alterations of the lateral wall and/or the presence of intraluminal pathology. Results were statistically analyzed using chi-square tests.

Results: Among 207 ears from 119 donors, cochlear endosteal invasion was identified in 37 ears (17.9%). The distribution of invasion grades was: Grade I, 21.6%; Grade II, 43.2%; and Grade III, 35.1%. Multifocal invasion was significantly associated with higher-grade lesions ($p < 0.0001$). The lower basal turn had the lowest overall frequency of lesions, with an invasion rate of 53.9% compared to other turns. Notably, however, all 7 cases with basal turn involvement demonstrated severe (Grade III) endosteal invasion.

Conclusions: Cochlear endosteal invasion was present in 17.9% of otosclerosis cases and showed site- and grade-specific variability, with the lower basal turn most often affected by severe lesions. This classification system highlights distinct spatial and morphological patterns that may serve as a standardized framework for future clinicopathological studies and could help guide both the timing of medical treatment (e.g., bisphosphonates) and surgical planning.

Hypoxia-Driven Metabolic Reprogramming in Vestibular Schwannoma

8:45 a.m. - 9:00 a.m.

Mikhail Marasigan*¹, Olena Bracho¹, Bryan Souza¹, Diane Jung¹, Olivia Kalmanson¹, Michael Ivan¹, Carolina Benjamin¹, Vivek Kanamuri¹, Simon Angeli¹, Fred Telischi¹, Pei-Ciao Tang¹, Daniela Frasca¹

¹*Miller School of Medicine, University of Miami*

Background: Cancer cells adapt their metabolism to sustain proliferation and survive under nutrient limitation and hypoxia, promoting growth and therapy resistance. Vestibular

schwannomas (VS) are benign intracranial tumors of the vestibulocochlear nerve that often cause hearing loss, dizziness, and neurological deficits. Although VS express hypoxia-related factors, their metabolic pathways remain poorly defined. Elucidating these mechanisms may uncover metabolic vulnerabilities that can be targeted to improve clinical outcomes for VS patients.

Methods: Primary VS cell cultures were established from patient tumors. In parallel, wild-type (WT) and NF2-mutant Schwann cells (SCs) were generated from human induced pluripotent stem cells. Cells were maintained in proliferative Schwann media at 37°C, 5% CO₂, under oxygen tensions of 1%, 5%, or 21% O₂. After seeding (2,500 cells/well, 384-well CellBIND plates) and cell adherence, media was refreshed and metabolic assays (CellTiter-Glo, RealTime-Glo MT, Lactate-Glo, Glucose-Glo, Glutamine-Glo) were performed at 72 hours. Luminescence was measured, and data analyzed by nonparametric analysis of variance.

Results: ATP levels correlated with viability measurements, with the highest levels observed at 21% O₂, indicating mitochondrial respiration as the predominant means of energy production when oxygen is readily available. All cell types utilized glucose and secreted lactate (byproduct of glycolysis), though VS exhibited the lowest levels overall. Notably, VS cells increased glutamine consumption at 1% and 5% O₂ compared to 21% O₂, suggesting hypoxia-dependent reliance on glutamine metabolism.

Conclusions: VS, WT, and NF2-mutant SCs display distinct metabolic profiles shaped by oxygen availability. Our pilot study shows VS demonstrate limited glycolysis but enhanced glutamine utilization under hypoxia, pointing to metabolic dependencies that may be exploited therapeutically. Targeting these adaptive pathways could inform novel strategies for VS control.

Intraoperative Electrically Evoked Stapedial Reflex Thresholds (eSRT) for Cochlear Implant Programming: A Postoperative Validation Study

9:00 a.m. - 9:15 a.m.

Eric Cunningham^{*1}, Isabelle J Chau¹, Rivka Bornstein², Regina Albinus², Pal Sudhirkumar Shah¹, Katrina Stidham²

¹New York Medical College, ²Westchester Medical Center

Background: Cochlear implants (CIs) restore hearing in severe-to-profound sensorineural loss by delivering electrical stimulation to the auditory nerve. Programming requires determining the lower (T-level) and upper (C-level) stimulation limits, which define the electrical dynamic range. In patients unable to provide reliable behavioral feedback, the electrically evoked stapedial reflex threshold (eSRT) can approximate C-levels and improve programming accuracy. The eSRT correlates with behavioral C-levels, but postoperative testing is limited by middle ear pathology, patient intolerance, or low clinical adoption. Intraoperative eSRT may overcome these barriers and offer an initial programming reference, but volatile anesthetics can suppress the reflex. Whether intraoperative eSRT predicts early postoperative values, particularly at middle and apical electrodes, remains unclear.

Methods: In this prospective cohort study, CI recipients underwent routine intraoperative eSRT testing with Cochlear Americas devices. Exclusion criteria included absence or disruption of the stapedial tendon, anatomic barriers, medical instability, or volatile anesthetic exposure within 10 minutes of testing. A single surgeon measured intraoperative eSRTs visually with volatile

anesthetics withheld. Postoperative eSRTs were measured ~1 month later. Response rates were compared via chi-squared tests with Benjamini-Hochberg correction. Threshold changes were analyzed with paired t-tests, and intra- vs. postoperative correlations assessed using Spearman's rank.

Results: Eighty-four cochlear implants in 77 patients met inclusion criteria, with intraoperative eSRT attempted in 72 ears and postoperative testing in 50. Intraoperative response rates were significantly higher than postoperative rates overall (83.1% vs. 70.9%, $p = 0.0005$), with the highest rates at middle and apical electrodes. Median intraoperative thresholds were significantly higher than postoperative thresholds (21.2 vs. 15.6, $p < 0.0001$), but no significant correlations were observed between the two time points.

Conclusions: Intraoperative eSRT was feasible and yielded high response rates, particularly at apical and middle electrodes. However, intraoperative thresholds did not correlate with early postoperative values and cannot currently predict programming levels. These findings support the utility of intraoperative eSRT as a qualitative intraoperative tool, but further refinement is needed to improve its predictive value for postoperative cochlear implant programming.

Linking Data-Driven Audiometric Phenotypes to Speech Perception in Quiet and Noise

9:15 a.m. - 9:30 a.m.

Varsha Athreya*¹, Jwala Rejimon², Malcolm Slaney¹, Matthew Fitzgerald²

¹*Stanford University*, ²*Stanford University School of Medicine*

Background: The pure-tone audiogram (250–8000 Hz) remains the clinical gold standard for assessing hearing, yet it only partially captures suprathreshold deficits. Here, we apply unsupervised, data-driven profiling to derive phenotypes that reflect both audibility loss and suprathreshold performance (word recognition in quiet and speech-in-noise). This approach refines hearing-loss classifications by capturing natural variability in audiogram shape and severity, and by characterizing speech outcomes within each cluster to support precision audiology. In addition, we will identify specific diseases within each cluster (e.g., Ménière's disease, vestibular schwannoma) to probe disorder-linked audiometric and speech-perception signatures. Finally, we will link these phenotypes to real-world device behavior, specifically the adoption of hearing aids and cochlear implants, to inform targeted fitting strategies and treatment selection.

Methods: We conducted a retrospective analysis of audiological records collected at our academic medical center since 2006, excluding cases with conductive or mixed hearing loss (air-bone gap ≥ 10 dB HL). Using K-means clustering (scikit-learn, Python) on 66,956 unique pure-tone audiograms measured at eight frequencies (250–8000 Hz), we derived distinct, data-driven audiometric phenotypes. To relate these phenotypes to functional hearing, we examined speech-perception performance using Word Recognition in Quiet (WRQ) and QuickSIN (speech-in-noise) measures. Within each cluster, we selected individuals with Ménière's disease and vestibular schwannoma to evaluate relative prevalence and to describe diagnosis-linked speech-perception profiles. Finally, we linked cluster membership and diagnosis to real-world device behavior of hearing-aid and cochlear-implant adoption.

Results: K-means clustering uncovered a set of distinct audiometric phenotypes, highlighting diverse configurations and severities across the cohort. Hearing loss increased with age, most prominently at higher frequencies. Despite similar pure-tone averages, audiograms show age-dependent variability in configuration. As hearing loss increases, the likelihood of sub-optimal word recognition in quiet increases, however, most patients display excellent performance. In contrast, even small amounts of hearing loss, particularly in higher frequencies, worsens speech-in-noise performance. In addition, SPIN performance showed greater individual variability than WRQ scores, demonstrating sizable differences in suprathreshold processing under challenging listening conditions. Ménière's disease tends to show rising configurations in younger patients, possibly linked to recent diagnosis, and flat or sloping losses in older patients. In contrast, vestibular schwannomas more often manifest as sloping losses of variable severity.

Conclusions: These findings emphasize that audiometric thresholds alone cannot capture the full complexity of hearing impairment. Clustering revealed distinct phenotypes tied to age and diagnosis, while differences between word recognition in quiet and speech-in-noise performance suggest that the latter is more sensitive to subtle deficits, reflecting challenges in suprathreshold processing. Incorporating speech-in-noise testing alongside audiometric profiling is therefore essential for both accurate diagnosis and tailored rehabilitation. Together, these age- and diagnosis-specific patterns provide insight into the disease course and may inform more targeted rehabilitation strategies.

Swab-Based Genetic Analysis of HPV for Precise Detection and Tumor Profiling in Head and Neck Cancer

9:30 a.m. - 9:45 a.m.

Ella Jackert*¹, Swar Vimawala², Liyang Tang², Daniel Kwon², Niels Kokot², Uttam Sinha², Albert Han²

¹*Keck School of Medicine of USC*, ²*USC Caruso*

Background: Current methods to detect and genotype human papillomavirus (HPV) in oropharyngeal squamous cell carcinoma (OPSCC) rely on tissue specimens or assays with limited specificity. We validated a minimally invasive swab-based strategy with potential to improve diagnosis, tumor characterization, and surveillance.

Methods: Twenty-five OPSCC and 20 oral cavity cancer patients were included. All controls tested HPV-negative. HPV16 was detected in 21/25 OPSCC tumor swabs (84%). Mean HPV16 fold change was 7,503.08 in tumors versus 1.29 in contralateral normal mucosa ($p < 0.0001$). One qPCR-negative swab was HPV33-positive on sequencing. Overall sensitivity was 88% and specificity 100%.

Results: A total of 25 patients with biopsy-proven OPSCC and 20 patients with oral cavity squamous cell carcinoma were included in the study. All oral cavity samples tested negative for HPV. 21 of 25 OPSCC swab samples tested positive for HPV16 on qPCR (84%). The mean fold change of HPV16 was 7,503.08 for tumor swabs compared to 1.29 for contralateral normal oropharyngeal mucosa ($p < 0.0001$). Of the swabs that tested negative for HPV16, one swab sample was positive for MY09/MY11 and was determined to be serotype HPV33 by Sanger sequencing. The overall sensitivity was thus 88% and specificity was 100%.

Conclusions: Here, we validate a novel swab-based detection method of HPV DNA in OPSCC. This method is highly sensitive, specific, minimally invasive, and has potential for tumor characteristic including HPV genotyping that would otherwise only be able to be assessed through labor intensive tissue pathological analysis. This swab-based pathway provides a site-specific scalable diagnostic strategy that holds promise for improving early detection and strengthening surveillance of HPV-associated OPSCC in routine clinical practice.

The Molecular Landscape of Inner Ear Schwannoma

9:45 a.m. - 10:00 a.m.

Jonas Scheffler*¹, Sandra Leisz¹, Eric Lehner¹, Jessica Stieber¹, Elisa Darnstaedt¹, Sabine Koitzsch¹, Tony Gutschner¹, Arne Liebau¹, Stefan K. Plontke¹

¹*University Medicine Halle (Saale)*

Background: Inner Ear Schwannoma (IES) represent a rare subset of vestibulocochlear schwannoma (VS). Their intralabyrinthine location and close proximity to sensitive modiolar structures, including spiral ganglion and sensory hair cells, imply diagnostic, prognostic and therapeutic challenges compared to VS in the cerebellopontine angle (CPA) or internal auditory canal (IAC). Moreover, the microenvironment surrounding IES differs substantially from that of VS adjacent to the brainstem. Although clinical reports and case series on IES are steadily increasing, the tumor biology remains poorly understood. This study aims to provide a comprehensive overview of the key molecular characteristics of IES at both the RNA- and DNA-levels.

Methods: Fresh-frozen tumor samples from 15 patients with IES were collected during surgical resection. Bulk RNA sequencing was performed on all 15 samples, and whole-genome sequencing on 10. A control cohort comprised of published data of VS from CPA/IAC. Bioinformatic analyses included differential gene expression, pathway enrichment, cell-type deconvolution, as well as variant calling, copy-number/ structural variation analysis, and mutational signature profiling. Integrated RNA–DNA analyses were conducted to characterize molecular features of IES in relation to their specific location within the inner ear.

Results: Integrative genomic and transcriptomic analyses identified molecular features of IES. The datasets showed alterations at transcriptional levels, involving pathways relevant to tumor biology, location and the tumor microenvironment.

Conclusions: This study provides the first integrative molecular characterization of IES. These findings advance the understanding of IES biology and provide a foundation for the development of improved diagnostic and therapeutic approaches.

Podium 4: Multi-disciplinary Research of the Middle Ear

8:00 a.m. - 10:00 a.m.

Meeting Room 208ABC, Floor 2

Moderators: Regina Gendzelevski Kelmann and Z. Jason Qian

Impact of Age and Sensorineural Hearing Loss on Sound Transmission Through the Middle Ear

8:00 a.m. - 8:15 a.m.

Stefan Stenfelt*¹

¹*Linköping University*

Background: Sound transmission typically occurs through air conduction (AC): sound waves enter the outer ear, are converted into vibrations by the tympanic membrane, and are transmitted via the ossicles to the inner ear. Bone conduction (BC) provides an alternative pathway, bypassing the middle ear. Traditionally, middle ear sound transmission—assessed through the difference between AC and BC thresholds—has been regarded as stable and unaffected by aging or sensorineural hearing loss (SNHL). However, recent evidence suggests that age and SNHL may influence this relationship. The present study aimed to evaluate how aging and SNHL affect middle ear sound transmission, measured as the AC–BC threshold difference.

Methods: Audiometric data from 13,417 participants (ages 4–102 years, mean 59.3 years) were extracted from the Linköping University Hospital audiology database (2018–2019). Bilateral AC and BC thresholds between 250–4000 Hz were analyzed. Ears with presumed conductive hearing loss, defined as ≥ 25 dB difference between AC and BC at two or more frequencies, were excluded. Effects of age, gender, and SNHL on AC–BC differences were assessed using regression modeling.

Results: Across the cohort, significant AC–BC differences were observed: ~ 5 dB at 250, 1000, and 3000 Hz, and 11 dB at 4000 Hz. Females demonstrated slightly greater differences (~ 1 dB) than males, likely reflecting reference threshold standards. Children and adolescents (< 20 years) exhibited higher AC–BC discrepancies than adults. Regression analysis showed negligible influence of age on AC–BC differences, except at 500 Hz where middle ear transmission improved slightly (~ 0.5 dB per decade). When AC thresholds were used as reference, regression models indicated poorer middle ear transmission at ≤ 1 kHz with greater hearing loss, whereas using BC thresholds suggested the opposite—improved transmission. At higher frequencies, both reference systems indicated worsening transmission with increased loss. However, detailed analysis suggested these findings were largely attributable to measurement constraints, particularly at the extremes of AC and BC testing ranges.

Conclusions: Children exhibited systematically larger AC–BC differences, likely due to developmental or calibration-related factors, producing spurious indications of conductive loss. Small gender-related differences appear to arise from anatomical variation. In adults, middle ear transmission remains stable across age, with no meaningful impact of SNHL. Previously reported effects of aging or SNHL on middle ear sound transmission are most likely artifacts of test limitations, particularly with BC at threshold extremes. Additional contributors to variability may include vibrotactile responses, harmonic distortion, airborne radiation, binaural summation, and calibration differences between AC and BC transducers.

Improved Automatic Segmentation of the Ossicular Chain From Cone-Beam Ct Using Nnu-Net With an Expanded Dataset of 2,000 Scans

8:15 a.m. - 8:30 a.m.

Liam Barrett^{*1}, Talisa Ross², Anne Schilder³, Nishchay Mehta²

¹*University College London*, ²*Royal National Ear Nose and Throat Hospital*, ³*Ear Institute University College London*

Background: Automated segmentation of the ossicular chain from medical imaging is crucial for otological diagnosis, surgical planning, and treatment monitoring. Whilst convolutional neural networks have shown promise in middle ear segmentation, existing studies have been severely limited by dataset size. Our systematic review identified only 866 scans across all published studies, with individual studies typically using fewer than 200 scans. The stapes has proven particularly challenging, with even the best-performing architectures achieving Dice similarity coefficients of only 0.84, compared to over 0.90 for the malleus and incus. This research addresses these limitations by leveraging a substantially larger dataset to determine whether increased training data improves segmentation performance, particularly for challenging anatomical structures.

Methods: We utilised 2,000 cone-beam CT scans from University College London Hospitals, representing a three- to ten-fold increase over previous studies. Between 200 scans were manually annotated by expert clinicians for the complete ossicular chain and individual components (malleus, incus, stapes). The nnU-Net architecture was selected based on its self-configuring capabilities and proven performance in medical image segmentation. We trained three model variants: 3D low-resolution, 3D full-resolution, and 3D cascade, using five-fold cross-validation. Performance was evaluated using Dice similarity coefficient, average symmetric surface distance, modified Hausdorff distance, and 95th percentile Hausdorff distance. We investigated the relationship between training set size and segmentation accuracy through incremental training experiments.

Results: Analysis indicates improved segmentation performance across all ossicular components compared to literature benchmarks. The expanded dataset demonstrates particular benefit for stapes segmentation, historically the most challenging structure. Performance scaling analysis reveals a distinct pattern in the relationship between dataset size and segmentation accuracy across ossicular structures. The malleus and incus achieved state-of-the-art performance after approximately 70 training scans, with Dice coefficients plateauing at 0.92 and 0.93 respectively. In contrast, stapes segmentation continued to improve with increasing dataset size up to 120 scans (Dice=0.88), demonstrating that smaller anatomical structures benefit disproportionately from larger training datasets. Notably, we did not observe a ceiling effect in model capacity; more complex architectures (3D full-resolution and 3D cascade) consistently outperformed simpler models without exhibiting overfitting, suggesting that both data quantity and model complexity contribute to optimal performance. These results demonstrate that the combination of expanded training data and sophisticated architecture selection enables clinically viable automated segmentation across all ossicular components.

Conclusions: This study demonstrates that substantially larger training datasets can overcome historical limitations in automated ossicular chain segmentation, particularly benefiting small anatomical structures like the stapes. Our findings suggest that data scarcity has been a significant constraint in achieving clinically viable segmentation accuracy. These results have immediate implications for clinical workflow integration, potentially enabling automated preoperative planning and quantitative assessment of middle ear pathology. Future work should focus on validating performance across multiple institutions and extending to pathological cases.

Background and Procedure-Related Histologic Findings in Otic Tissues of Four Laboratory Species

8:30 a.m. - 8:45 a.m.

Cory Howard*¹, Rachel Tapp², Mee Ja Sula²

¹Michigan State University Veterinary Diagnostic Lab, ²Charles River Laboratories

Background: Preclinical ototoxicity studies evaluate drug candidates intended for human use and typically include histologic examination of the external, middle, and inner ear, along with auditory brainstem response (ABR) and cytochleogram assessments. Larger mammalian species such as guinea pigs, rats, nonhuman primates, and chinchillas are commonly used as animal models. Despite the importance of these studies for investigational new drug applications to proceed with clinical trials, limited information is available on background and procedure-related histologic findings in control animals. Such information is critical for determining whether observed changes represent test article-related effects.

Methods: Histologic observations were retrospectively collected from ototoxicity studies conducted at Charles River Laboratories (formerly MPI Research; Mattawan, MI). Only control groups (vehicle- or placebo-treated animals) were included. Fifty-one studies met inclusion criteria, encompassing 42 cynomolgus macaques, 437 guinea pigs, 217 Sprague Dawley rats, and 56 cats. Observations were grouped by route of administration: cynomolgus macaques received transtympanic injection through the tympanic membrane with deposition of test article into the tympanic cavity (n = 31) or mastoidotomy and direct administration into the cochlea via the round window membrane or semicircular canals (n = 11); guinea pigs received middle ear catheter (n = 105), transtympanic (n = 268), or systemic (n = 64) administration; rats received systemic (n = 83), transtympanic (n = 128), or topical (n = 6) administration; and cats received only transtympanic administration (n = 56). Histopathologic observations were combined regardless of severity or laterality. Percent incidence was calculated for each observation.

Results: Distinct species-specific patterns were observed. In systemically treated guinea pigs, the most common histologic findings were new bone formation in the ossicles (40.6%) and tympanic bulla (35.9%), while in Sprague Dawley rats, mucoperiosteal mineralization (31.3%) and tympanic cavity infiltration/inflammation (26.5%) were most common. Guinea pigs with indwelling catheters had middle ear new bone formation (7.6%), as well as extensive fibroplasia (45.7%) and inflammation (35.2%) centered on the catheter insertion site. In cynomolgus macaques, tympanic cavity new bone formation and fibroplasia were seen in all animals (100%) undergoing mastoidotomy and intracochlear administration while only a few animals (6.5%) undergoing transtympanic administration had new bone formation. Mastoidotomy was also associated with hemorrhage (45.5%), foreign material (90.9%) and inflammation (54.5%) in the tympanic cavity. Tympanic membrane fibrosis was common in both mastoidotomy (81.8%) and transtympanic (77.4%) administration. Across all species and routes of administration, pigmented/foamy macrophages in the tympanic cavity was common.

Conclusions: Species and route of administration affect the background and procedure-related incidence of histologic findings in preclinical ototoxicity studies. These observations must be considered when determining whether findings represent test article-related effects.

The Effects of Basic Fibroblast Growth Factor and Gelatin Sponge Administration on Blast-Induced Tympanic Membrane Perforation in Mice

8:45 a.m. - 9:00 a.m.

Shingo Yasutake^{*1}, Kunio Mizutani², Takaomi Kurioka³, Yasushi Satoh¹

¹National Defense Medical College, ²Tokyo Women's Medical University Adachi Medical Center, ³Kitasato University School of Medicine

Background: In recent conflicts and terrorism, blast injuries caused by bombs and explosives are a common possibility. Although tympanic membrane perforation (TMP) is known to be the most frequent auditory complication of blast injuries, its healing rate is generally poor. While basic fibroblast growth factor (bFGF)-containing gelatin sponges (gel) have been shown to be effective in the treatment of TMP, studies on their use for blast-induced TMP haven't been conducted. Using and developing a blast injury mouse model, we have previously researched inner ear and middle ear injuries. In the present study, we investigated the effects of bFGF and gelatin sponge administration on blast-induced TMP in mice.

Methods: Male CBA/J mice, 10-12 weeks of age, were divided into five groups: (1) control (non-blast-exposed), (2) no treatment (untreated blast-exposed TMP ears), (3) bFGF (blast-exposed TMP ears treated with bFGF eardrop), (4) gel (blast-exposed TMP ears treated with gel placement into the TMP), and (5) bFGF + gel (blast-exposed TMP ears treated with bFGF immersed gel placement into the TMP). The blast-tube system generated a peak pressure of 330 ± 11.3 kPa from the blast shock wave and irradiated the mice from the front of their heads. TMP size was measured over time, auditory function was assessed using auditory brainstem response (ABR) and distortion product otoacoustic emissions (DPOAEs), and cochlear damage was evaluated via hair cell survival. Two months after the blast exposure, the fixed middle ear of mice embedded in paraffin, and the tympanic membrane (TM) was histologically evaluated for thickness.

Results: Combination treatment with bFGF and gel promoted better TMP healing, with thinner, structurally improved tympanic membranes compared to other groups. There were no effects of drug administrations, such as bFGF or gel, on ABR, DPOAE and hair cell survival rates.

Conclusions: These findings suggest that bFGF with a gelatin scaffold may effectively enhance TMP repair following blast injuries. This study provides new insights into potential therapeutic strategies for blast-related auditory injuries, which we will discuss alongside detailed auditory and histological assessments.

Osteoclasts Begin to Migrate From the Perivascular Area in Lps Induced Otitis Media Mouse Model

9:00 a.m. - 9:15 a.m.

Sho Kanzaki^{*1}, Yukiko Kuroda², Koichi Matsuo²

¹National Institute of Sensory Organ Tokyo Medical Center, ²Laboratory of Cell and Tissue Biology, Keio University School of Medicine, Tokyo, Japan

Background: Recurrent or chronic otitis media has long been associated with hearing loss, yet the mechanisms that underlie this relationship remain incompletely defined. One possible explanation is that hearing loss arises as a consequence of inflammation-induced activation of osteoclasts, the specialized bone-resorbing cells. Inflammatory conditions create an acidic microenvironment that weakens the bone matrix, and osteoclasts accelerate this degradation, leading to histologically distinct resorption. Repeated or chronic episodes of otitis media are more likely to result in progressive bone destruction. However, it is not yet clear whether acute otitis media itself is sufficient to mobilize osteoclasts and initiate ossicular bone damage, or from which cellular niche these osteoclasts arise. Clarifying the dynamics of osteoclast recruitment in the setting of otitis media is therefore essential to understanding disease-related bone pathology and its link to hearing loss.

Methods: To investigate this question, we established an experimental model of otitis media in mice. Lipopolysaccharide (LPS), a component of Gram-negative bacterial cell walls known to elicit strong inflammatory responses, was injected into the middle ear cavity to induce otitis media. As a control, phosphate-buffered saline (PBS) was injected into the middle ear of separate mice. Ossicles were harvested for histological and imaging analyses. Osteoclast localization was assessed using tissue sections, and three-dimensional visualization was achieved with light-sheet microscopy on optically cleared ossicular samples. This approach allowed us to evaluate not only the number of osteoclasts but also their spatial relationship to surrounding vascular structures.

Results: Our analyses revealed the presence of osteoclasts in perivascular regions of the ossicles. A higher number of osteoclasts was observed in LPS-treated mice compared to PBS controls, with the malleus demonstrating the most pronounced difference. These findings indicate that osteoclast activity is upregulated in response to LPS-induced middle ear inflammation. Importantly, the perivascular positioning of these osteoclasts suggests that blood vessels act as a key site for their recruitment and activation,

Conclusions: Osteoclasts were consistently found in perivascular regions within the ossicles of LPS-inoculated mice. The perivascular localization of osteoclasts implies that osteoclasts may originate from circulating precursors and subsequently contribute to bone resorption from within the ossicular chain. This osteoclastic activity may create focal porosity in the ossicles during otitis media, thereby weakening their structural integrity. Our findings highlight a potential mechanism by which inflammatory processes in otitis media drive osteoclast formation and subsequent ossicular bone resorption. This insight not only advances understanding of how chronic infections lead to hearing loss but also points to possible preventive strategies that target osteoclast recruitment or function, with the ultimate goal of mitigating disease-related auditory impairment.

Regulation of Middle Ear Genes During Otitis Media by Changes in Dna Accessibility

9:15 a.m. - 9:30 a.m.

Allen F. Ryan^{*1}, Nathan Zemke¹, Arwa Kurabi¹

¹*University of California, San Diego*

Background: The middle ear (ME) mounts a three-pronged initial defense when invaded by bacteria: mucus, innate immune receptors, and effectors including cytokines, chemokines and

antimicrobial peptides which are mobilized when innate immune receptors are activated. While gene expression studies document these defense processes during otitis media (OM), how they are regulated is less well known.

Methods: Single-cell RNA-Seq was used to assess expression of genes, including regulatory transcription factors (TFs), throughout an episode of acute OM in the mouse. Single-nuclear ATAC was employed to document changes in defense gene DNA accessibility in the neighborhood of their transcribed regions. Transcription factor binding sites within altered DNA regions were mapped, and compared to TF expression.

Results: OM-associated changes in DNA accessibility were identified for many defense genes whose expression was also altered, exposing binding sites for TFs. For other defense genes, accessibility changes were minimal. For a few genes, some accessible regions were eliminated by infection. TFs associated with binding sites in accessible regions that showed significant changes during OM included HIF1A.

Conclusions: Changes in DNA accessibility appear to be involved in the regulation of many genes expressed by ME cells during otitis media. The presence of HIF1A binding sites, coupled with increased expression during OM, suggests a role for hypoxia in middle ear gene regulation. For genes in which changes in DNA accessibility were minimal or absent, altered expression may be regulated by changes in TF expression, DNA methylation, and/or alterations in DNA accessibility at distant sites.

Rare and Low-Frequency Genetic Variants in Families With Otitis Media

9:30 a.m. - 9:45 a.m.

Regie Lyn Santos-Cortez¹, Christina Elling¹, Helen Gomez¹, Elisabet Einarsdottir², Juha Kere², Petri Mattila², Lena Hafrén², Allen Ryan³

¹University of Colorado Anschutz Medical Campus, ²University of Helsinki, ³University of California San Diego

Background: Otitis media is a highly frequent diagnosis in children that causes significant morbidity but remains understudied as a genetic trait despite significant heritability in families. Our goal was to identify rare or low-frequency variants within genes that confer susceptibility to otitis media.

Methods: Exome sequence data of 287 individuals from 243 families were analyzed. Identified variants were tested for co-segregation with otitis media in family members. Genome sequence data from a case-control cohort was imputed and analyzed for association of specific genes with otitis media. Single-cell RNA-sequence data of identified genes were noted in acutely infected mouse middle ears.

Results: Thirty-three variants within 24 genes co-segregated with otitis media in 28 families, of which 18 variants were considered pathogenic or likely pathogenic. An additional 81 variants in 21 of the same genes were identified in 83 unrelated probands with otitis media. Of the 24 genes, twelve were associated with otitis media in mouse models, while fifteen genes were replicated from previous human studies. A common variant EYA4 c.829G > A was associated with otitis media in the case-control cohort. Using network analysis, twenty-two of the 24 genes were connected in a subnetwork enriched in various signaling pathways, Th1/Th2/Th17 cell

differentiation and viral infections. Majority (87.5%) of the identified genes were expressed in mouse middle ear cells, with differential expression after acute infection.

Conclusions: The identification of novel genes and variants for susceptibility to otitis media will be useful in future risk screening and clinical management in children that require a more personalized approach due to poor response to standard treatments.

Unexplained Conductive Hearing Loss in Down Syndrome: Evidence From Audiometric and Imaging Data

9:45 a.m. - 10:00 a.m.

Gabrielle Merchant^{*1}, Heather Porter¹, Kristen Janky¹, Keelin Fallon², Aaron Remenschneider³

¹Boys Town National Research Hospital, ²University of Massachusetts Chan Medical School,

³Boston Children's Hospital; Massachusetts Eye and Ear Infirmary

Background: Conductive hearing loss (CHL) affects 50-80% of individuals with Down syndrome (DS), typically attributed to chronic middle ear disease such as otitis media. However, conventional treatments like placement of pressure equalization tubes often fail to resolve CHL, and clinical observations reveal that many individuals with DS demonstrate persistent air-bone gaps without signs of active middle ear pathology. We define this audiometric pattern as unexplained conductive hearing loss (uCHL). While recognized anecdotally, uCHL remains poorly quantified and it is underrepresented in the literature. Notably, inner ear anomalies have been reported in up to 75% of individuals with DS, such as enlarged vestibular aqueducts, superior semicircular canal dehiscence, and cochlear hypoplasia. This study aims to quantify uCHL and explore its association with structural anomalies of the auditory system using audiometric and imaging data.

Methods: We analyzed two preliminary datasets:

1. Retrospective cohort: 46 ears from individuals with DS without active middle ear disease who underwent both audiologic evaluation and temporal bone computed tomography (CT) imaging within a 6-month window (Aug 2023–Aug 2024). CT scans were reviewed for anomalies of the outer, middle, and inner ear.
2. Prospective cohort: 92 ears from 46 individuals with DS, recruited regardless of hearing status, who completed behavioral audiometry, bilateral masked bone conduction testing, tympanometry, and wideband tympanometry (WBT).

Results: In the retrospective cohort, all 46 ears exhibited air-bone gaps (29 ears had CHL and 17 had mixed hearing loss), yet 70% had normal tympanometry, consistent with uCHL. CT findings showed inner ear anomalies in 91% of ears, middle ear anomalies in 83%, and outer ear anomalies in 70%, challenging the assumption that CHL in DS arises solely from middle ear dysfunction. Additional associations between imaging and audiometric data will be presented.

In the prospective cohort, 63% of ears (58/92) demonstrated air-bone gaps, and 76% of those (44/58) had normal tympanometry. WBT confirmed normal middle ear absorbance in 64% (37/58) using conservative normative criteria. Notably, masked bone conduction thresholds were frequently seen in the negative dB HL range in conjunction with air-bone gaps, suggesting

hypersensitive bone conduction. These findings were absent in neurotypical controls using identical equipment and protocols, ruling out calibration artifacts.

Conclusions: uCHL is prevalent in DS and often co-occurs with normal middle ear function on standard assessments, indicating that conventional diagnostic models may be insufficient. The high prevalence of inner ear anomalies and enhanced bone conduction thresholds suggests multifactorial or novel mechanisms, such as third window effects or altered bone conduction dynamics. These findings highlight the need for expanded diagnostic approaches in DS and further research into the pathophysiology and mechanism of uCHL in this population.

Symposium 1: In Vitro Models as Relevant Tools to Support Translational Hearing Research

8:00 a.m. - 10:00 a.m.

Meeting Room 209ABC, Floor 2

In Vitro Models as Relevant Tools to Support Translational Hearing Research

Natalia Smith-Cortinez, *University Medical Center Utrecht*

Symposium Description: Despite decades of dedicated research, hearing loss remains without a single FDA-approved therapeutic for its treatment—a stark reflection of the translational challenges facing the field. A key barrier to progress is the limited predictive power of traditional animal models and the scarcity of physiologically relevant in vitro systems that can bridge the gap between discovery and clinical application. This symposium will spotlight the need for a critical shift in regulatory and scientific strategy. We will highlight emerging high-throughput platforms and human centered strategies designed to accelerate therapeutic discovery. This include cochlear and inner ear organoids derived from patient-specific induced pluripotent stem cells (iPSCs), which offer new opportunities to model genetic forms of deafness. We will also discuss the potential of patient- or cadaver-derived cochlear stem cells for drug screening and precision medicine. This encompasses traditional models such as explants to human based organoids A particular focus will be given to recent advances in the in vitro expansion of auditory progenitor cells, which enable regenerative strategies and improve experimental scalability. By bringing together diverse voices from across auditory neuroscience, bioengineering, and the clinic, the symposium aims to catalyze interdisciplinary dialogue, inspire innovative collaborations, and build new bridges within the hearing research community. From a translational perspective, we will examine how these in vitro approaches can complement and enhance existing clinical standards, including cochlear implants, and how researchers might improve their efficacy and integration. Together, these platforms form a comprehensive translational framework for inner ear research, bridging basic science and clinical application and driving the development of next-generation therapeutics for hearing loss.

Human Cellular Models of the Inner Ear

Konstantina Stankovic, *Stanford School of Medicine*

Individual Abstract: Hearing loss represents a significant global health challenge, reaching pandemic levels. The most prevalent form of this condition is sensorineural hearing loss (SNHL), which typically arises from damage to the inner ear's cellular structures. Human induced pluripotent stem cells (hiPSCs) can be derived from individuals, including those affected by various types of SNHL. Advancements in differentiation protocols aimed at producing inner ear cells, such as hair cells (HCs) and spiral ganglion neurons (SGNs), hold great promise for enhancing and understanding of human ear disease, evaluating potential treatments, and developing cell-based therapies. We demonstrate how hiPSCs-derived otic progenitor cells, Schwann cells, and organoids offer fresh perspective on virally-induced SNHL, including those lined to cytomegalovirus, Zika virus, and SARS-CoV-2. Additionally, we highlight how these innovative cellular models of the inner ear facilitate research into the impact of oxidative stress on the structure and function of inner ear tissues.

Human Inner Ear Organoids as a Versatile Platform to Model and Treat Acquired and Genetic Hearing Loss

Heiko Locher, *Leiden University Medical Center*

Individual Abstract: Human inner ear organoids derived from induced pluripotent stem cells (hiPSCs) are emerging as a powerful in vitro platform to study sensorineural hearing loss. These 3D models recapitulate key aspects of human inner ear development and cellular complexity, enabling investigation of both genetic and acquired causes of hearing loss. We employed inner ear organoids to model monogenic disorders, assess antisense oligonucleotide (ASO) therapies, and to study environmental insults such as ototoxic drug exposure and congenital cytomegalovirus (CMV) infection. To include relevant genotypes, inner ear organoids were generated from healthy, patient-derived, and isogenic mutant hiPSC lines. For genetic modeling, we focused on mutations in *USH2A* and *COCH*, applying ASOs via gymnotic delivery to modulate RNA expression. Organoids from healthy hiPSC lines were also exposed to known ototoxic agents (cisplatin, gentamicin) and CMV laboratory and clinical strains to assess damage and cell-type-specific vulnerability. Disease and treatment effects were evaluated using immunohistochemistry, RNAscope, qPCR, and confocal microscopy. All organoids exhibited hallmark features of the inner ear, including stereociliated hair cells and periotic mesenchyme. Patient-specific and gene-edited lines recapitulated expression of mutant transcripts and disease phenotypes. ASO treatment led to significant reductions in mutant RNA levels and partial rescue of molecular defects. Additionally, ototoxic agents and CMV infection induced selective damage to hair cells and neuronal structures, demonstrating the model's utility for studying acquired hearing loss. Our work highlights the value of using human inner ear organoids as a translational platform to dissect the molecular mechanisms underlying genetic and acquired forms of hearing loss. They enable therapeutic testing across a range of etiologies, from RNA-targeted therapies to

infection and drug-induced damage, paving the way for more personalized and predictive treatment strategies.

Progenitor Cells in the Adult Human Express Lgr5 and Have the Potential to Produce MYO7A+ Cells in Vitro

Louise Straatman, *University Medical Center Utrecht*

Individual Abstract: In the embryonic cochlea, supporting cells give rise to sensory hair cells. In adult mice, supporting cells retain expression of progenitor markers such as Lgr5 and Sox2, yet spontaneous hair cell regeneration does not occur. Most previous studies have focused on neonatal mouse cochlear explants, which limits translational relevance due to species and developmental differences, as hearing loss primarily affects adults. For translational purposes this study assessed the regenerative potential of the adult human inner ear.

We evaluated LGR5 expression in adult human inner ear tissue obtained within 12 hours postmortem from bodies donated to science. We also assessed the progenitor potential of inner ear sensory epithelium from adult patients undergoing skull-base surgery, and from young adult and aged Lgr5-GFP mice with normal hearing or hearing loss. Cells were cultured in 3D and key signaling pathways were manipulated to induce proliferation and differentiation of the cells.

Our findings show that LGR5 is expressed in the adult human cochlea and vestibular organ. Supporting cells from sensory epithelium from human inner ear and adult mouse cochlea demonstrated the capacity to proliferate and form organoids in vitro. After differentiation, MYO7A+

hair cell-like cells were generated in these organoids.

These results indicate that progenitor cells with regenerative potential are present in the human and mouse adult cochlea and vestibular organ. When activated through targeted manipulation of signaling pathways, these cells can proliferate and give rise to hair cell-like cells. This highlights their promise as therapeutic target cells for future therapies to restore hearing in adults.

A Scalable in Vitro Platform for High-Throughput Drug Development in Primary Auditory Neurons

Francis Rousset, *University of Geneva*

Individual Abstract: Sensorineural hearing loss remains an incurable condition, primarily due to

the irreversible loss of cochlear hair cells and auditory neurons. A major barrier to therapeutic development is the lack of in vitro models that faithfully recapitulate auditory neurobiology while

supporting high-throughput screening (HTS). Although rodent explants and in vivo models have provided valuable insights, their limited throughput and logistical constraints limit their utility in early-stage drug discovery, where screening large compound libraries is essential.

We have recently established a robust in vitro protocol to expand auditory neuroprogenitor cells

(ANPGs), enabling the scalable production of auditory neuron-like cells. By simultaneously activating WNT signaling and inhibiting the TGF β /Smad pathway, quiescent ANPGs are reprogrammed into a highly proliferative state. These so-called Phoenix cells combine sustained self-renewal with robust neuronal differentiation capacity, offering a stable, primary-like model system. Furthermore, they can be frozen and thawed, eliminating the need for continuous animal tissue supply while ensuring reproducible, batch-consistent assays.

Building on this foundation, we developed a high-throughput platform to screen large libraries of compounds that promote auditory neuron protection or regeneration. To enable real-time monitoring of auditory neurogenesis and neuroprotection, we implemented a live-cell genetic reporter system in 384-well plate assays. This automated system supports both phenotypic and genetic screening approaches, facilitating the discovery of novel genetic targets and candidate compounds.

Altogether, the Phoenix platform offers a scalable, reproducible, and physiologically relevant alternative to animal-based models, accelerating early-stage drug discovery and advancing the preclinical pipeline for inner ear therapeutics.

Building Your Own Toolbox: A Journey Developing and Utilizing in Vitro 3D Tissue Models to Enable High-Throughput Screening of Novel Othotherapeutics and Drug Delivery Devices

Joachim Veit, *University of Montana, Missoula*

Individual Abstract: Despite otic disorders affecting a substantial portion of the global population, othotherapeutics, particularly those intended to treat hearing loss, have seen limited development or innovation. This is in part due to the limited tool set available to the field which consequently relies heavily on costly and low throughput preclinical animal models with often ambiguous human relevance. This presentation highlights our journey in developing in vitro tympanic and round window membrane 3D human tissue models to enable high-throughput screening of topically applied othotherapeutics. These models were subsequently employed in the characterization of several novel topical therapeutics targeting the oxidation- and inflammation-mediated damage to inner ear cells which is concurrent in nearly all insults causing hearing loss. Finally, these in vitro models were utilized to prototype a series of microneedle-based drug delivery devices with tailorable tympanic residence times. These devices facilitate the transtympanic permeation of topically applied othotherapeutics to allow for recurring therapeutic access to the middle and inner ear. Together, this project highlights the value of targeted efforts to develop and make use of novel in vitro research tools which can provide lower cost, higher throughput, and increased human relevance options over preclinical animal models for translational otic research and beyond.

Cochlear Explant as a Reference Ex Vivo Model and a Platform for Developing in Vitro Systems

Marianne Aincy, *Cilcare*

Individual Abstract: Cochlear explant cultures offer a valuable and reliable approach for studying drug-induced ototoxicity and potential otoprotective effects, although validation through in vivo models remains necessary. This model provides a versatile, ethical framework suitable for multiple applications: dose-response assessments of ototoxic compounds, exploration of their mechanisms of action, and efficacy evaluation of protective treatments. It also serves as reference for developing human in vitro models such as organoids derived from hiPSCs.

To facilitate screening for otoprotective drugs while adhering to 3Rs principles (Replacement, Reduction, Refinement), we developed and optimized a robust ex vivo cochlear explant model. This model employs cochlear explants exposed to cisplatin and aminoglycosides, widely used chemotherapeutic and antibiotic agents known to cause irreversible cochlear hair cell damage and permanent hearing loss.

Our model uses neonatal rodent pups, significantly reducing animal usage by minimizing gestating females required. It offers advantages, including avoidance of systemic administration and associated ethical issues. It provides precise control over experimental conditions, ensuring consistent, direct exposure of cochlear cells to dosed treatments. The model is efficient, with standardized culture limited to 96 hours.

However, technical challenges exist. Successful explant preparation and maintenance require specialized expertise in dissection, culture media selection, and aseptic techniques. The limited lifespan of explants restricts their use in long-term studies. Additionally, the developmental immaturity of cochleae from pups aged P1-P4 may limit translational applicability to mature auditory systems. Importantly, explant models complement but do not fully replicate systemic complexity found in living organisms.

Our goal was to refine this model by addressing critical technical parameters: choice of rodent species (mouse vs. rat), pup age, dissection techniques, culture medium composition, and exposure specifics for ototoxic agents (cisplatin, kanamycin, gentamicin, tobramycin). Ototoxic severity can be adjusted by modifying these parameters to selectively target particular cochlear structures.

We validated multiple cellular markers to visualize and quantify essential cochlear components: hair cells, supporting cells, nerve fibers, ribbon synapses, and neurons. Advanced laser scanning confocal microscopy and histological analyses were employed for comprehensive qualitative and quantitative assessments.

Our cochlear explant model provides a powerful, flexible method for studying ototoxicity and identifying promising otoprotective agents, ultimately reducing reliance on in vivo testing. Building on this robust reference system, our ongoing efforts focus on developing complementary human in vitro models, including inner ear organoids and 3D-printed round window platform. Together, these models bridge fundamental research and translational applications, paving the way for innovative therapeutic approaches to hearing preservation.

Why Don't Cochlear Implants Work Better?

Manohar Bance, *University of Cambridge*

Individual Abstract: The cochlear implant-neural interface is difficult to interrogate in living CI users, and in animals the interface can differ significantly because of the size and shape of the cochlea, and different implants. CI users present with varying symptoms and complaints, and to back project to the underlying cause requires some methods to understand what is happening at the CI-neural interface. We have used a variety of models to try to understand how changes at this interface might manifest in terms of hearing performance, cross stimulation of other structures, or insertion trauma. The types of models I will discuss are: 1) Computational models which try to understand how nerves are activated by CIs, and the physical spread of current in the cochlea. 2) Physical 3D printed which help us understand insertion trauma forces, and electric field distribution inside the cochlea. 3) Cadaveric models which allow us to make measurements in realistic human like geometries. 4) Cellular models which let us measure responses of neurones to different types of stimulation, and also to simulate scarring and fibrosis. I will discuss the lessons learned from these various models, and the clinical applications of what we have learnt.

Cortical Encodings of Acoustic and Electrical Cochlear Stimulation Are Distinct

10:30 a.m. - 10:45 a.m.

Ariel Hight^{*1}, Michele Insanally², Julia K. Scarpa³, Yew Song Cheng⁴, Michael Trumpis⁵, Jonathan Viventi⁵, Mario Svirsky¹, Robert Froemke¹

¹New York University Grossman School of Medicine, ²University of Pittsburgh School of Medicine, ³Weil Cornell New York Presbyterian Hospital, ⁴UCSF, ⁵Duke University School of Medicine

Background: Cochlear implants are neuroprosthetic devices that restore hearing to folks with severe to profound hearing loss, providing abilities to attain open-set speech perception without aids of other sensory cues such as lip reading. Despite widespread adoption, there is limited understanding of how these devices restore functionality and the sense of hearing. One long-standing question has been how central auditory pathways are activated by stimulation by cochlear implants and to which degree this activation overlaps with activation evoked by similar acoustic stimuli under normal hearing conditions. In this study, we determined the spatial and temporal representations of both tones and cochlear implant channels across the broad extent of the auditory cortex (A1) by using micro-electrocorticography (μ ECoG), a subtype of intracranial electroencephalography (iEEG).

Methods: Stimulus evoked responses were acquired from 60 cortical surface electrodes (3.25 x 3.25 mm grid) placed over the auditory cortex. Evoked responses were analyzed using either event related potentials (ERPs, 2-100 Hz) or high gamma (HG, 70-140 Hz) signals. Tone evoked

responses (1.4-32 kHz) were measured and analyzed from N=7 normal hearing (NH) rats and cochlear-implant evoked responses were recorded and analyzed from N=7 bilaterally deafened rats unilaterally implanted with an 8-channel intracochlear array (CI). Of these rats, 4 underwent both tone-evoked and implant-evoked recordings. We trained classifiers to determine whether we could successfully decode stimulus identity from single trial iEEG measurements for both NH and CI rats-- first we reduced evoked responses using either principal component analysis (PCA) or tensor component analysis (TCA), then trained a linear discriminant analysis (LDA) decoder on 13 randomized trials and then computed prediction probabilities for the remaining trials.

Results: Both tones (NH) and intracochlear electrodes (CI) evoked clear single-trial and trial-averaged transients, and we found that A1 encoding of these responses were topographically organized for both NH and CI stimuli. Next, we found that single-trial evoked responses were more variable for CI vs NH rats, but only in the spatial and not the temporal domain. Then, we trained and tested classifiers on single trials of NH and CI evoked responses and found that stimulus identity could be correctly predicted for both NH and CI evoked responses. Lastly, for the N=4 animals with both NH and CI recordings, we trained a classifier on tone-evoked responses, tested these classifiers on intracochlear-evoked responses, and found minimal information transfer between responses evoked by both modalities.

Conclusions: Our findings provide evidence that acoustic and electrical cochlear implant stimulation evoke fundamentally distinct patterns of cortical activity. The lack of transferable representations suggest that cochlear implant users may experience qualitatively different precepts that cannot be entirely predicted by acoustic hearing. Our results also suggest that refinement of cortical responses may improve inter-neuronal variance at the population level and improve auditory perception.

Why Ramped Pulses Are Reliable Solutions for Coding Sound Intensity in Cochlear Implants : An Electrophysiological Study in the Guinea Pig Auditory Cortex

10:45 a.m. - 11:00 a.m.

Elie Partouche¹, Victor Adenis^{*2}, Pierre Stahl³, Chloe Huetz⁴, Jean-Marc Edeline⁴

¹Paris-Saclay Institut of Neurosciences, ²Mass Eye and Ear, Harvard Medical School, ³Oticon Medical/ Neurelec, ⁴NeuroPSI UMR CNRS 9197

Background: For decades, cochlear implant (CI) is the most successful neuro-prosthetic device allowing more than a million of patients to recover hearing sensation and speech understanding. The performance is usually good in silence, but CI patients have difficulties in the presence of background noise. Potentially, these limitations stem from the large spread of currents diffusing in the cochlea's perilymph when the different electrodes are activated at high current levels. To reduce the spread of current, one potential strategy is to change the shape of the electrical pulses. In human, studies have tested asymmetric rectangular pulses (Macherey et al., 2006, 2008). A new pulse shape, called "ramped pulse", has been proposed (Ballesterio et al., 2015) but only two studies have showed that such pulses elicited responses with lower thresholds than rectangular pulses (Navntoft et al 2020, Partouche et al 2023). Here, we report the consequences of using different types of ramped pulses on responses of auditory cortex (ACx) neurons to increasing electrical charges in anesthetized guinea pigs.

Methods: The intracochlear stimulating array was a shortened version of the EVO electrode array used by Oticon Medical and was composed of 6 ring-shaped Platinum-Iridium electrodes with a 0.0046mm² surface. Four shapes of ramped pulses were tested, each at 20 charge levels (from 3 to 31.5nC), to obtain the growth functions of ACx neurons. Recordings in ACx were collected by 16-channels electrodes composed of two rows of 8 electrodes. Two types of doubles ramped pulses were tested: one with the ramps on the 1st and 4th phases, a second with the ramps on the 1st and 3rd phases. We also tested single ramp pulses with the ramp on the 3rd phase

Results: Compared with the responses obtained with rectangular pulses, all ramped pulses generated (i) responses with lower thresholds (ii) higher maximal firing rates (FR) (iii) higher FR at threshold (iv) longer response latencies and (v) longer durations. These effects were always significant with cathodic-first phase, and were in the same direction (but less often significant) with anodic-first phase. The responses to increasing levels of charges were also compared with the responses to pure tones presented at eight intensities (from 5 to 75dB SPL).

Conclusions: These results indicate that ramped pulses should be considered as a good alternative to rectangular pulses, even if polarity of the first phase matters to benefit from this shape.

Comparison of Two Subjective Tests for Cochlear Implant Users Using Reverberant Speech Processed With an Established Dereverberation Algorithm

11:00 a.m. - 11:15 a.m.

Shaliza Merchant^{*1}, Christiaan Stronks¹, Nienke Langerak¹, Daphne Geijssen¹, Esther Van Marrewijk¹, Jeroen Briaire¹, Johan Frijns¹

¹*Leiden University Medical Center*

Background: Cochlear implants (CI) effectively restore speech perception in quiet conditions for individuals with severe-to-profound sensorineural hearing loss. However, speech intelligibility (SI) in background noise is severely impaired and reverberant environments are challenging for CI users. To mitigate the impact of background noise and reverberation, a variety of speech enhancement strategies have been developed. Performance is often assessed in terms of their effects on SI. However, it is known that algorithms not affecting SI may still be perceived as helpful, while algorithms that effectively enhance SI may be disliked because of speech distortion, underscoring the need for subjective assessment. Here, we compare two subjective tests using reverberant speech processed with an established dereverberation algorithm. The first test was the gold standard in subjectively perceived sound quality: the Multiple Stimulus with Hidden Reference and Anchor (MuSHRA) method. This method was compared with a simplified version, dubbed ‘MuSHRA-lite’.

Methods: Two cohorts of eighteen post-lingually deafened CI users participated. One cohort performed the MuSHRA, in which processed speech stimuli were subjectively compared to one common reference. Participants rated each stimulus on a scale from 0 - 100, for three outcome measures: SI, naturalness and listening effort, relative to an openly labeled reference of unprocessed speech and a hidden anchor. The other cohort performed the MuSHRA-lite, which

consisted of pairwise comparisons of processed speech producing preference scores for the same outcome measures. RM-ANOVA and linear mixed modeling were used to test for statistical significance between the ratings of clean speech, and reverberant and de-reverberated speech.

Results: Both methods confirmed that reverberation significantly degraded SI, naturalness, and listening effort relative to clean speech. However, the perceived benefits of the algorithm differed substantially between methods. MuSHRA-lite consistently revealed statistically significant benefits of the algorithm on all outcomes measures. By contrast, MuSHRA failed to reveal significant effects of the algorithm on any of the outcomes. This lack of statistical power could be coupled to greater variance in the data. Qualitative feedback indicated that performing the MuSHRA was experienced as challenging for many participants, the MuSHRA rating scales were also described as being “difficult” and the task overall as “confusing” (n=4/18).

Conclusions: Both methods captured the detrimental impact of reverberation, but only MuSHRA-lite revealed statistically significant benefits of the dereverberation algorithm on perceived SI, naturalness, and listening effort. Furthermore, MuSHRA-lite was less complicated to implement, easier to execute and interpret. MuSHRA-lite reflects preference between stimuli, while MuSHRA yields quality ratings, which may explain why MuSHRA results were more conservative. We conclude that MuSHRA-lite offers a practical and robust alternative for assessing subjectively perceived speech quality for CI users, especially when preference-based judgements are sufficient and participant burden must be minimized without sacrificing reliability.

Strength–Duration Analysis of Optical and Electrical Auditory Nerve Stimulation Across Species

11:15 a.m. - 11:30 a.m.

Yinchou Zhou¹, Jennifer Silva-Nash¹, Joaquin Cury¹, Xiaodong Tan¹, Claus-Peter Richter¹

¹*Feinberg School of Medicine, Northwestern University*

Background: Cochlear implants (CIs) restore hearing through electrical stimulation of spiral ganglion neurons, yet performance remains constrained by limited frequency resolution and spatial selectivity due to current spread. Optical approaches, including optogenetics (OG) and infrared neural stimulation (INS), promise greater spatial selectivity but require higher energy. While thresholds for these modalities have been reported, a systematic comparison using classic excitability metrics—chronaxie and rheobase—has not been established. Such analyses provide a unified framework for evaluating efficiency, safety, and translational potential across modalities and species.

Methods: We recorded auditory brainstem responses (ABRs) in transgenic mice carrying the optogenetic tool ChR2. We applied light at 460 nm (OG) and at 1375–1550 nm (INS) with a 400 μ m optical fibers at the round window. Electrical stimulation was performed through round window electrodes. For each modality, pulse duration (10–1000 μ s) and radiant exposure/current were systematically varied. Strength–duration curves were fit with the Weiss–Lapicque equation to extract chronaxie and rheobase.

Results: Electrical stimulation showed short chronaxies (~100–200 μ s) with rheobase energies in the sub- μ J range (0.01–0.05 μ J/pulse), confirming efficiency. OG stimulation in mice

exhibited intermediate chronaxies (~300–400 μ s) and rheobase values of ~4–6 μ J/pulse, reflecting selective but energy-intensive activation. INS required the highest energies (10–15 μ J/pulse) with chronaxies > 500 μ s. Across modalities, extending pulse duration beyond the chronaxie failed to further reduce threshold, leading to unnecessary energy expenditure.

Conclusions: By placing electrical, OG, and INS stimulation into a single strength–duration framework, this study identifies fundamental efficiency gaps and defines the optimal temporal regimes for each modality. Cross-species analysis highlights how cochlear anatomy shapes chronaxie/rheobase, underscoring the translational value of guinea pig models. Importantly, the findings support hybrid coding strategies: electrical pulses delivered at threshold can prime neurons, thereby reducing optical thresholds and minimizing thermal load while preserving spatial selectivity. This work provides a physiological basis for designing energy-efficient, opto-electrical cochlear implants aimed at improving pitch perception and spectral resolution in human users.

Effect of Electrode Array Type and Surgical Approach on Structure Preservation Rates During Cochlear Implantation: A Prospective Randomized Controlled Trial (CIPRES Study)

11:30 a.m. - 11:45 a.m.

Imogen van Beurden*¹, Saad Jwair¹, Robert J. Stokroos¹, Huib Versnel¹, Hans G.X.M. Thomeer¹

¹*University Medical Center Utrecht*

Background: Preservation of residual low-frequency hearing during and after cochlear implantation contributes to improving hearing with a cochlear implant (CI), especially in noisy environments. Scalar translocation (STL) is a major threat to hearing preservation during cochlear implantation surgery. Selection of the optimal combination of electrode array and surgical approach could add to better preservation of residual hearing and thus improved hearing with a CI.

Methods: This study is still ongoing. The last participant will be included in September 2025. Forty-seven of 48 adult patients with severe to profound sensorineural hearing loss (SNHL) receiving a CI in a tertiary referral center (UMC Utrecht) were included between January 2020 and September 2025 in an ongoing prospective randomized controlled trial (RCT) comparing surgical approaches (round window or cochleostomy insertion) and electrode arrays models (lateral wall SlimJ array (LW) or perimodiolar MidScala (PM) array, by Advanced Bionics). Participants were randomly assigned to one of four study groups, with 12 participants each: group 1 RW + LW array; group 2 CO + LW; group 3 RW + PM array (Jwair et al., 2021, *Trials* 22:895). Participants underwent preoperative high resolution computed tomography (HRCT) of the mastoid. Postoperative cone beam computed tomography (CBCT) imaging was performed within five hours after surgery. A radiological tool as developed by Advanced Bionics was used to analyze implant array position by pre- and postoperative imaging in terms of occurrence of STL and insertion depth (aDOI). STL rates and aDOI were compared between all groups.

Results: Analyses pre- and postoperative imaging of 43 participants have been performed thus far, of which 34 (9/11 in group 1; 7/10 in group 2; 8/10 in group 3; 10/12 in group 4) were

successful. Preliminary results showed that STL was observed in 9/34 (26.5%) successfully analyzed images. For group 1 (RW + LW) STL occurred in 1/9 participants (11.1%). For group 2 (CO + LW) STL occurred in 2/7 participants (28.6%). For group 3 (RW + PM) STL occurred in 3/8 participants (37.5%). For group 4 (CO + PM) STL occurred in 3/10 participants (30%). A mean cochlear width B of 6.93 (± 0.35) mm was found in the first 43 participants. A mean aDOI of 405 (± 45) degrees was found in the 34 successfully analyzed images. After completion of all 48 inclusions, between group analysis will be conducted of pre- and postoperative images to compare results between the four study groups.

Conclusions: To improve hearing preservation, preoperative planning before cochlear implantation surgery could potentially include the selection of an electrode model in combination with a surgical approach.

Post-Surgical Hearing Loss With Cochlear Implantation: Measures and Models

11:45 a.m. - 12:00 p.m.

Rachel Scheperle¹, Stephen Neely², Peizhe Wu¹, Marlan Hansen¹

¹*University of Iowa Hospitals and Clinics*, ²*Boys Town National Research Hospital*

Background: Preservation of acoustic hearing post cochlear implantation (CI) is achievable, though with variable success rates (Snels et al., 2018; Gantz et al., 2022). Post-surgical changes in hearing status can be categorized according to their underlying mechanism (e.g. middle ear sound transmission, cochlear transduction, or neural excitation). Identifying the responsible mechanism is critical to hearing preservation and influences audiological management. This project aims to evaluate the changes observed in longitudinal electrocochleography (ECochG) measurements in relation to behavioral thresholds, and to assess whether a cochlear model can provide insights regarding the identification of underlying mechanisms.

Methods: Forty-eight CI recipients with varying degrees of residual acoustic hearing are enrolled in a longitudinal study that includes serial measurements of behavioral thresholds and ECochG. ECochG were elicited at a supra-threshold level using alternating-phase tonebursts. The difference waveform was Fourier transformed. Both magnitude and phase at the stimulus frequency were tracked longitudinally to compare with behavioral thresholds. Exemplar data sets were chosen to compare with the cochlear model, with attention to changes in measurements elicited at 500-Hz.

A time-domain model of cochlear mechanics that includes a middle-ear preprocessing stage followed by a cochlear processing stage was used to produce a simulated ECochG (Neely and Rasetshwane, 2017). The model was extended to estimate the voltage at an intracochlear location, which was adjusted to fit individual ears, by including volume-conduction impedance to combine individual OHC current across the cochlea (van Gendt, 2020). Selected model parameters were then manipulated to produce a combination of middle ear conductive hearing loss (CHL) and outer hair cell (OHC) dysfunction that would simulate the 500-Hz threshold shift observed in the exemplar ears. The effects of these model manipulations on delay of the simulated ECochG were compared to the measured ECochG.

Results: Behavioral hearing thresholds are typically poorest in the first weeks after implantation and recover slightly across subsequent weeks or months. While ECoChG amplitude reductions follow roughly similar patterns as threshold shifts, delay changes could be either positive or negative. Threshold shifts and ECoChG delay changes were simulated by a specific combination of CHL and OHC dysfunction. The phase of middle-ear input impedance in the model was affected by CHL but not OHC dysfunction.

Conclusions: Changes in acoustic hearing status post CI reflect various underlying mechanisms. Although (partial) recovery of audiometric thresholds at early time points has been interpreted to suggest a transient conductive loss, comparison of ECoChG delay with model results suggest intracochlear contributions may also be present. In future work, middle-ear input impedance estimated from acoustic measurements could have value in distinguishing whether threshold losses are conductive or sensory.

Otogenetic Stimulation in a High-Resolution Model of Human Cochlea

12:00 p.m. - 12:15 p.m.

Siwei Bai¹, Albert Croner¹, Guanyu Chen¹, Lukas Driendl¹, Werner Hemmert*¹

¹*Technical University of Munich*

Background: Conventional cochlear implants (CIs) are one of the most successful achievements of medical technology. However, their performance is limited by the wide spread of electric current in the highly conductive perilymph inside scala tympani. As a solution, optogenetic cochlear implants (oCIs) may achieve a much more focal stimulation. As the cochlea in humans is embedded within the skull and thus not directly accessible to electrophysiological recordings, computational models of the human cochlea are indispensable to gain more insight into how oCIs excite fibers within the population of auditory nerve fibres and how the excitation patterns compare with conventional CIs.

Methods: An anatomically realistic model of the cochlea and auditory nerve was reconstructed from a high-resolution μ CT scan of a human cochlea with 6 μ m voxel size (Bai et al., 2019). In this preliminary study, we acquired only half of the basal turn of the cochlea with the nerve. We imported the model into Ansys Speos to perform Monte-Carlo ray-tracing simulations of light spread in the cochlea. Volumetric optical properties of the model tissues were based on Khurana et al. (2022), and surface properties were based on Ugnell and Öberg (1997) and Stelzle et al. (2010, 2011). Both waveguide-based and LED-based oCIs were simulated with an emission power of 30mW and a wavelength of 655nm, facing directly towards Rosenthal's canal. The incident irradiance values were obtained along the centerline of Rosenthal's canal, along the centerline between Rosenthal's canal and the edge of the spiral lamina, and along the auditory neural fibre closest to the emitter.

Results: The number of rays from the emitter has an impact on the convergence of the simulation outcomes, and we found that five million rays provided the optimal convergence for our simulations. Using more realistic surface properties, compared to the Fresnel Laws, waveguide-based oCIs produced a slightly more diffuse emission profile, whereas LED-based oCIs produced a slightly more focal profile. Their maximum irradiances were, however, all reduced.

Conclusions: The passive waveguide oCIs resulted in a much more focal and more intense stimulation at the region where the emitter was facing; the smaller the numerical aperture was, the stronger the effect it showed. While this type of emitter has a potential benefit of supreme spectral selectivity, it may be extremely sensitive to the implantation technique, as it requires precise orientation. In comparison, the LED-based oCIs resulted in a broader stimulation, and the strongest irradiance appeared not at the soma, where the emitter was facing, but at the peripheral axon.

Uncovering Patterns in Post-Operative Cochlear Implant Hearing Outcomes Through Group Based Trajectory Modeling

12:15 p.m. - 12:30 p.m.

Connie Chang-Chien¹, Max Jiam¹, Yew Song Cheng¹, Nicole Jiam¹

¹*University of California - San Francisco*

Background: While machine learning methods have increasingly been applied to predict cochlear implant (CI) outcomes, they primarily focus on cross-sectional predictions rather than capturing the dynamic, longitudinal rehabilitation progress. This study aims to apply GBTM (group-based trajectory modeling) to longitudinal WRS data to uncover discrete rehabilitation tracks post-implantation, addressing a critical gap in personalized outcome monitoring and intervention.

Methods: A retrospective cohort study was conducted on 122 adult CI users with bilateral sensorineural hearing loss implanted at a tertiary academic center. The primary tracked outcome was word recognition score (WRS) per appointment from pre-operative baseline to 60 months post-implantation. Patient demographic information and bilateral pre-operative PTA and WRS for both implanted and contralateral ears were included as GBTM context. Missing data were imputed using forward and backward fill methods, and trajectories were standardized by converting each time point measurement to z-scores. Longitudinal trajectory analysis was performed using Gaussian Mixture Models (GMM) to identify distinct outcome groups by minimizing entropy via Bayesian Information Criterion (BIC), first with all patient data, then for two age-stratified groups (age at implantation < 60 and ≥60). Statistical analysis of covariate group differences was evaluated based on data distributions.

Results: GBTM identified three general trajectory groups across all patients (BIC=-8524.5, $p < 0.001$), with significant separation for age at implantation (Kruskal-Wallis statistic (KW)=7.10, $p=0.029$). For the < 60 age cohort (n=31), we identified three trajectory groups (BIC=504.9, $p < 0.001$) with significant non-zero slopes, where implanted ear pre-operative WRS was the only

significant predictor of group membership (KW=6.58, $p=0.037$). The implanted ear pre-operative WRS for < 60 sub-groups were 6.56 ± 11.30 , 17.60 ± 17.5 , and 26.42 ± 21.72 , with trajectory slopes of 0.231, 0.428, and 0.149 via least squares linear regression ($p < 0.05$). In the ≥ 60 age cohort ($n=91$), we identified four trajectory groups (BIC=780.6, $p < 0.05$), but only one with a significant non-zero slope (-0.286 , $p=0.003$). Notable features for the down-trending subgroup included a lower pre-implantation WRS in the implanted ear (17.79 vs 19.56-24.24), but having a similar contralateral ear PTA and WRS, implantation age, and demographic features as others in the same age cohort.

Conclusions: Younger adults (< 60) exhibited more predictable rehabilitation trajectories characterized by pre-implantation baseline hearing status, with those starting with lower pre-operative implanted ear WRS and private insurance demonstrating the most rapid early improvements. In contrast, older patients (≥ 60) exhibited greater rehabilitation heterogeneity, including a subgroup with poor post-CI adaptation and no distinguishing study demographic and clinical predictors besides a lower implanted ear pre-operative WRS compared to other patients in the same age cohort. These findings highlight that younger adult CI users may follow more uniform recovery pathways, while older adults may require closer longitudinal monitoring and individualized interventions. Incorporating trajectory-based models into clinical care could enhance risk stratification, guide rehabilitation strategies, and inform counseling about expected recovery patterns.

Podium 6: OTOF Gene Therapy Trial Updates and New Targets: GJB2 and STRC

10:30 a.m. - 12:30 p.m.

Meeting Room 209ABC, Floor 2

Moderators: Jeffrey R. Holt and Aara Patel

International Expert Consensus on Gene Therapy for Hereditary Hearing Loss: Based on Clinical Trials

10:30 a.m. - 10:45 a.m.

Background: Hereditary hearing loss is one of the most common disabling disorders in children and lacks effective pharmacological treatments. Recent breakthroughs in OTOF gene therapy clinical trials necessitate standardized frameworks to guide emerging therapies. This study aimed to establish the first international consensus on clinical application of gene therapy for hereditary hearing loss.

Methods: A modified Delphi process was conducted from March 2024 to March 2025, involving 46 multidisciplinary experts from several countries across otology, genetics, audiology, gene therapy, and hearing rehabilitation. After a systematic literature review, as well as integration of research and clinical expertise and experience, three iterative voting rounds (two anonymous surveys and one online consensus meeting) were performed. Statements required $\geq 75\%$ agreement for inclusion.

Results: From 9093 publications, 69 were used to draft and support the consensus statements. A total of 30 statements relevant to six domains achieved consensus on gene therapy for hereditary hearing loss, including ethical review (1 statement), patient selection criteria (12 statements), diagnosis and preoperative evaluation (9 statements), gene therapy drug delivery (4 statements), follow-up (3 statements), and post-treatment auditory and speech rehabilitation (1 statement).

Conclusions: This consensus provides the first globally endorsed framework for gene therapy in hereditary hearing loss. It standardizes clinical trial design and patient management, accelerating translation from research to practice while ensuring safety. The guidelines are immediately applicable to OTOF-related hearing loss and adaptable to other genetic forms.

Multicenter Gene Therapy for Otof-Related Deafness Followed up to 2 Years

10:45 a.m. - 11:00 a.m.

Hospital (The Affiliated Hospital of Chongqing University) ⁴The Second Xiangya Hospital, ⁵Harvard Medical School

Background: Autosomal recessive deafness 9 (DFNB9), caused by OTOF gene mutations, is characterized by prelingual or congenital, severe-to-complete bilateral hearing loss. While the benefit of gene therapy has been proven in a limited number of DFNB9 patients, its efficacy and safety across a broader age range and longer follow-up remain to be evaluated.

Methods: In this single-arm, multicenter trial conducted at 4 centers, patients aged ≥ 6 months with severe-to-complete hearing loss resulting from OTOF mutations were eligible. Patients receive a single cochlear administration of AAV1-hOTOF via the round window membrane at three vector dose groups. The primary endpoint was dose-limiting toxicity within 6 weeks. The secondary endpoint assessed efficacy, including auditory function and speech perception, and safety including adverse events.

Results: 31 DFNB9 participants (aged 1.0 to 32.3 years) received gene therapy, with a follow-up up to 2 years. No dose-limiting toxicities or serious adverse events were observed. Grade 3 events included decreased neutrophil count (3 of 31). Hearing recovered in 90% (28 of 31) of participants, with the improvement of the auditory brainstem response thresholds from > 96 dB at baseline to 55, 51, and 37 dB at 1, 1.5, and 2 years, respectively. Participants with hearing recovery exhibited an improvement in speech perception.

Conclusions: AAV1-hOTOF is well-tolerated and efficacious across a broader patient population, with sustained therapeutic benefits up to 2 years.

Safety and Efficacy of DB-OTO Gene Therapy in Children With Profound Deafness Due to Otoferlin Variants: Data From the Chord First-In-Human Registrational Trial

11:00 a.m. - 11:15 a.m.

Background: Genetic deficiency of otoferlin (OTOF) disrupts synaptic transmission by the auditory sensory hair cells, causing congenital deafness. Children with OTOF-related deafness are typically treated with cochlear implants. DB-OTO is a gene therapy based on a dual adeno-associated virus 1 which delivers human OTOF complementary DNA regulated by a hair cell-specific promoter.

Methods: The CHORD trial is an open-label, single-arm, first-in-human registrational study evaluating DB-OTO (NCT05788536). Twelve children with profound deafness carrying biallelic OTOF pathogenic variants received an intracochlear DB-OTO infusion (7.2×10^{12} vector genomes/ear) unilaterally or bilaterally. The primary efficacy endpoint was the achievement of average thresholds ≤ 70 decibel hearing level (dBHL) by behavioral pure tone audiometry (PTA) at Week 24, a clinical standard that generally allows for natural acoustic hearing without the need for cochlear implants. The key secondary endpoint was the presence of auditory brainstem response to a 90 decibel normal hearing level (dBnHL) click stimulus. Incidence and severity of adverse events was a primary safety endpoint. Laboratory, limited vestibular, and immunogenicity testing were also performed.

Results: Following single DB-OTO administration, 11 of 12 participants (92%) with profound deafness at baseline were able to hear for the first time. Nine of 12 participants (75%) achieved clinically significant hearing improvements ($P < 0.0001$), enabling natural hearing, meeting the primary and key secondary endpoints, and obviating the need for cochlear implants. Six of 12 participants (50%) were able to detect soft speech without assistive devices (average PTA ≤ 45 dBHL), and 3 of 12 participants (25%) achieved complete normalization of hearing sensitivity (≤ 25 dBHL) by Week 24 as measured by average PTA. (Average PTA ≤ 25 dBHL). Preliminary data from 1.5 years of follow-up indicate sustained or improved hearing, as well as improvements in speech and language development. No DB-OTO-related adverse events were recorded.

Conclusions: In this first-in-human registrational gene therapy trial, DB-OTO resulted in significant hearing improvements in participants with OTOF-related deafness. DB-OTO administration enabled natural acoustic hearing for the first time, and normalized hearing sensitivity in some participants.

Marmoset Monkeys With a Non-Mosaic Disruption of the Otof Gene as a Model of Human Deafness

11:15 a.m. - 11:30 a.m.

*Center*⁴*Institute for Auditory Neuroscience, University Medical Center Goettingen*⁵*Max Planck Institute for Multidisciplinary Sciences*

Background: About 5% of the world's population suffers from disabling hearing loss. In newborns, 50% of hearing loss is attributed to genetic factors. One of the deafness genes is OTOF, causing the auditory synaptopathy DFNB9, which makes up 2-8% of congenital hearing loss. Within the last year's great progress has been made in gene therapy of DFNB9 from proof of concept in mice, to favorable biosafety data in non-human primates (NHP) and promising results in clinical trials. Yet questions of safety, efficacy, and longevity of different OTOF gene therapy strategies remain to be answered. Therefore, the need of a NHP model of DFNB9 is eminent. Moreover, such a model could be used to study other methods of hearing restoration, bridging the gap between mouse experiments and clinical trials.

Methods: Marmoset oocytes harvested upon ovary stimulation, were used for in vitro fertilization. Subsequently these fertilized oocytes were injected with Cas9 and four guide RNAs. At the 6 to 12-cell-stage the embryos were transferred to the uterus of surrogate mothers. After birth PCR genotyping of all germ layers was performed and the PCR products were subcloned to obtain single-clone DNA sequences. The phenotype of the animals was characterized, monitoring the weight development of the animals, analyzing their vocalizations and testing their hearing. Three to four vocalization recordings each lasting 10 min were performed at two to four weeks after birth. At 6 months of age, auditory brainstem responses to clicks and pure tones of different frequencies were probed and DPOAEs were acquired. Furthermore, immunohistofluorescence staining was performed on the organ of Corti of one of the OTOF-knockout marmosets.

Results: Two marmosets were born carrying biallelic mutations of OTOF, resulting in a knockout. They were born naturally and cared for normally by their parents. The OTOF knockout had no effect on the overall development. The mutations were detected in all germ layers, indicating the absence of mosaicism. Auditory brainstem recordings revealed a profound hearing loss, while the detection of otoacoustic emissions indicated the functionality of the cochlea upstream of synaptic sound encoding. The structural integrity of the organ of Corti was confirmed by immunohistofluorescence. Moreover, this method confirmed the loss of OTOF within the inner hair cells. Preliminary data suggest that the vocalizations of the deaf marmosets were largely unaltered compared to age-matched WT animals. They used the full vocal repertoire, and their vocal activity was similar to WT marmosets.

Conclusions: We generated OTOF-knockout marmosets via CRISP/Cas9 injection into in vitro matured and fertilized oocytes. OTOF-knockout marmosets present a non-mosaic NHP model for DFNB9. They provide a model for testing and optimizing safety, efficacy, and longevity of OTOF gene therapy and serve the development of other methods for hearing restoration such as optical cochlear implants.

SENS-601, a Novel Adeno Associated Vector-Based Gene Therapy as a Treatment for the Autosomal Recessive Non-Syndromic Deafness 1A (DFNB1A)

¹SENSORION SA, ²Institut de l'Audition/ Institut Pasteur

Background: The estimated prevalence of severe or profound deafness in humans is 1/1000 neonates, and genetic factors account for half of the cases. Pathogenic variants of GJB2, the gene encoding Connexin 26 (Cx26), are involved in 50% of congenital deafness and are mostly associated with autosomal recessive non-syndromic DFNB1A. In the cochlea GJB2, is largely expressed in the majority of supporting cells (SCs) of the neuroepithelium but not in sensory hair cells (SHCs).

Today, gene therapy strategies for autosomal recessive forms of deafness have shown, in clinical trials, promising hearing recovery. In some cases, some patients tend to show more rapid improvements in auditory and speech performance than those with cochlear implants. To this aim, we have developed SENS-601, an AAV vector for DNFB1A with proprietary cis-regulatory elements for a safe and targeted transgene expression. SENS-601 efficiently transduces human cell lines to produce Cx26 protein that is adequately addressed to the plasma membrane and allows functional gap junctions.

Methods: Several conditional mouse models were generated to elude embryonic mouse lethality caused by complete loss of Gjb2 expression, mimicking the most common forms of DFNB1A and severe/profound hearing loss and a deficit of the endocochlear potential. Intracochlear injections of SENS-601 lead to improvement of hearing thresholds as early as 3 weeks post-injection in a dose-dependent manner.

Results: Microscopic examination confirmed that SENS-601 efficiently and adequately restores Cx26 expression. Dose-response experiments show that intracochlear SENS-601 injection is safe over a wide range of doses administered and provides a significant therapeutic benefit in DFNB1A mice. Restoration of the endocochlear potential is currently being addressed.

Early tolerability and biodistribution of SENS-601, or SENS-601-FLAG, studies were conducted in mice and Non-Human Primates (NHP) after injections through the round window (RW). Transgene expression was observed in most cells that naturally express Gjb2 along the tonotopic axis of the cochlea, with good local and systemic tolerability. In particular, no SHCs express the transgene, confirming the specificity of the expression cassette in both species. Furthermore, SENS-601 long-term safety studies conducted in wild-type mice demonstrate persistence of transgene expression with no impact on auditory function or cochlear cytoarchitecture. High-dose intravenous injection of SENS-601 does not induce any adverse events or changes in behavior. A combined 3- and 6-month GLP toxicology and biodistribution study of SENS-601 is currently ongoing in NHP, following a single intra-cochlear injection administered using the surgical procedure and injection device intended for clinical use, to evaluate the local tolerability and safety of SENS-601.

Conclusions: Overall, efficacy, biodistribution and early safety data package support SENS-601 development to restore physiological hearing in DFNB1A patients

Capsid and Promoter Engineering for AAV Gene Therapy and Genome Editing in GJB2-Related Hearing Loss

Background: Mutation of GJB2 (encoding Gap Junction Beta 2) is the most frequent cause of hereditary deafness worldwide and accounts for up to 50% of non-syndromic sensorineural hearing loss. GJB2 encodes connexin 26, a component of cochlear gap junctions that help maintain ion balance in the cochlea. We previously demonstrated that GJB2 deficiency in mice impairs auditory function (Kamiya, *J. Clin. Invest.*, 2014) and that immediate postnatal delivery of wild-type GJB2 to the inner ear via adeno-associated virus (AAV) vector restored the hearing loss in mice (Iizuka, *Hum. Mol. Genet.*, 2015). However, delivery of GJB2 to the mature cochlea did not restore hearing. The early postnatal period in mice corresponds to the embryonic period of inner-ear developmental in humans. Thus, to develop a feasible clinical approach for human gene therapy, mature mice should be used for delivery of AAV to the inner ear. To achieve this, the development of an optimal AAV vector platform for GJB2-related hearing loss is indispensable.

Methods: We generated the several AAV capsids that effectively infect cochlear supporting cells by shuffling capsid sequences between wild serotypes or directed evolution with AAV library. And the promoters were modified to express only in GJB2 expressing cells and form proper gap junctions. Then the vectors were tested with adult GJB2 deficient mice (Kamiya, *J. Clin. Invest.*, 2014) and our supporting cell model derived from human patient iPS (induced pluripotent stem) cells with typical GJB2 mutation (Fukunaga, *Stem Cell Reports*, 2016, *Hum. Mol. Genet.* 2021). As part of a preclinical study, we administered the novel AAV vector to non-human primates (NHPs).

Results: We generated novel AAV vectors by shuffling capsid sequences between wild serotypes and selecting those that effectively infect cochlear GJB2-positive cells. To avoid transgene expression in non-target cells such as hair cells, we developed a specific promoter for GJB2-expressing cells. Novel AAV-mediated delivery of GJB2 significantly restored hearing loss in mature GJB2-deficient mice, and gap junction recovery was confirmed in both animal (GJB2-deficient mice) and cellular models (patient iPS cell-derived models). In NHPs administered with our novel AAV vector, AAV-derived protein expression in the target cells (cochlear supporting cells and fibrocytes) was broadly detected.

Conclusions: These findings indicate that our AAV vector carrying the novel capsid/promoter could serve as an optimal platform for gene therapy of GJB2-related hearing loss.

Dual AAV Gene Therapy Achieves Sustained Recovery of Hearing and Auditory Processing in a DFNB16 Mouse Model

12:00 p.m. - 12:15 p.m.

Sepideh Iranfar¹, Sophie Bagur², Chloé Felgerolle², Maxence Cornille², Hélène Le Ribeuz², Marie Giorgi², Sara Jamali², Amel Saoudi², Marie-José Lecomte², Vincent Michel², Brice Bathellier², Saaïd Safieddine^{*2}

¹Université Paris Cité, Institut Pasteur, AP-HP, INSERM, CNRS, Fondation Pour l'Audition, Institut de l'Audition, IHU reConnect, Paris, F-75012, France, Sorbonne Université, Ecole Doctorale Physiologie, Physiopathologie et Thérapeutique, Paris, France, ²Université Paris Cité, Institut Pasteur, AP-HP, INSERM, CNRS, Fondation Pour l'Audition, Institut de l'Audition, IHU reConnect, Paris, F-75012, France

Background: DFNB16, the second most common cause of hearing loss, accounting for ~11% of reported cases, with a carrier frequency of 1.6–1.8% in the general population. It is caused by mutations in the stereocilin (STRC) gene which encodes a protein predominantly expressed in outer hair cells (OHCs). STRC plays a crucial role in maintaining OHC bundle cohesion and in enabling their function as cochlear amplifiers. Loss of STRC function results in mild-to-moderate deafness in humans. Despite its prevalence, no curative treatment exists for DFNB16. *Strc*^{-/-} mice, which lack stereocilin, display severe to profound deafness and constitute a relevant preclinical model for DFNB16 (Verpy et al., 2008). Here, we developed an AAV-based gene therapy specifically targeting OHCs to achieve robust and sustained restoration of hearing function and central auditory processing.

Methods: Because the STRC cDNA exceeds the packaging capacity of a single AAV vector, we employed a dual-AAV delivery strategy, previously validated for DFNB9 (Akil et al., 2019). STRC expression and structural integrity of OHCs were analyzed by immunohistochemistry and confocal imaging and scanning electron microscopy. Hearing function was evaluated by recording distortion product otoacoustic emissions (DPOAEs) and auditory brainstem responses (ABRs) responses, which assess OHC function and synchronized neural activity from the auditory nerve to the brainstem, respectively. Auditory perception was evaluated through a Go/No-Go auditory frequency discrimination task combined with psychometric analysis.

Results: Dual-AAV-mediated *Strc* gene delivery successfully restored stereocilin expression, OHC bundle architecture, and stereocilia attachment to the tectorial membrane in *Strc*^{-/-} mice. This structural recovery led to the restoration of cochlear amplification and hearing to near-normal thresholds, as confirmed by DPOAE and ABR measurements. Importantly, dual-AAV administration up to postnatal day 5 (P5) restored auditory thresholds to levels not significantly different from those of wild-type controls, indicating a critical developmental window for effective intervention. Finally, behavioral assessments further demonstrated that treated *Strc*^{-/-} mice regained auditory frequency discrimination abilities comparable to wild-type littermates. These perceptual improvements were maintained for at least 100 days post-treatment, indicating long-term functional rescue at both peripheral and central auditory levels.

Conclusions: This study provides the first proof-of-principle that AAV-based gene therapy can restore OHC function, cochlear amplification, and central auditory perception in a DFNB16 model. Our findings highlight the therapeutic potential of dual-AAV approaches for STRC-related hearing loss and underscore their translational relevance for clinical application in humans.

In Vivo Evolved AAV Variants Enable Dual-AAV Stereocilin Delivery and Outer Hair Cell Rescue

12:15 p.m. - 12:30 p.m.

Josephine Wilkes¹, Jennifer Marx¹, Nico Jaeschke¹, Lisa Prager¹, Sabrina Just¹, Philipp John-Neek¹, C Wiehlmann¹, A Gardenstaeeter², Matthias Gerlitz², Erdem Yildiz², Athanasia Warnecke¹, Odett Kaiser¹, Hinrich Staecker^{*3}, Hildegard Buening¹

³Univeristy of Kansas Medical Center

Background: Hearing loss (HL) affects ~20% of the global population, yet current interventions are limited to hearing aids and cochlear implants. Gene therapy offers a promising alternative by directly addressing the molecular causes of HL. Adeno-associated virus (AAV) vectors are powerful gene transfer tools, but most variants used in the inner ear originate from libraries selected in other tissues or in silico designs. Directed evolution in the inner ear can generate optimized capsids with higher tropism for auditory cell types. This is particularly relevant for DFNB16, the second most common cause of autosomal recessive non-syndromic HL, resulting from mutations in the stereocilin (STRC) gene. The large size of STRC necessitates dual-AAV strategies, such as RNA trans-splicing systems, to enable full-length gene delivery.

Methods: AAV peptide display libraries based on AAV1, AAV2, and AAV6 with random 7-mer insertions in capsid region VIII were screened in vivo in adult mice (n=4/library) using alternative administration routes, requiring vectors to overcome robust biological barriers. High-throughput sequencing identified enriched capsids, which were produced as vectors carrying a dTomato reporter and tested in mice and pigs. For therapeutic application, the most promising OHC-targeting capsid (Var1) was employed in a dual-AAV system encoding split STRC genomes (dual-AAV1.Var1). Strc-deficient mice were treated at one month of age, and auditory brainstem responses (ABRs), stereocilia morphology, and transgene expression were assessed up to six months post-treatment.

Results: Selection enriched distinct capsids, with AAV2-derived variants accumulating up to 5% and AAV1-derived up to 2.5%. Top variants showed improved transduction compared to parental serotypes, including efficient targeting of outer and inner hair cells, stria vascularis, and spiral ganglion neurons (SGNs). In pigs, two lead candidates (Var1, Var3) reproducibly transduced cochlear cells. Using Var1 in a dual-AAV strategy, full-length STRC expression was confirmed in vitro within 48 h. In vivo, treated Strc-deficient mice showed modest ABR threshold improvements: small recovery at 16 kHz after 7 weeks and significant shifts across all tested frequencies at 6 months, though thresholds remained above 60 dB, indicating moderate-to-severe HL. In contrast, untreated ears showed severe-to-profound HL (> 80 dB). Whole-mount imaging revealed partial stereocilia recovery on 50–80% of OHCs in treated ears, and FLAG immunostaining confirmed STRC expression in OHCs, with additional expression in SGNs and spiral ligament, likely reflecting mRNA regulatory sequences.

Conclusions: This work establishes a panel of inner ear-optimized AAV variants with distinct tropisms and demonstrates the first in vivo application of dual-AAV STRC system in mature Strc-deficient mice. While hearing recovery was partial, the combination of OHC transduction, stereocilia rescue, and stable STRC expression validates the therapeutic potential of dual-AAV

delivery for DFNB16. These findings highlight the feasibility of tailoring AAV capsids for the inner ear and advance gene therapy approaches for large-gene hearing loss disorders.

Young Investigator Symposium 1: Real-World Acoustic Environments and Their Impact on Hearing and Well-Being

The Daily Auditory Environments of People With Tinnitus

Erika Skoe, *University of Connecticut*

Individual Abstract: Background:

Tinnitus is the sensation of sound in the absence of an external stimulus. The connection between long-term noise exposure and tinnitus has been the target of many studies, but little attention has been given to noise exposure patterns after the onset of tinnitus. A deeper understanding of the auditory environments of people with tinnitus is needed to aid the clinical management of tinnitus.

Methods:

For a week, participants (n=108) wore a personal noise dosimeter during all waking activities to measure their daily noise exposure. Participants also kept a journal of their activities during the week. The total sample size includes both tinnitus (n=61) and control groups (n=56). Dosimeter data were analyzed first using summative metrics of daily sound exposure, followed by functional data analysis (FDA) to reveal finer temporal differences in sound exposure between groups. The journal data were coded into 17 different categories to identify activities associated with noisy periods in the dosimeter record (> 85 dBA) and to compare groups with respect to their activity levels.

Results:

We found that daily personal noise exposure, measured using the time-weighted average sound pressure levels (LAeq,8h), was lower for the Tinnitus group relative to the Control group. Based on the dosimeter data, neither group was at ongoing risk of noise-induced hearing loss, as

average daily sound levels did not exceed 75 dB LAeq,8h for either group. Yet, the Tinnitus group spent less time engaged in noisy activities (> 85 dBA) compared to the Control group, with notable differences for home and workplace settings. However, overall, the groups did not differ in the total overall time they spent in these settings during the week of dosimetry. The FDA revealed that group differences were maximal around noon and evenings, periods when an individual is likely to have more control over their environment.

Conclusions:

Overall, we find that people with tinnitus tend to have quieter environments, suggesting that they lead quieter lives. Differences between groups may be explained by greater awareness of the risks of noise exposure in the tinnitus group or decreased sound tolerance among this group. Ongoing work seeks to replicate findings using smart Watch technology. One of the primary advantages of smart Watch technology is that, unlike personal noise dosimeters, it can provide data on headphone usage. Preliminary data will be presented.

Cultural Differences in Listening Environments Between Hispanic and White Non-Hispanic Cochlear Implant Users

Emily Spitzer, *New York University Grossman School of Medicine*

Individual Abstract: Introduction: Cochlear implant (CI) speech processors can track usage via “data logging”, including the number of hours on air, time spent in different acoustic environments and loudness levels. These data are important, as high noise levels and poor signal to noise ratios (SNRs) can decrease speech intelligibility, impairing communication and speech perception outcomes. Louder environments can have a detrimental impact on learning and cognition and have been associated with both socioeconomic disparity and cultural factors. A study found that normal hearing Latinx-identifying college students experienced higher levels of environmental noise and lower SNRs, possibly due to cultural importance of collectivism and music listening at louder levels. This study investigates whether similar listening patterns exist in CI users and examines how data logging variables relate to speech perception outcomes.

Methods: Retrospective chart review of CI patients at a tertiary medical center in New York City identified 30 Hispanic and 31 White non-Hispanic adults for further review. Demographic variables were compiled and home zip codes were used to obtain population-based socioeconomic data. Outcome measures included speech perception scores (in noise and quiet) conducted in the participant’s primary language and data logging information extracted from the CI speech processor. The datalog included hours of total use and time spent in different listening environments, classified by the CI software into sound levels (in dBA) and sound scenes (noise, quiet, speech, music, and “other”).

Results: There were no significant differences detected in total hours of CI usage, age at CI, or gender between the Hispanic and White non-Hispanic groups. There was a significant difference in the percentage of time spent in each scene: Hispanic Americans spent more time in “speech in noise”, “music”, and “noise”; non-Hispanics spent more time in “quiet”. Hispanic participants lived in neighborhoods with higher population densities, which correlated to higher CI sound

levels (dBA > 70) in the environment. The percentage of time spent in noise positively correlated with sentence-in-noise perception scores for Hispanic participants, but not for White non-Hispanic participants.

Conclusion: Cultural differences appear to exist between Hispanic and White non-Hispanic listening environments, like normal hearing listeners. While device use was similar, the Hispanic group had greater noise exposure, which was linked to better speech-in-noise performance. This relation may suggest an auditory training mechanism, reinforced by cultural values. Audiologists should consider cultural background and listening preferences when counseling CI users, as these may influence performance and adaptation to noisy environments.

Linking Hearing Ability, Acoustic Environments, Hearing Aids, and Social-Emotional Health Outcomes

Erik Jorgensen, *University of Wisconsin-Madison*

Individual Abstract: Background

Hearing loss is linked to increased loneliness and depression, but the mechanisms behind this association remain unclear. A leading hypothesis is that hearing loss leads to social-emotional difficulties by changing hearing-related behaviors—particularly by prompting people to avoid speech-in-noise (SiN) environments, which are often social and especially challenging for individuals with poor speech perception in noise (SPIN). This study tested that hypothesis by examining the relationships among hearing, hearing aid use, hearing-related behaviors, and social-emotional health.

Methods

The study included 54 younger adults with typical hearing, 55 older adults with hearing loss who did not use hearing aids, and 52 older adults with hearing loss who did. Participants completed standardized measures of SPIN, depression, and loneliness. They also wore body-worn recorders near the head for all waking hours for one week (younger adults) or two weeks (older adults). A deep neural network classified the acoustic environment in 0.5 s intervals, and the percent of time in each environment was computed. Descriptive statistics and structural equation modeling were used to analyze moderated mediation models linking acoustic environments, SPIN, loneliness, and depression.

Results

Younger adults spent the most time in SiN environments. Surprisingly, older hearing aid users spent significantly less time in SiN and more time in silence compared to non-users. Among younger adults, more time in SiN was associated with lower loneliness, especially for those with better SPIN, which indirectly reduced depression. For older non-users, a similar pattern emerged: more SiN exposure was associated with lower loneliness, especially with better SPIN. In contrast, for hearing aid users, more time in SiN was linked to greater loneliness. SiN exposure and SPIN ability were not associated with depression in older adults. An “environment-person fit” effect was also observed: those with poor SPIN who spent less time in SiN had lower

loneliness. Among older adults, time in SiN, SPIN ability, hearing aid use, and loneliness were all related to perceived hearing-related disability.

Conclusions

Acoustic environments vary by age and hearing status, with implications for social-emotional health. In younger adults, SPIN moderates the link between SiN exposure and loneliness, which in turn affects depression. Among older adults, hearing aid use does not mitigate loneliness or increase time in SiN; hearing aid users had poorer SPIN, spent less time in SiN, and reported higher loneliness than non-users. Poor SPIN and perceived hearing disability likely underlie avoidant hearing-related behaviors, pursuit of hearing aids, and loneliness.

Acoustic Environments for Children Who Are Deaf or Hard of Hearing

Carlos Benitez-Barrera, *University of South Florida*

Individual Abstract: Objectives:

Children who are Deaf or Hard of Hearing (CDHH) who develop spoken language are at increased risk for language delays. These delays are influenced by hearing-related factors (e.g., age of amplification) and reduced exposure to caregiver language input. Emerging models of language acquisition emphasize that environmental noise also limits access to caregiver input, further impacting language development. Our previous work showed that real-world speech-to-noise ratios (SNRs) predict language outcomes in children with typical hearing, beyond the effect of caregiver talk. Building on this, we propose that CDHH exposed to both limited input and poor acoustic access face the highest risk for language delays.

This presentation underscores the importance of assessing the quality of CDHH children's acoustic environments. Specifically, we highlight: (1) how wearable audio recording devices can objectively quantify children's auditory experiences, including access to caregiver input, and (2) how these experiences relate to language development.

Design:

We are recruiting 40 preschool CDHH (ages 3–6) and an age-matched control group with typical hearing. Our goal is to develop and validate a novel Speech Accessibility Index (SAI), which quantifies children's access to spoken language in everyday settings. The SAI integrates two metrics: (a) each child's Speech Reception Threshold (SRT) in noise, and (b) SNRs calculated from daylong LENA recordings collected at home. The SAI estimates the percentage of conversations with SNRs above the child's SRT, serving as a proxy for real-world language access. This approach builds on our prior work and extends conventional measures of language exposure to include the quality of acoustic input available to the child.

Results:

To date, we have collected data from 20 children (10 CDHH). Preliminary analyses indicate that both caregiver input and access to language (as indexed by the SAI) are significantly associated with language outcomes when combining both groups. We expect that, with the full dataset, both predictors will remain independently associated with language skills, even after controlling for relevant covariates.

Conclusions:

The SAI captures dimensions of children's language environments that go beyond caregiver speech alone, offering clinical value in assessing real-world speech access. It shows promise as a screening tool for identifying CDHH at risk for language delays and for informing home-based interventions (e.g., remote microphone systems) aimed at enhancing children's language access and outcomes.

Poster Session II with Coffee

1:30 p.m. - 3:00 p.m.

Ballroom A, Floor 3

Due to the policies of the Puerto Rico Convention Center, the Poster Hall will be available to attendees between the hours of 7AM – 11PM (local time), with a 1- hour break every day between 11AM and 12 PM (Noon) to facilitate setup for the next poster session. This is an appreciated extension of their normal permitted hours. ePosters are available on the conference website and the ARO MWM mobile app. and nbsp;

SU1. Silence and Solitude: Effects of Noise Exposure and Social Isolation on Serotonergic Function and Behavior

Megan Walker¹, Jessica Bush¹, Lauren Hadland¹, Laura Hurley*¹

¹*Indiana University*

Background: The social isolation that can accompany hearing impairment in aging co-occurs with other health concerns, including depression, anxiety, and cognitive decline. A contributing factor to these negative outcomes may be dysfunctional communication driven by deficits in auditory processing and perception. Animal models of these related risk factors can help elucidate the neural mechanisms underlying these functional challenges. Serotonin-auditory interactions are responsive to both hearing loss and social isolation in mice.

Methods: We therefore assessed the effects of noise exposure and a period of individual housing on serotonergic function and social and open field behaviors in female CBA/CaJ mice, using a factorial design. At 6 weeks of age, mice were exposed to noise from 8-16 kHz at 100 dB, or to sham treatment, for 2 hrs. At 11 months, mice were placed in individual housing for 4 weeks or maintained in social groups, after which they were placed in an opposite-sex social interaction with socially housed male partners. Following brain fixation and slicing, sections were labeled with antibodies for tryptophan hydroxylase plus c-Fos, or the serotonin transporter (SERT).

Results: Social isolation had strong effects on behavior, elevating vocal behavior in both the female subjects and their male partners, and increasing time in the edges of the open field. In contrast to previous studies in younger mice, social isolation did not alter the density of SERT+ fibers in the inferior colliculus or neurons double labeled for c-Fos and TPH in the dorsal raphe nucleus (DRN). Although noise exposure significantly elevated ABR thresholds, it did not affect vocal behavior or SERT+ density. Noise exposure did increase the density of neurons double

labeled for c-Fos and TPH in the dorsal raphe nucleus. However, the effect of noise was significant only in mice in the isolated treatment group. Further, the density of double labeled neurons in the DRN correlated with ABR threshold and with USV number.

Conclusions: These findings suggest that noise exposure and social isolation interact to influence the activity of serotonergic neurons during social interaction.

SU2. How Reverberation Shapes the Subcortical Encoding of Speech in Aging and Hearing Loss

Ebtesam Sajjadi*¹, Samira Anderson¹

¹*University of Maryland*

Background: Everyday communication often occurs in environments with reverberation, such as classrooms, restaurants, and auditoriums. Mild reverberation levels can enhance overall speech audibility, but excessive levels of reverberation blur temporal and spectral cues and deteriorate speech understanding. This difficulty is more pronounced for older adults and individuals with hearing loss. The purpose of this study was to examine how reverberation affects subcortical speech encoding to gain a better understanding of factors that may contribute to perceptual declines.

Methods: The current project uses frequency-following responses (FFRs) to investigate the subcortical neural encoding of reverberation in older adults. Prior work has shown that age-related declines in temporal precision particularly compromise encoding of dynamic formant transitions in speech, whereas steady-state vowel segments may be relatively preserved. Therefore, FFRs have been recorded to the syllables /da/ and /ah/ to represent dynamic (formant transition) and static (steady-state vowel) components of speech, respectively. Stimuli are presented under no reverberation, short decay (RT60 = 0.46 s), and long decay (RT60 = 2s) conditions. FFRs have been recorded from older adults with normal hearing (ONH) and mild to moderate hearing loss (OHI) at 80 dB SPL. Responses are analyzed using phase locking to the envelope and temporal fine structure and stimulus-to-response correlations to assess the fidelity of neural encoding across different time regions of the speech signal.

Results: Preliminary results show that reverberation reduces phase locking and decreases stimulus-to-response correlations for both /da/ and /ah/ stimuli. Early findings suggest that long decay reverberation particularly weakens encoding of the transition region in /da/. This result is consistent with the previous findings that dynamic cues are more vulnerable to temporal smearing. While no statistically significant group effects have yet been observed, OHI participants generally show weaker envelope encoding under reverberant conditions than ONH participants.

Conclusions: These findings provide initial evidence that reverberation exacerbates age-related declines in neural precision, particularly for dynamic speech regions. Ongoing data collection will provide evidence about the differential effects of reverberation on steady-state and transition regions, and whether OHI listeners are at greater risk for degraded neural synchronization. This work aims to increase our understanding of how reverberation shapes subcortical encoding in aging populations and propose future strategies for improving the ability of this population to understand speech in acoustically complex environments.

SU3. Vascular Senescence and Microcirculatory Pathology as Contributors to Age-Related Hearing Loss

Marta Konopka^{*1}, Maria Luque¹, Rudolf Glueckert¹, Elisabeth Pechriggl¹, Erich Brenner¹

¹*Medical University of Innsbruck*

Background: Age-related hearing loss (ARHL) is one of the most prevalent sensory disorders in the elderly and is closely associated with cognitive decline and reduced quality of life. Increasing evidence suggests that vascular dysfunction, including endothelial alterations, chronic low-grade inflammation, and systemic vascular remodeling, contributes to cochlear degeneration. Human-based studies are required to clarify these mechanisms in the context of aging and diabetes.

Methods: Human postmortem specimens from donors older than 60 years were analyzed, including cochlea, internal carotid artery, kidney, and skin. Donors with type 2 diabetes mellitus were compared with non-diabetic controls. Tissues were processed using conventional histology and immunohistochemistry to assess four domains: vascular aging, low-grade inflammation, microangiopathies, and macroangiopathies. For this purpose, α -smooth muscle actin (α -SMA) was used to evaluate vascular smooth muscle remodeling, CD31 to assess endothelial integrity and vascularization, and CD68 to detect macrophage infiltration. Quantitative image analysis was applied where tissue quality allowed, enabling comparison of vascular remodeling, endothelial changes, and inflammatory burden across diabetic and non-diabetic groups.

Results: Macrovascular remodeling in the carotid artery was characterized by thickened media and pronounced intimal hyperplasia, consistent with advanced atherosclerotic change. Microvascular alterations were observed in cochlear and systemic tissues, including focal basement membrane irregularities and altered vascular density. A trend toward higher CD31 expression was detected in diabetic donors compared with non-diabetic controls, likely reflecting compensatory endothelial proliferation and remodeling in the setting of diabetic vasculopathy. Inflammatory infiltration was consistently observed, with CD68-positive macrophages located in arterial walls and cochlear regions. Quantification demonstrated higher macrophage infiltration in diabetic donors, supporting the association between chronic low-grade inflammation and vascular pathology. These findings currently represent trends, but with a larger donor database we expect not only confirmation of these patterns but also significant differences to emerge, clarifying the extent of vascular involvement in ARHL. Comparable alterations in kidney and skin underline the systemic nature of these changes.

Conclusions: By integrating inflammatory, microvascular, and macrovascular findings across cochlea and systemic tissues, this study supports the concept that ARHL represents a manifestation of systemic vascular aging rather than an isolated disorder of the inner ear. All findings will be correlated with progression of age-related hearing loss, providing a translational framework that links vascular pathology to auditory decline. These results highlight vascular dysfunction as a promising therapeutic target and emphasize the need for preventive strategies aimed at maintaining vascular integrity to preserve auditory function in aging and metabolically compromised populations.

SU4. Oncomodulin Attenuates Oxidative Stress-Induced Senescence in Auditory HEI-OC1 Cells

Janith Nilmika Halpage Hewa Halpage*¹, Santha Ranganathan¹, Ian Stahl¹, Dwayne Simmons¹

¹*Baylor University*

Background: Age-related hearing loss (ARHL) is characterized by the progressive dysfunction/loss of cochlear outer hair cells (OHCs), yet the molecular mechanisms contributing to their decline remain unclear. Cellular senescence, a permanent state of cell cycle arrest triggered by stress, is increasingly recognized as a contributor to age-related tissue degeneration including in the auditory system. Oncomodulin (OCM), a calcium-binding protein highly expressed in OHCs, is essential for calcium homeostasis. The hypothesis for this project is that the loss of OCM accelerates OHC senescence in auditory cells.

Methods: To investigate the potential role of OCM in regulating stress-induced senescence, we used the HEI-OC1 cochlear cell line and induced senescence using hydrogen peroxide (H₂O₂). Cells were transfected with plasmids encoding OCM (fused to GFP or mCherry). Senescence-associated β -galactosidase (SA- β -gal) and p16INK4a immunofluorescence were looked at to measure levels of senescence. To investigate the relationship between autophagy and senescence, immunofluorescence analysis was performed using antibodies against LC3B and p62.

Results: OCM-expressing cells exhibited significantly reduced senescence-associated β -galactosidase (SA- β -gal) activity compared to controls, along with decreased expression of the senescence marker p16INK4a. Morphological analysis showed increased nuclear enlargement, a characteristic feature of senescent cells, in control cells compared to OCM-transfected cells. Further investigation revealed that OCM modulates autophagic signaling. Immunofluorescence analysis of LC3B and p62 puncta demonstrated decreased autophagic stress in OCM-expressing cells, suggesting reduced autophagic flux. Additionally, gene expression analysis showed downregulation of p53, key regulator of the senescence pathway. Notably, mitochondrial DNA expression level was elevated in OCM-transfected cells, indicating enhanced mitochondrial integrity and resilience to oxidative stress.

Conclusions: These findings suggest that OCM suppresses cellular senescence in cochlear cells through the preservation of autophagic function and maintenance of mitochondrial health. This work identifies increased calcium buffering as a novel protective factor and highlights its potential relevance in mitigating ARHL.

SU5. Impact of Auditory Training on Cortical Neural Tracking of Rapid Speech

Ciaran Stone*¹, Ebtesam Sajjadi¹, Samira Anderson²

¹*University of Maryland, College Park*, ²*University of Maryland*

Background: Age-related hearing loss, and aging itself, can make understanding rapid speech challenging, as degraded processing in the auditory system limits the ability to process temporal cues. Current research suggests that these difficulties are linked to changes in the brain's temporal dynamics, including delayed and exaggerated responses to speech, which may represent compensatory mechanisms that often fail to fully restore speech perception. This

study's main goal is to explore whether auditory training with time-compressed speech can improve both behavioral performance and cortical processing, and if these improvements can be observed across different hierarchical levels of neural representation.

Methods: In this study, 94 participants were recruited: a younger normal-hearing (YNH) group, an older normal-hearing (ONH) group, and an older hearing-impaired (OHI) group. Each participant underwent pre- and post-training sessions. During these sessions, a behavioral assessment was conducted to determine each participant's threshold for 50% keyword recognition of time-compressed speech. Electroencephalography (EEG) was used to record cortical envelope tracking of continuous speech of audiobooks in both unprocessed and time-compressed conditions. All participants completed six adaptive training sessions where the time-compression rate was adjusted based on their performance.

Results: Our findings showed a significant improvement in behavioral measures after training. Both the ONH and OHI groups demonstrated better performance at the post-test. Notably, while the younger listeners still had the highest overall performance, the post-training thresholds for the ONH group approached the pre-training levels of the YNH group. These results suggest that this targeted training can partially restore rapid speech recognition, especially in older adults with normal hearing. To further understand the neural basis of these improvements, the cortical EEG data will be analyzed using a Temporal Response Function (TRF) framework to evaluate changes in neural encoding at various levels, from sensory (e.g., acoustic features) to linguistic (e.g., phonemes, words, phrases, and sentence onsets). We will present how the exaggerated cortical tracking responses previously observed in older adults change with training.

Conclusions: Our findings provide new and important insights into the potential for auditory training to improve rapid speech perception in older adults, and perhaps for their speech perception in general. The behavioral results suggest a partial restoration of function, which has impactful clinical relevance for aging adults. This type of targeted training could provide a valuable tool to help individuals overcome challenges with speech comprehension in everyday situations. Future research may investigate the long-term effects of such training and its potential application in home and clinical settings. A key takeaway is that auditory training can drive beneficial neuroplastic changes that improve speech recognition, especially in older adults with normal hearing. This work was supported by NIA P01AG055365.

SU6. Maturation of Cortical Auditory Evoked Potentials in Response to Tones and Noise

Bruna Mussoi^{*1}, Julia Huyck²

¹*University of Tennessee Health Science Center*, ²*Kent State University*

Background: Brain structure and function undergo important changes during adolescence. Although the most significant neuroplastic changes happen during the first few years of life, cortical auditory evoked potentials (CAEPs) and auditory perceptual abilities do not become adult-like until early adulthood. The few studies that have investigated maturational changes in CAEPs during adolescence focused on a single type of stimulus, such as clicks, pure tones, or speech stimuli. However, given prior research indicating that children and adolescents may be more susceptible than adults to the negative effects of background noise during speech perception tasks, a comparison of CAEPs to tones vs. noises might yield valuable information

about the auditory encoding underlying these perceptual differences. Thus, the goals of this study were to examine (1) maturational changes in CAEPs to tones and noise, and (2) the relationship between CAEPs and speech recognition in noise in adolescents and young adults.

Methods: Ninety-four adolescents and young adults (10 – 23 years old) took part in this study. CAEPs were obtained in response to 400 ms long, 1000 Hz pure tones and band-pass noise, presented at 70 dB SPL via an insert earphone to the left ear. 800-1000 responses were recorded using surface electrodes (3-channel) and band-pass filtered between 1-30 Hz. Peak latencies and amplitudes (relative to 100 ms pre-stimulus baseline) were compared as a function of age. Speech perception in noise was assessed with the QuickSIN test.

Results: CAEP morphology differed in response to tones and noise, in that responses to noise stimuli had smaller N1 amplitudes and larger P2 and N2 amplitudes. From early adolescence to young adulthood, P1 and N1 latencies decreased in response to both tones and noise. In contrast, P2 latencies increased (tones only), as did N2 latencies (both tones and noise). P1 and N1 amplitudes tended to decrease from adolescence to young adulthood, while P2 and N2 amplitudes increased. Speech perception in noise improved during the course of adolescence, but this improvement did not appear to be associated with CAEP latencies and amplitudes to tones or noise.

Conclusions: There were extensive changes in CAEPs in the period between early adolescence and young adulthood. Results confirmed previous findings of continued maturation of CAEPs during adolescence and extend these findings in response to noise stimuli. CAEP responses to noise were markedly different from responses to tones, but results did not indicate a differential impact of age during adolescence. Other factors not examined in this study may be able to better predict maturational effects of adolescence on speech recognition in noise.

SU7. Cortical Representation of Attended and Ignored Acoustic Features Under Binaural Unmasking

Madeline Johnson*¹, Zilong Xie¹

¹*Florida State University*

Background: Binaural unmasking refers to the auditory system's ability to utilize interaural differences to segregate a target sound from background noise. This mechanism has been linked to enhanced cortical encoding of the acoustic features of attended continuous speech. Interestingly, even when background noise is not the focus of attention, its acoustic features still manifest in cortical responses. These observations raise an important question: To what extent does binaural unmasking influence the cortical representation of ignored auditory input during continuous speech processing in noise?

Methods: Twenty young adults with clinically normal hearing participated in a listening task involving audiobook stories embedded in speech-shaped noise at a signal-to-noise ratio of -2 dB. To examine the effects of binaural unmasking, two listening conditions were employed: S0N0, where both speech and noise were presented in-phase across ears, and S π N0, where speech was delivered out-of-phase while noise remained in-phase. EEG recordings were collected throughout the task. After each trial, participants responded to comprehension questions and provided subjective ratings on how well they grasped the story's gist and the effort required to understand it. Cortical tracking of acoustic features was analyzed using multivariate temporal

response functions (mTRFs), which modeled cortical EEG responses from spectrotemporal features (envelope and acoustic onsets) of both the target speech and the noise.

Results: Compared to the S0N0 condition, the S π N0 condition yielded enhanced behavioral performance, including higher accuracy in story comprehension, stronger ratings for gist understanding, and reduced perceived effort during listening. At the neural level, cortical TRFs to both envelope and acoustic onsets of the target speech were stronger and occurred earlier in the S π N0 (vs. S0N0) condition. Moreover, the mTRF models showed higher predictive accuracy for the target speech in the S π N0 (vs. S0N0) condition when using combined acoustic features or acoustic onsets alone. Finally, although cortical tracking of acoustic features of the noise was observed, no significant differences in TRFs or model prediction accuracy were found between the two listening conditions.

Conclusions: These findings reveal an interaction between top-down selective attention and binaural unmasking in cortical processing of continuous speech in noise. Future work should explore this interplay in multi-talker conditions.

SU8. Electroencephalographic Correlates of Auditory Selective Attention in Hearing Loss

Sharadhi Umesh Bharadwaj^{*1}, Olivia Flemm², Shaina Wasileski², Hari Bharadwaj²

¹*Carnegie Mellon University*, ²*University of Pittsburgh*

Background: Current clinical practices for sensorineural hearing loss (SNHL) emphasize audibility, and provide amplification to compensate for elevated audiometric thresholds. Yet, even with amplification, many patients with SNHL struggle to understand speech in noisy environments. Although most research on SNHL focuses on sensory deficits, relatively little is known about how top-down selective attention processes may be altered in individuals with hearing loss. To investigate this, we simultaneously record 32-channel EEG and behavioral responses.

Methods: Simultaneous 32-channel EEG recordings and behavioral measurements data has so far been collected from 8 subjects with normal hearing and 14 subjects with mild to moderate hearing loss. The matrix sentence test material was used to create a speech-on-speech task where the target and masking streams were constructed using the same group of words in the same speaker's voice at 0 dB target-masker ratio. The target and masker streams are lateralized to opposite hemifields using interaural time differences and staggered in time. This design minimizes acoustic overlap and thus reduces peripheral sensory interference, allowing our measures to primarily reflect top-down attentional processes rather than peripheral deficits. We examined two EEG correlates of spatial attention, (1) lateralized alpha-band oscillations (7–15 Hz) in parietal and occipital regions which reflect endogenous attention allocation during the preparatory phase, and (2) enhanced evoked potential amplitudes which reflect how the top-down attention modulates the sensory representation under focused attention. Stimuli and target location were counterbalanced across trials.

Results: To quantify alpha lateralization, we used the multitaper technique to compute alpha band power over parieto-occipital channels, comparing power between 'attend-left' and 'attend-right' trials. Attentional modulation was quantified by computing evoked potentials to stimulus onset and comparing the amplitudes between 'attend-lead' and 'attend-lag' trials.

Preliminary results suggest reduced alpha lateralization in individuals with hearing loss and trends of lower attentional modulation of sensory stimulus.

Conclusions: These data (if trends hold) would provide evidence that top-down attention is also altered in SNHL over-and-beyond sensory deficits that are known to exist. Our ongoing work aims to expand our dataset and characterize how top-down attentional control is affected in SNHL, shedding light on the interplay between sensory deficits and higher-order processes.

SU9. Probing Invariances in Auditory Event Categorization Using Model Metamers

Hee So Kim^{*1}, Malinda McPherson-McNato², Abigail Noyce¹, Jenelle Feather¹

¹*Carnegie Mellon University*, ²*Purdue University*

Background: Real-world acoustic inputs contain rich sensory information that we parse into discrete auditory objects and categories. However, the transformation from acoustic waveforms to neural representations is complex and poorly understood, especially as neural representations are invariant across some feature changes, such as variation in the exact pitches or timing. Further, previous investigations of auditory category representations have largely explored speech, music, or tone structures, with very few studies exploring categorical representations of non-speech stimuli. Computational modeling allows researchers to explicitly probe the transformation from input waveforms into higher-level representations, with recent work suggesting that deep neural networks (DNNs) are well-suited to model human auditory processing. Here, we test whether the invariances of DNNs trained to categorize non-speech sound stimuli are aligned with the invariances of human observers.

Methods: We developed an experimental paradigm to compare humans and DNNs using forced-choice classification across 25 non-speech sound categories using sounds obtained from the FSD50K dataset. For the tested models, we generated ‘model metamers’—stimuli whose activation produces the same response as the natural stimulus at a given model stage. We then tested whether humans (n=4) could recognize the model metamers as well as they could recognize the original audio. Recognizable model metamers imply that invariances of the model are shared with those of human observers. We tested DNNs pretrained on three different tasks: (1) word recognition only, (2) auditory event recognition only, and (3) a multi-task model for word recognition, speaker recognition, and auditory event recognition. These models were trained to be robust to small “adversarial” perturbations in the input cochleagram, a technique that was previously shown to help align the invariances of models with the invariances of human observers in the speech domain. For comparison of including this type of training, we also tested a multi-task model without adversarial training.

Results: First, humans and models can reliably categorize the natural sounds, demonstrating that our novel behavioral paradigm is well suited for testing invariances in auditory categories. For all models, we found that recognition accuracy for model metamers dropped significantly, but there was variability across models. Metamers generated for the adversarially trained auditory event recognition model were the most recognizable among the four models. This result indicates that task-specific optimization plays a significant role in creating human-like invariances. Among the multi-task models, metamers from the adversarially trained model had significantly

higher accuracy, confirming that training with adversarial perturbations helps align model invariances more closely with those of humans.

Conclusions: The results indicate that model metamers provide a powerful tool for probing human auditory perception in the domain of categorical representations of auditory events. These findings provide additional evidence that adversarial training and task-specific optimization can improve model alignment with human perception.

SU10. Neuronal Correlates Underlying Auditory Categorization in Mice

Anjali Sinha^{*1}, Gozde Erdil¹, Jared Collina¹, Yale Cohen², Maria Geffen¹

¹*University of Pennsylvania*, ²*University of Pennsylvania School of Medicine*

Background: Categorization of sensory stimuli is a fundamental computation in cognition, and is critical for many aspects of learning, perception, and prediction. Auditory categorization (AC) has been linked to the neuronal activity in the auditory cortex, however, it remains poorly understood how categorical representations emerge in population neuronal activity with learning.

Categorization is often influenced by prior information and experience and can be modified by new information. We recently showed that during categorization learning, mice use multiple complementary strategies (Collina et al., 2025). These strategies affect the animals' perception of stimuli category under uncertain conditions, e.g., for stimuli that surround the categorization boundary. Additionally, animals modify these strategies based on their training. To understand neuronal correlates of auditory categorization, we recorded neuronal activity from the auditory cortex of mice using implanted high-density electrodes while training them to perform an auditory categorization task.

Methods: Mice were implanted with custom-made chassis housing Neuropixels electrodes in the auditory cortex and trained to discriminate between high and low frequency tones in 2-alternate forced choice (2AFC) task. Once their behavioral performance reached criterion %, we tested how well population neuronal activity categorized ambiguous tones around the categorization boundary, and how this boundary was affected by biasing the distribution of the stimuli toward high or low frequency tones.

Results: Single neuron analysis indicated that approximately 30% of the recorded neurons exhibited category preference, as measured by the difference in the firing rate of neurons was for stimuli between categories than within categories. Additionally, population decoding accuracy to between categories stimuli increased with training. To examine how neuronal population reflect behavior, we compared the neurometric and psychometric thresholds across sessions. Training increased alignment between thresholds of neurometric and psychometric curves with well aligned threshold estimates in fully trained animals. Moreover, a subpopulation of neurons was choice-selective, as their firing rate reflected the choice of the mouse across trials. Additionally, we also identified components in the population responses that signaled reward prediction, reward response and reward prediction error in AC.

Conclusions: Our results show that neuronal activity in the auditory cortex during auditory categorization reflects behavioral performance. We are currently analyzing how the neuronal

population activity evolves throughout auditory learning and how biasing the category distribution across different sessions affects neuronal activity.

SU11. Reduced Sound Tolerance due to Enhanced Central Gain in a Rat Model of Fragile X Syndrome

Benjamin Auerbach^{*1}, David Gauthier¹, Shang Ma¹, Xiaopeng Liu¹, Noelle James¹

¹*University of Illinois at Urbana-Champaign*

Background: Atypical sound processing is one of the most common and quality-of-life affecting symptoms seen in autism spectrum disorders (ASD). Fragile X Syndrome (FXS) is the leading inherited cause of ASD and a majority of FXS individuals present with auditory processing issues. Despite this prevalence and centrality to the autistic phenotype, relatively little is known about the nature and mechanisms of auditory perceptual impairments in FXS and ASD.

Methods: We characterized auditory processing in adult male Fmr1 KO rats and wildtype littermates using a comprehensive battery of behavioral tasks that take advantage of the highly trainable nature of rats and their innate capacity to express complex behavior. We combined these behavioral assays with multi-region electrophysiological recordings and computational modeling to determine the neural origins of atypical sound-driven behavior in these animals.

Results: We found that Fmr1 KO rats exhibited heightened perceptual sensitivity and impaired gating of incoming auditory information, resulting in reduced sound tolerance and exaggerated avoidance behavior. Despite this behavioral evidence for sound hypersensitivity, Fmr1 KO rats exhibited diminished suprathreshold sound-evoked responses at the level of the auditory nerve and brainstem. However, this reduced afferent drive was progressively amplified along the ascending auditory pathway, culminating in several cortical network alterations that could account for observed perceptual differences, including increased spontaneous firing rates, steeper sound intensity-response functions, and broader frequency tuning. Using an experimentally informed Bayesian population decoder, we demonstrated that we could recapitulate behavioral deficits from auditory cortical but not subcortical neurophysiological recordings.

Conclusions: These findings are reminiscent of central gain changes observed along the central auditory pathway in response to hearing loss, suggesting a potential shared etiology for hyperacusis of diverse origin. Moreover, our results indicate that cortical hyperexcitability may account for a range of auditory behavioral phenotypes in FXS, providing a potential locus for development of novel biomarkers and treatment strategies that could extend to other forms of ASD.

SU12. Somatostatin Interneurons Drive Contrast Adaptation in the Mouse Primary Auditory Cortex

Omer Zeliger^{*1}, Christopher Angeloni², Valerie Baubet², Erin Michel², Maria Geffen¹

¹*University of Pennsylvania*, ²*University of Pennsylvania School of Medicine*

Background: In natural environments, behaviorally-relevant sounds such as speech often co-occur with background noise such as wind or traffic. In order to effectively identify and respond to relevant sounds, the auditory system must isolate signal from noise. This ability is reduced in

people with hearing impairments and auditory processing disorders, posing unique challenges in navigating everyday environments. In order to develop effective treatments, it is vital to understand the mechanisms underlying hearing in noise.

One strategy for isolating signal from noise is to adapt to the current auditory environment. In the primary auditory cortex (A1), neurons adapt to changes in stimulus variability (contrast) by adjusting their gain. This process is known as contrast gain control (CGC). Though CGC has been demonstrated across many organisms from mice to humans, its mechanisms are still unknown.

In this study, I test the hypothesis that two different classes of inhibitory interneurons, parvalbumin (PV)- and somatostatin (SST)-positive interneurons, drive contrast gain control in mouse A1.

Methods: In order to test the role of different inhibitory interneuron subtypes in driving CGC, we optogenetically suppress PV or SST populations in A1 of mice presented with stimuli of changing contrasts. We test for CGC using two methods: behavioral performance on a target-detection task, and extracellular electrophysiological recordings in A1.

First, we tested how optogenetically suppressing different populations of interneurons affected behavioral performance on a target-detection task. Mice were presented with stimuli of low and high contrasts and trained to respond when they detect an increase in sound pressure level. Previous experiments in mice and humans show that performance on similar tasks increases in low-contrast backgrounds, corresponding to increased neuronal gain. If PV or SST neurons drive CGC, we expect optogenetic suppression of these populations to reduce the change in performance between the two contrasts.

Second, we performed acute extracellular recordings in mice passively exposed to auditory stimuli with high and low contrasts. Using these neuronal responses, we can directly calculate neuronal gain changes across stimulus contrasts. If PV or SST neurons drive CGC, we expect optogenetic suppression to reduce the degree of gain adaptation between the two contrasts.

Results: We find that SST suppression, but not PV suppression, impairs CGC between high and low contrast conditions. Though analysis of the extracellular data is still in progress, we observe a similar trend of decreased CGC during SST but not PV suppression. These results suggest that SST-positive interneurons drive CGC in mouse A1.

Conclusions: This research finds that SST neurons are involved in driving contrast adaptation in the cortex. This opens up new avenues of research into the potential role of SST neurons in auditory processing disorders.

SU13. Multiscale Adaptation Dynamics Reflect Hierarchical Predictive Processing in the Ferret Auditory Cortex

Meysam Amirsardari^{*1}, Wing Yiu Ng¹, Rupesh Chillale¹, Shihab Shamma¹

Background: The mammalian brain encodes regularities with adaptation across multiple timescales: from rapid stimulus-specific adaptations in short-scale, to predictive processing of complex sequence structures. Previous studies, across species, suggest a cortical gradient of integration windows, from A1 to higher auditory and supramodal areas, but details of both their flow and temporal generalization remain unknown. Our goal is to dissociate responses to omission, local, and global violations in ferret A1 and PEG and to quantify their shared information and integration depth.

Methods: We recorded 32-channel electrocorticography (ECoG) covering the primary auditory cortex (A1) and the posterior ectosylvian gyrus (PEG) in ferrets, while presenting hierarchical sequences of pure tones or natural syllables. We used the local-global oddball structure as the main framework for our experiment design, and the sequences with various lengths comprised a repetition stage followed by a final event that either conformed to, violated, or was omitted in relation to the learned temporal pattern.

Across experiments, we manipulated: (i) final-item change after repetition (local violation), (ii) omission at sequence end, and (iii) higher-order pattern changes across different trials of the experiment run (global violation), including cross-item substitutions and re-ordering. Analyses combined condition-wise ERPs, time-resolved linear decoding, and temporal generalization matrices within and across areas. Finally, a dynamic Bayesian observer estimated per-channel integration depth by fitting trial-wise neural “surprise” derived from the event-locked mismatch windows.

Results: Local violations expressed an early MMN-like offset-locked response (< 200 ms) with strong shared information between A1 and PEG. Linear decoders indicated a stronger A1 contribution at this stage. A later component (≈ 250 – 500 ms) was more temporally sustained in PEG, showed broader temporal generalization within PEG compared to A1, and reduced cross-area decodability between A1 and PEG, representing area-specific updatings. Global violations emerged later (≈ 450 – 700 ms), partially dependent on the presence and magnitude of the earlier local response, and appeared as short sets of pulse-like signals in temporal generalization rather than sustained, time-invariant codes.

The Bayesian observer showed predictions consistent with the general pattern of our recorded surprisals. The model used to estimate the best-fitting integration depths and compare them in A1 and PEG. These effects are observable in tone sequences to syllabic sequences with different lengths and stimulus structures.

Conclusions: The results are consistent with hierarchical predictive processing with parallel mechanisms: fast, MMN-like, shared prediction errors tied to terminal-event changes are strongly expressed in both A1 and PEG, followed by longer-window, field-specific positive ERPs that are more prominent in PEG for the local deviation. We also observed meaningful responses for omission and global effects. Model-based estimations can investigate the scale of effective integration windows in each area. Together, these results quantify how cortical fields coordinate prediction errors and updates across timescales, linking computational prediction of surprise to mesoscale physiology.

SU14. Binaural Interaction Creates Diverse Azimuth Tuning Curve Shapes Across Auditory Midbrain Neurons

Emili Garretson¹, Joshua Mencsik¹, Mitchell Day^{*1}

¹*Ohio University*

Background: Neurons in the central nucleus of the inferior colliculus (ICC) exhibit spatial receptive fields due to underlying neural sensitivity to acoustic cues that covary with sound source location, including binaural cues (interaural time difference [ITD] and interaural level difference [ILD]), and monaural cues (spectral shape and acoustic gain within each ear). The present study examines how these cues shape each neuron's azimuth tuning curve (i.e., the function of firing rate vs. source location within the front horizontal plane), and whether the effects of cues differed with neural characteristic frequency (CF).

Methods: Broadband noise stimuli were presented to awake rabbits of both sexes in virtual acoustic space using each rabbit's own head-related transfer functions. Stimuli were presented either monaurally (contralateral ear) or binaurally, with transfer functions digitally manipulated in some conditions to isolate neural sensitivity to ITD or ILD.

Results: For low-CF neurons (< 2.8 kHz), azimuth tuning curves measured under monaural presentation were mostly flat, whereas curves measured under binaural presentation took on a diversity of shapes, such as functions sloping upwards or downwards from ipsilateral to contralateral azimuths; functions with broad, bell-shaped tuning to various azimuths; and functions with complex shapes. Binaural interaction (i.e., the effect on firing rate of two ears vs. contralateral ear only) caused facilitation of rates in most low-CF neurons; rate facilitation or suppression was not biased to particular azimuths and could be driven by neural sensitivity to ITD, ILD, or the covariation of both. Unlike low-CF neurons, high-CF neurons (> 2.8 kHz) had azimuth tuning curves measured under monaural presentation that took on a diversity of shapes; binaural interaction in these neurons changed the shapes of tuning curves, but the shapes remained diverse. Binaural interaction caused suppression of rates in most high-CF neurons, which was biased towards ipsilateral azimuths; however, rate facilitation found in a minority of neurons was not biased to particular azimuths. Unlike low-CF neurons, rate suppression or facilitation in high-CF neurons was overwhelmingly driven by neural sensitivity to ILD.

Conclusions: Consistent with a diversity of tuning curve shapes found across both low- and high-CF neurons, the distribution of firing rates over the neural sample evoked by the noise stimulus was constant across azimuths except for a small decrease at the most extreme ipsilateral locations (60°–90°). Therefore, the pattern of firing rate activity across ICC neurons was inconsistent with azimuth decoding models that rely upon summed population activity.

SU15. Aging and Synaptopathy Lead to Impaired Temporal and Binaural Processing in the Auditory Brainstem, and Spatial Hearing, in the Mongolian Gerbil

Matthew Sergison^{*1}, Nathaniel Greene¹, Daniel Tollin¹

¹*University of Colorado Anschutz Medical Campus*

Background: Aging is known to lead to difficulty in binaural and spatial hearing, often before affecting hearing thresholds. One potential source of this may be Cochlear Synaptopathy (CS), or the loss of synapses between inner hair cells and auditory nerve fibers. CS occurs during aging, and is present prior to raised hearing thresholds. The mechanisms of how age-related CS could disrupt binaural hearing are unclear, but they likely involve the auditory brainstem, the first site to receive input from the auditory nerve fibers and the earliest site for binaural processing. Here, we assess behavioral, physiological, and histological measures of auditory brainstem dysfunction from aging and synaptopathy in the Mongolian Gerbil (*Meriones unguiculatus*).

Methods: Cohorts consisted of young (2-10 month) and aged (> 30 month) gerbils. We recorded auditory brainstem responses (ABRs), envelope following responses (EFRs), spatial hearing behavior, and in vivo single-cell electrophysiological responses from cochlear nucleus and trapezoid body units. From the ABRs, we also measured the Binaural Interaction Component (BIC), a biomarker of spatial hearing abilities. To see if these measurements correlated with behavioral changes, gerbils were tested utilizing prepulse inhibition of the acoustic startle response (PPI) on two sets of tasks: 1) gap detection in broadband noise and 2) sound location spatial acuity. We also assessed synaptopathy by staining cochlea for presynaptic (Ctbp2) and postsynaptic (GluA2) markers and inner hair cell bodies (Myosin VIIa).

Results: We found an increase of synaptopathy, quantified by a decrease of colocalized pre- and postsynaptic markers per inner hair cell, in aged gerbils compared to the young cohort. This corresponded with a decrease in ABR Wave I and Wave III amplitudes, but not a significant reduction in hearing thresholds. The impaired ABRs and lack of threshold shifts indicate an impairment of neural synchrony in the brainstem. Aged animals exhibited reduced BIC amplitude, as well as impaired modulation of BIC amplitude with variation of interaural time differences (ITDs), indicating a reduction of brainstem binaural encoding in aged animals. We also found a reduced synchrony in EFR recordings, further showing physiological dysfunction in the auditory brainstems of the aged cohort. These findings corresponded with a reduction of synchrony to amplitude modulated stimuli recorded in vivo from bushy cell axons and medial nucleus of the trapezoid body (MNTB) neurons. Behaviorally, aged animals had higher thresholds of detection for both gap length and spatial acuity, indicating impaired temporal and spatial hearing behaviors.

Conclusions: Collectively, these data reveal that aged gerbils have impaired auditory brainstem physiology, partly as a result of synaptopathy, which underlies behavioral issues in temporal and spatial auditory processing similar to that exhibited by aged humans. [Supported by NIDCD 1F31DC021622-01]

SU16. Impaired Temporal Precision in Auditory Brainstem Processing Underlies Sound Localization Deficits in a Novel Mouse Model of Spinocerebellar Ataxia Type 13

Oskar Markkula^{*1}, Mihai Stancu², Viviana Ritacco², Theo Cercia², Ian Forsythe³, Conny Kopp-Scheinpflug²

¹Ludwig Maximilian University Munich, ²Division of Neurobiology, Faculty of Biology, LMU Munich, ³Auditory Neurophysiology Laboratory, College of Life Sciences

Background: Spinocerebellar Ataxia Type 13 (SCA13) is an inherited motor disorder characterized by an additional deficit in sound localization, despite otherwise normal hearing. This deficit arises from point mutations in the gene encoding the voltage-gated potassium channel Kv3.3, which is essential for neurons that support high-frequency firing, such as those in the auditory brainstem. To investigate the neural circuit mechanisms underlying this auditory impairment, we developed a novel CRISPR-Cas9 mouse model expressing the human R420H Kv3.3 mutation, which disrupts the S4 voltage sensor and impairs channel function.

Methods: The investigation was conducted using whole-cell patch-clamping, in vivo single unit recordings and imaging using immunostaining.

Results: Histological analysis of the auditory brainstem in R420H mutant mice revealed only a mild, age-unrelated reduction in cell numbers within the Lateral Superior Olive (LSO), without evidence of significant neurodegeneration. This suggests that the observed deficits are primarily functional rather than due to degenerative cell loss. A slight disruption in Kv3.3 protein transport was also noted, which might further contribute to the phenotype. However, the most pronounced effects of the mutation were observed in action potential (AP) dynamics.

Whole-cell patch-clamp recordings from brainstem slices demonstrated that the R420H mutation substantially broadens APs, particularly in the LSO (with a 2–3-fold increase in AP half-width) and to a lesser extent in the medial nucleus of the trapezoid body (MNTB; 1.5–2-fold increase). As a result, both MNTB and LSO neurons showed high failure rates during high-frequency stimulation (500 Hz in MNTB and 200 Hz in LSO). In the LSO, firing failures were strongly correlated with prolonged AP duration and were further exacerbated by significantly extended excitatory and inhibitory postsynaptic currents.

In vivo single-unit recordings confirmed that broadened APs reduce the maximum firing rates of MNTB and LSO neurons. Importantly, we found a marked imbalance between ipsilateral excitation and contralateral inhibition converging onto LSO principal cells. This disruption in synaptic integration manifested as a significantly reduced binaural interaction component (BIC) in auditory brainstem response (ABR) recordings.

Conclusions: Collectively, these results demonstrate that the R420H Kv3.3 mutation compromises the temporal fidelity of auditory brainstem neurons, disrupting the precise balance of excitation and inhibition necessary for accurate sound localization. This establishes a direct mechanistic link between ion channel dysfunction, neural circuit impairment, and the specific auditory deficits observed in SCA-13.

SU17. Active Sensorimotor Strategies for Sound Localization in Complex Acoustic Scenes

Rachel Cassidy^{*1}, Ross Williamson¹

¹*University of Pittsburgh*

Background: In natural environments, animals must react appropriately to behaviorally relevant sounds, such as those signaling predators or food sources, while ignoring competing auditory signals. Effective responses require identifying both the identity and location of sounds. The psychophysics of sound localization have been well characterized by presenting stimuli at varying positions relative to an animal's head, which is kept stationary for precise spatial control.

However, such approaches do not capture the sensorimotor strategies animals use during active navigation. In real-world settings, auditory spatial perception is shaped by environmental noise, behavioral context, and self-motion. Animals frequently orient their heads and bodies to reduce perceptual ambiguity and improve localization accuracy. To investigate the behavioral strategies that support naturalistic sound localization, we developed a freely-moving auditory discrimination task.

Methods: We trained C57BL/6J mice to localize a target sound along the perimeter of an open, circular arena while ignoring a distractor presented simultaneously from another azimuthal position. Stimuli were bandpassed white noise of varying center frequencies. After trial initiation, both stimuli played continuously until mice approached and licked a water spout beneath the perceived target. Since mice were free to explore before making a decision, this design enabled observation of how animals integrate dynamic sensory input with self-motion.

Results: Over several weeks of training, mice adopted characteristic sensorimotor strategies that facilitated task learning, including rapid head and body “scanning” movements at stimulus onset and 180° turns to correct errant approaches towards the distractor. These behaviors became more frequent with learning and coincided with increased accuracy, shorter reaction times, and more stereotyped trajectories.

Conclusions: These results demonstrate that in an unconstrained sound localization task, mice resolve spatial ambiguity with dynamic movement strategies and update motor plans continuously in response to ongoing acoustic input. Our ongoing work investigates the neural circuits underlying this dynamic sensorimotor loop. While auditory cortex encodes spectral features and learned associations, it lacks a map of egocentric space. In contrast, its projection targets in the midbrain, such as the superior and inferior colliculi, are spatially tuned and mediate orienting behaviors. We are currently using pharmacological and optogenetic perturbations to dissect how corticocollicular circuits contribute to spatial decision-making, offering new insight into how animals transform auditory input into adaptive action.

SU18. The Impact of Response Method on Sound Localization Performance

Andrina MacDonald^{*1}, Sebastian Ausili¹, Sandra Prentiss¹, Jean Laguerre¹, Hillary Snapp¹

¹*University of Miami*

Background: Sound localization is a key marker of binaural hearing, relying on the brain’s integration of interaural timing and level cues. Despite its clinical relevance, conventional localization assessments lack ecological validity and do not capture the reflexive nature of natural orienting. Standard methods, such as pointing or reporting a speaker number, require conscious decision-making and are susceptible to visual biases, potentially limiting their sensitivity to true auditory spatial perception. In natural listening, orienting to a sound involves a coordinated sequence of eye and head movements: the eyes typically move first, providing a rapid, low-latency estimate of target location, followed by slower head adjustments that align auditory and visual cues. We hypothesize that combined reflexive head-and-eye orienting offers a more direct and automatic measure of spatial hearing. This study examines how response modality influences localization performance in normal-hearing adults, with attention to both accuracy and precision.

Methods: Fifteen normal-hearing adults participated in a within-subject, repeated-measures design. Localization was assessed under two hearing conditions: normal binaural hearing and simulated monaural hearing (earplug + muff). Broadband Gaussian white noise (0.2–20 kHz) was presented at 50, 60, or 70 dBA from 19 loudspeakers spanning $\pm 90^\circ$ in azimuth, separated by 10° . Tasks were performed in both vision-allowed and vision-denied conditions to examine the influence of visual cues while eliminating feedback during trials. Participants completed three response modalities: (1) head movement alone, (2) combined head and eye tracking, and (3) verbal reporting of speaker number (vision only). For each trial, head and eye trajectories, reaction times, and response times were recorded. Localization performance was quantified using regression of target azimuth onto participant responses, providing gain, bias, and R^2 . Mean absolute error measured overall accuracy, while trial-to-trial variability captured precision.

Results: Response modality significantly influenced localization outcomes. Combined head-and-eye tracking demonstrated lower mean absolute error and reduced variability compared with head-only responses. Verbal reporting was associated with longer reaction times and higher variability, reflecting additional cognitive and motor demands. Simulated monaural hearing amplifies these differences, with reflexive orienting responses maintaining greater sensitivity to spatial cues than verbal responses. Regression analyses suggests improved alignment for combined head and eye tracking with true target locations.

Conclusions: Response method shapes both the accuracy and temporal dynamics of measured localization. These results suggest that reflexive orienting responses, particularly combined head and eye movements, provide a more precise and sensitive measure of auditory spatial perception than traditional methods. These findings underscore the importance of ecologically valid response modalities in both experimental and clinical assessments of spatial hearing. Careful consideration of response method has implications for evaluating auditory performance, designing experiments, and interpreting outcomes in hearing-impaired populations or users of hearing-assistive devices.

SU19. The Impact of Chloride Homeostasis on the Development of LSO Neurons

Jinrong He¹, Tamara Radulovic¹, Christian Keine*¹, Ivan Milenkovic¹

¹*Carl von Ossietzky Universität Oldenburg*

Background: In the developing nervous system, inhibitory inputs are often transiently depolarizing due to high intracellular chloride concentrations, a process thought to guide neuronal maturation and synaptic refinement. In the auditory brainstem, this chloride gradient is primarily regulated by the transporters NKCC1 and KCC2. However, the specific role of this early depolarizing inhibition in shaping developing auditory circuits remains unclear.

Methods: To investigate the functional impact of early depolarizing inhibition, we used a mouse line with a double mutation in the KCC2 gene that enhances chloride extrusion and abolishes depolarizing GABA/glycinergic responses. We performed whole-cell patch-clamp recordings in acute brainstem slices targeting principal neurons of the lateral superior olive (LSO), a nucleus with well-characterized inhibitory inputs. Experiments were performed in animals at postnatal day 14 (P14) and P20, corresponding to the period shortly after hearing onset and following early auditory experience.

Results: We found that gross morphological development and intrinsic membrane properties of LSO neurons in KCC2 mutant mice were comparable to those in wildtype animals. However, afferent fiber stimulation revealed that amplitudes of inhibitory postsynaptic current (IPSC) amplitudes were significantly reduced with no change in IPSC kinetics or short-term plasticity. A similar reduction in current amplitude was observed with direct application of glycine, suggesting that the decrease in IPSC size is due to postsynaptic alterations such as a reduction of glycine receptors.

Conclusions: Our preliminary findings suggest that while early depolarizing inhibition is not essential for gross morphological development or maturation of intrinsic membrane properties of LSO neurons, it might be critical for fine-tuning synaptic strength, likely through a postsynaptic mechanism involving the regulating glycine receptor expression.

SU20. Maturation of Intrinsic Membrane Properties in Octopus Cells of the Mouse Cochlear Nucleus

Renee Taing¹, Julian Caesar¹, Abigail Gemechu¹, Ella Waldman¹, Lauren Kreeger^{*1}

¹*University of Pennsylvania*

Background: During postnatal development, synaptic refinement and electrophysiological maturation occur simultaneously to finely tune auditory brainstem circuits. Before ear canal opening, spontaneous peripheral activity establishes precise circuitry across the central auditory system. When sound-driven activity begins, further refinement occurs through synaptic pruning. For octopus cells of the mammalian ventral cochlear nucleus, extreme intrinsic membrane properties are essential for the submillisecond temporal integration that supports spectral edge detection. Octopus cells in mature mice have low input resistances ($\sim 4\text{--}10\text{M}\Omega$), fast time constants ($\sim 200\mu\text{s}$), and large low-voltage-activated potassium and hyperpolarization-activated conductances ($\sim 40\text{nS}$ and $\sim 60\text{nS}$ at rest, respectively). These membrane properties, combined with the large diameter dendrites, allow for rapid and precise integration of auditory nerve input. We aim to define when these anatomical and physiological specializations emerge relative to the onset of hearing.

Methods: We examined the timeline of octopus cell maturation using in vitro whole-cell current clamp recordings from postnatal day 4 to 35 (P4–35) mice. Active and passive membrane properties including input resistance, time constant, HCN sag ratio, and action potential half-width were assessed. Auditory nerve inputs were evoked by electrical stimulation, and cells were filled with biocytin for post hoc three-dimensional reconstruction of dendritic arbors.

Results: By the time of ear canal opening (P10–12), intrinsic properties of octopus cells are relatively mature. Measures of input resistance, time constant, HCN sag ratio, and spike half-width are comparable at P10 and P16. Further, reconstructions of dendritic arbors revealed no meaningful changes between P10 and P16. Despite this stability at the onset of hearing, octopus cells underwent a rapid transformation between P4 and P10. During this early period, dominated by spontaneous cochlear activity, input resistance decreased, time constant shortened, sag ratio increased, and action potentials narrowed.

Conclusions: The timeline for anatomical and physiological development suggests that the properties underlying octopus cell function are established by the time sound-driven activity begins. Octopus cells rapidly mature when spontaneous waves of activity from the cochlea

dominate activity patterns in the octopus cell circuit. The rapid maturation that precedes ear canal opening highlights a critical developmental window shaped by spontaneous activity rather than acoustic experience. Octopus cells thus enter the onset of hearing configured for fast temporal integration. Future work will test how altering peripheral activity during this early window influences octopus cell development. By comparing normal and disrupted activity patterns, these experiments will define the contribution of spontaneous cochlear activity to the emergence of octopus cell function.

SU21. The Effect of Electrode Placement on the Auditory Brainstem Response

Thomas Stoll¹, Ross Maddox¹

¹*University of Michigan*

Background: The auditory brainstem response (ABR) is commonly used both in the clinic and the lab to estimate hearing thresholds and examine the subcortical auditory system. However, the location of the neural generators and the size of the responses lead to poor signal-to-noise ratio (SNR), requiring long test times to acquire an adequate signal. Typically, earlobes or mastoids are used as the reference electrodes, but other reference locations may improve signal quality and speed response acquisition. Previous work has shown that the nape of the neck reduces muscle artifact in subcortically generated frequency-following responses, which may also benefit the ABR.

Methods: Subjects were presented with one hour of randomly timed click stimuli at 80 dB peSPL with a mean rate of 40 clicks per second. EEG was recorded using a Biosemi Active3 system with a 64-channel cap, and additional electrodes were placed on the earlobes, nose, nape of the neck, and collarbone for offline re-referencing during analysis. Two more electrodes were placed by the left eye to aid in the removal of eye-related artifacts.

Responses were computed separately for the left ear and right ear clicks. The SNRs of the responses were estimated based on the variance of the waveform in the response window compared to the baseline variance. For each reference electrode, responses were re-referenced and the SNR was calculated for the response from each electrode in the cap to identify optimal placement of electrodes to obtain the ABR.

Results: Preliminary results indicate the nape and earlobes to be the best choices for reference electrodes, producing responses with the highest SNRs. The nape provides a larger ABR wave V and less muscle artifact than earlobes. The combined earlobes had the next best SNR. Wave I was most visible when referenced against the ipsilateral earlobe. The positive electrodes with the best SNRs were located near the vertex of the head for all references, with commonly used frontal electrodes showing worse SNR.

Conclusions: The specific electrode montage can have a large impact on the SNR of ABRs. In a bipolar montage, the location of both electrodes should be considered in the context of the specific goals of the recording (e.g. fast overall response detection versus examination of wave I). Selecting the optimal montage may yield substantial improvements in response quality, which is especially important when recording time is limited.

SU22. Dopamine Receptor Expression in the Mouse Superior Olivary Complex

Sonia Weimann*¹, R. Michael Burger¹

¹*Lehigh University*

Background: Neuromodulatory circuits influence auditory neural computations by regulating presynaptic and/or postsynaptic mechanisms at multiple levels of processing. However, modulation in auditory regions between the periphery and the cortex have remained largely unexplored. Recent work by our laboratory has demonstrated several mechanisms of modulation in the superior olivary complex (SOC) by a network of cholinergic inputs (Beebe et al. 2021, Zhang and Burger 2024, Weimann et al. 2024). In addition to cholinergic input, dopaminergic projections to the SOC have been documented (Nevue et al. 2016). However, there have been no studies demonstrating expression of dopaminergic receptors or physiological modulation by dopamine in SOC neurons. While dopaminergic neurons compose a small population in the brain, they have potent and widespread impacts on targets throughout the nervous system. A diverse array dopamine receptor subtypes (D1-5), underlie the variable physiological outcomes of dopaminergic modulation. Dopamine receptors are members of the G protein-coupled receptor family and divided into two classes. D1 and D5 belong to the D1-like family while D2, 3, and 4 are members of the D2-like family. Each of these families of dopamine receptor subtypes initiate unique downstream cascades.

Methods: To investigate the potential auditory processing function(s) of the dopaminergic input to the SOC, we first used immunohistochemistry to describe the expression patterns of dopamine receptor subtypes 1-5 in mouse SOC neurons in mice aged P10 and P30 before and after hearing onset (~P12). Antibodies directed against D1-D5 receptors were used to examine expression in the principal nuclei of the SOC. Presynaptic expression was confirmed by colocalization of dopamine receptor stain with VGLUT1.

Results: We demonstrate that all five DA receptor subtypes are differentially expressed in the mouse SOC. D1 is expressed in SOC nuclei pre and post hearing onset. In the MNTB, D1 appears to have weak expression early in development with strong post-synaptic expression later at P30. D2 appears to be both pre and postsynaptically expressed at P10 with primarily postsynaptic expression by P30. D3 demonstrates a primarily presynaptic expression pattern across development in the MNTB and the LSO. D4 exhibits presynaptic expression at P10 with stronger postsynaptic expression by P30 in the MNTB while the LSO exhibits primarily postsynaptic expression. Finally, our staining suggests that D5 receptors are weakly expressed across development in SOC nuclei.

Conclusions: Our results show for the first time that DA receptor subtypes 1-5 are expressed in the mouse SOC with unique expression profiles. These results strongly suggest that dopamine is likely to provide neuromodulatory signaling to the SOC.

SU23. Age-Dependent Regulation of Calcium Responses in the Mouse Medial Nucleus of the Trapezoid Body Neurons

TASMUNA TANMY*¹, Huimei Wang¹, Yong Lu¹

¹*Northeast Ohio Medical University*

Background: In the central auditory system, Ca²⁺ signaling plays a pivotal role in the regulation of cellular processes including neuronal development and maturation. Disruption of Ca²⁺ homeostasis and signaling causes abnormal development of auditory circuits, compromising auditory processing and behavior. Here, using Ca²⁺ imaging in brain slices obtained from mice that genetically expressed calcium indicator GCaMP in glycinergic cells, we investigated the underlying mechanisms for developmental Ca²⁺ regulation in neurons of the medial nucleus of the trapezoid body (MNTB), a brainstem nucleus involved in sound localization.

Methods: Brainstem slices with visually identified MNTB were prepared from GlyT2-Cre/tdT-GCaMP6f mice of either sex, which is a transgenic line obtained by crossing the glycine transporter 2-Cre recombinase mouse to the reporter line ROSA26-tdT-GCaMP6f. Ca²⁺ imaging experiments were performed at several milestone ages of development including P0, P7, P14 and P21, at 35 °C. Fluorescence images of principal MNTB neurons were obtained under excitation wavelength of 480 nm. Ca²⁺ signals were recorded in response to activation of various excitatory and inhibitory transmitter receptors through bath application of their respective agonists and under electrical stimulation applied to their afferent inputs.

Results: Prior to hearing onset at postnatal day 7 (P7), Ca²⁺ signals were produced in MNTB neurons when the glutamate receptors (NMDARs, AMPARs, group I mGluRs) were activated by bath application of their respective agonists (NMDA 200 μM, AMPA 100 μM, 3,5-DHPG 200 μM). After hearing onset (P14 and P21), the responses declined dramatically for NMDA receptors and group I mGluRs. AMPAR-mediated signals remained relatively high. In contrast, Ca²⁺ transients in response to GABA (100 μM) and glycine (200 μM) were only observed in neonatal mice and diminished a few days after birth. Transmitter receptor-mediated Ca²⁺ signaling was largely blocked by their specific antagonists. Furthermore, electrical stimulations applied to the excitatory afferent fibers innervating MNTB, triggered release of glutamate which elicited Ca²⁺ signals, in a stimulus intensity- and frequency-dependent manner, via glutamate receptors and potentially voltage-gated Ca²⁺ channels. Although, cells from all experimental age groups were able to generate action potentials with no significant differences, under whole cell patch-clamp recordings, using similar stimulation parameters. However, calcium signals elicited in response to electrical stimulations, followed similar down-regulation fashion as the drug applications, in the MNTB neurons, over the ages of development.

Conclusions: Taken together, Ca²⁺ signaling in MNTB neurons, mediated by various transmitter receptors was developmentally down-regulated and subject to refinement by hearing experience.

SU24. Effects of Cochlear Synaptopathy on Single-Unit Cochlear Nucleus Responses in the Budgerigar

Leslie Gonzales^{*1}, Margaret R. Youngman¹, Kenneth Henry¹

¹*University of Rochester Medical Center*

Background: Cochlear synaptopathy (CS) is a commonly occurring pathology in aging humans, defined as the loss of synapses between hair cells and auditory-nerve fibers (ANFs). CS is hypothesized to impair perception of sounds in noise, but underlying neural mechanisms are unknown. Recent studies suggest that CS can amplify auditory-nerve onset responses and alter temporal dynamics. However, effects of CS on brainstem encoding remain less explored. The current study quantified effects of CS on neural encoding in the nucleus angularis (NA) of the budgerigar, a parakeet species. NA is one of two avian brainstem cochlear nuclei receiving direct input from the auditory nerve. Budgerigars were selected based on recent studies of kainate-induced CS in this species and previous behavioral research demonstrating performance comparable to humans for various complex auditory discrimination tasks.

Methods: The current experiment compared basic NA response properties including frequency tuning curves, post-stimulus time histograms (PSTHs), and rate-level functions between control and CS-induced budgerigars. In CS animals, substantial (60-70%) ANF loss was induced via intracochlear infusions of 1-2 mM kainic acid. Distortion-product otoacoustic emissions were used to confirm normal hair-cell function. For in-vivo recordings of NA units, a craniotomy was made above the anterior, vertical semicircular canal. A glass electrode with 40 to 80 M Ω impedance was placed in the flocculus of the cerebellum and driven into NA to record single-unit responses. PSTHs were obtained with a characteristic-frequency (CF) tone presented 30 dB above threshold. Rate-level functions were created by randomly presenting CF tones of varying sound levels (0 to 80 dB SPL).

Results: NA neurons in control budgerigars had primary-like, onset, and chopping PSTHs in response to CF tones. Tuning curves were V-shaped, with characteristic frequencies within the range of the budgerigar's behavioral sensitivity (i.e., up to 5-6 kHz). Strength of synchrony was calculated from PSTHs using vector strength (VS). VS was greatest below 1 kHz and generally insignificant above 2 kHz, in contrast to budgerigar ANFs which show significant VS up to 4-5 kHz. From rate-level functions, we found that some NA units monotonically increased firing rate as sound levels increase, while others had nonmonotonic rate-level functions. NA units in CS-induced animals showed the same PSTH response categories and had broadly similar tuning curves, VS of phase-locking, and rate-level functions to control units. Population results are compared between groups to quantify changes in NA encoding with CS.

Conclusions: Preliminary results suggest that NA units in the CS-induced budgerigars have similar characteristics to control units. Further analyses will test population differences and characterize potential changes in onset activity, adaptation, and envelope encoding in CS-induced animals. Research in this species can provide important insight into the neural bases of normal and hidden hearing loss.

SU25. Semilunar Nucleus: Physiology, Connections, and mGluR Modulation

Huimei Wang^{*1}, Xiaoyu Wang², Yuan Wang³, Anton Sumser⁴, Oskar Markkula⁴, Conny Kopp-Scheinpflug⁴, Yong Lu¹

¹Northeast Ohio Medical University, ²Jinan University, ³Florida State University, ⁴Ludwig Maximilian University Munich

Background: Besides the calyx of Held input, additional non-calyceal inputs to the medial nucleus of the trapezoid body (MNTB) have been reported, but their functions and origins are largely unknown. Recently, a non-calyceal input originating from the semilunar nucleus (SLN) to the ipsilateral MNTB was identified in the rat (Gómez-Martínez et al. 2023, Front Neuroanat). To understand the function of this novel neural circuit, we investigated the physiology and connectivity of SLN in mice, with a focus on neuromodulation mediated by group I metabotropic glutamate receptors (mGluR1 and mGluR5).

Methods: We used a combination of brain slice electrophysiology, immunohistochemistry, and viral tracing. We conducted whole-cell patch clamp and cell-attached recordings at 35 °C in brainstem slices from mice of two age groups (< HO, before hearing onset, P7-P12; > HO, after hearing onset P13-P39). The SLN was identified by anatomical landmarks and/or calbindin1 expression pattern. Immunohistochemistry was used to examine the expression of mGluR1, mGluR5, and calbindin1. Retrograde viral tracing was used to reveal connections between SLN and other auditory structures. Mean and number of cells are reported.

Results: SLN neurons were highly excitable, with a low current threshold (< HO, 47.7 pA, n=60; > HO, 35.0 pA, n=12), partly owing to their high input resistance (< HO, 406.7 MΩ, n=56; > HO, 452.0 MΩ, n=13). A subpopulation of SLN neurons (< HO, 8/38 cells; > HO, 1/7 cells) exhibited spontaneous spikes at rest. Activation of group I mGluRs with 3,5-DHPG (200 μM) enhanced the excitability of SLN neurons and increased their spontaneous spike rate (< HO, control, 0.71 Hz, n=37; DHPG: 4.42 Hz, n=37; paired t-test p < 0.0001; > HO, control, 0.20 Hz, n=7; DHPG: 7.24 Hz, n=7; paired t-test p = 0.0156). The enhancement was partially blocked by an antagonist for mGluR5 (MPEP, 1 μM). The modulatory effect seemed long-lasting before and shorter after hearing onset. Electrical stimulation of the area dorsal to the SLN evoked EPSCs in SLN neurons, which summated temporally to 100 Hz synaptic stimulation. Ipsilateral electrical stimulation putatively activating the input from SLN to MNTB evoked glutamatergic EPSCs in MNTB neurons. Triple immunostaining confirmed the presence of mGluR1 and mGluR5 within the SLN, revealing a heterogeneous distribution pattern surrounding calbindin1-immunoreactive neurons. Retrograde viral tracing confirmed a descending projection of SLN neurons to the ipsilateral MNTB in mice. The MNTB-projecting SLN neurons in turn receive descending projections from the inferior colliculus and auditory cortex.

Conclusions: Neurons in the mouse SLN were intrinsically highly excitable and received a glutamatergic input via a descending pathway. Neurons in the MNTB received a non-calyceal glutamatergic projection originating from the ipsilateral side. Group I mGluRs enhanced the SLN excitatory output, potentially forming a tonic excitation in MNTB neurons, which may improve their temporal processing.

SU26. Why Some Listeners Shine in the Cocktail Party: Brainstem Envelope Coding Explains It

Anu Sreenivasan Nair*¹, Pedro Andres Alba Diaz¹, srikanta Mishra¹

¹*University of Texas at Austin*

Background: Understanding speech in complex acoustic environments is a fundamental challenge of everyday listening. Even among individuals with clinically normal hearing, there is

wide variability in the ability to follow a target voice amidst competing talkers. This “cocktail party problem” arises from both energetic masking (overlapping sound energy) and informational masking (confusion between similar voices), yet the neural mechanisms underlying individual differences remain poorly understood. One candidate mechanism is the precision of brainstem encoding of temporal envelope periodicity, which supports the extraction of pitch cues and voice segregation. While amplitude-modulated brainstem responses reliably reflect phase-locking to periodicity, it is unknown whether individual differences in suprathreshold envelope coding predict behavioral benefits in speech-in-speech tasks versus speech in steady-state noise. We hypothesized that individual differences in suprathreshold periodicity encoding, particularly at reduced modulation depths, would correlate with behavioral measures of talker-sex release from masking, but not necessarily with performance in steady-state noise.

Methods: we measured ASSRs at 101 Hz to amplitude-modulated stimuli at 40% and 100% AM depths in a cohort of normal-hearing adults ($n=30$; mean age = 20.73 years; females=28). Neural responses were quantified using phase-locking value (PLV) obtained from Wavelet transform and signal-to-noise ratio (SNR). Behavioral performance was assessed using a two-talker speech-in-speech task, designed to elicit talker-sex release from masking, and a digit triplet in speech-shaped noise.

Results: Revealed a selective relationship: PLV at 40% AM robustly predicted the magnitude of talker-sex release from masking ($r \approx 0.35$, $p = 0.015$), whereas PLV at 100% AM and SNR measures did not. No significant associations were observed between any neural metrics and speech-in-noise performance. These findings indicate that suprathreshold envelope encoding in the brainstem captures individual differences in neural fidelity that are critical for voice segregation, but not for overcoming energetic masking.

Conclusions: Our data support the idea that precision of suprathreshold temporal encoding at the brainstem level underlies listeners’ ability to exploit pitch differences between competing talkers. The absence of a relationship with speech in speech-shaped noise performance underscores the distinct neural mechanisms for informational versus energetic masking. These findings highlight the importance of assessing suprathreshold envelope encoding when predicting speech-in-speech perception and may inform future strategies for assessment and intervention for speech-in-noise deficits in listeners with normal audiograms.

SU27. Spatial Gradient of Synaptic Input Subtypes on Bushy Cells Along the Lateral- Medial Axis of the Anteroventral Cochlear Nucleus

Angela Wang*¹, Mina Shenouda¹, Zixu Guo², Shengyin Lin², Ruili Xie²

¹The Ohio State University Wexner Medical Center, ²The Ohio State University

Background: Bushy cells in the anteroventral cochlear nucleus (AVCN) are among the first central auditory neurons to receive input from the auditory nerve (AN). These principal cells are innervated by large, specialized synapses, known as the endbulbs of Held, from spiral ganglion neurons (SGNs) that enable precise transmission of temporal fine structure in sound. Our previous study showed that bushy neurons are innervated by various combinations of AN synapses from different subtypes of type-I SGNs. However, it remains unclear whether any spatial distribution pattern exists among different subtypes of AN synapses in AVCN bushy

neurons. In this study, we investigated whether bushy cells are spatially organized along the lateral-medial axis of the cochlear nucleus based on the distribution of different AN input subtypes.

Methods: To investigate this spatial organization, we performed immunohistochemical labeling in the cochlear nuclei of CBA/CaJ mice. Cochlear nuclei were dissected out, cryo-sectioned, and stained using antibodies against calretinin, vGluT1 and vGluT2 to probe the distribution of different AN input subtypes on bushy cells.

Results: We identified gradients of AN input subtypes along the lateral-medial axis of the AVCN. Calretinin-positive type Ia synapses were more densely expressed on the lateral side, whereas vGluT2-positive non-type Ia synapses showed higher expression medially. This spatial distribution suggests that bushy cells receive input from distinct AN subtypes depending on their position within the AVCN.

Conclusions: Our findings reveal a spatial gradient of synaptic input along the lateral- medial axis on bushy cells in the AVCN. It suggests that in addition to the tonotopic organization along the dorsal-ventral axis and the differential cell-type distribution along the rostral-caudal axis, the AVCN may also be functionally compartmentalized along the lateral-medial axis. This spatial differentiation likely contributes to the processing of complex auditory information from diverse AN inputs.

SU28. Expression of Kv4 Channels in Bushy Neurons of the Cochlear Nucleus: An Immunohistochemical Study

Mina Shenouda^{*1}, Angela Wang¹, Chuangeng Zhang², Zixu Guo², Shengyin Lin², Ruili Xie²

¹*The Ohio State University Wexner Medical Center*, ²*The Ohio State University*

Background: Bushy neurons housed in the anteroventral cochlear nucleus (AVCN) are specialized neurons that process temporal sound information critical for auditory function. These neurons possess unique biophysical membrane properties due to the expression of various ion channels. These include voltage-gated potassium channels. Our previous study used brain slice electrophysiology to isolate A-type currents mediated by Kv4 channels in most bushy neurons and revealed their role in regulating neuronal excitability and temporal precision of spikes. However, conflicting observations were reported by multiple studies, in which no A-type current was found in bushy neurons using electrophysiology. To further confirm our previous findings and characterize expression patterns of Kv4 channels in bushy neurons, we investigated the expression of Kv4.2 subunit channels in AVCN bushy neurons, using immunohistochemistry.

Methods: We investigated Kv4.2 expression in bushy cell through immunohistochemical staining and confocal microscopy in CBA/CaJ mice. Antibodies against vGluT1 and Kv4.2 subunit were utilized to identify bushy neurons and investigate their expression of Kv4 channels. Specifically, bushy neurons were identified through the innervation of end bulbs of held synapses around cell bodies labeled by vGluT1. Cell bodies were corroborated through DAPI staining. Bushy cell expression of Kv4 channels was qualitatively analyzed through Kv4.2 presence on cell bodies.

Results: Immunohistochemical staining showed that most bushy neurons of the AVCN were labeled by Kv4.2 antibody. No colocalization between vGluT1 and Kv4.2 staining was observed, suggesting that end bulb of Held synapses do not express Kv4 channels.

Conclusions: These results confirmed our previous findings that a majority of bushy neurons express Kv4 channels. These channels help shape the biophysical membrane properties and promote temporal precision of spikes in these neurons. Our study suggests that A-type currents play an important role in processing auditory information at the first neural station of the central auditory system. This is expected to impact higher auditory nuclei and promote hearing sensation.

SU29. Diffusion Tensor Imaging of Brainstem Auditory Pathway in Controls and Prospective Cochlear Implant Patients

Khoi Do¹, Dane Walock¹, Bhargav Rallapalli¹, Joshua Kastl¹, Ethan Bates¹, Madeline Webber¹, Dylan Clapp², Ruihong Lyu¹, Rebecca Reinert², Anne Vance², Jacqueline Weinstein², Lisa Wenstrup², Theresa Hammer², Steve Gordon², Daniel Sun², Thomas Talavage*¹

¹*University of Cincinnati*, ²*University of Cincinnati College of Medicine*

Background: Cochlear implants are implantable devices capable of partially restoring hearing via electrical stimulation of the auditory nerve, mimicking normal hearing conditions. Outcomes following implantation vary widely, particularly among patients with long durations of deafness. This variation limits clinicians' ability to predict who will benefit from the procedure. Neurobiological changes in the auditory pathway due to prolonged auditory deprivation may cause this variability, however, current objective markers are poorly characterized. Diffusion tensor imaging, a magnetic resonance imaging technique sensitive to white matter microstructure, offers a noninvasive means to assess subcortical auditory pathways. Some studies have reported a link between categories of auditory performance scores, but there is currently no set of biomarkers for candidate screening.

Methods: Data acquired from 23 participants were used in this project: 15 adult cochlear implantation candidates (aged 39-77) with sensorineural hearing loss, and eight high-school aged male students without reported hearing deficits as a reference group. MR imaging involved both T1-weighted and diffusion-tensor weighted scans (Patients: Philips MR7700, 1.7mm isotropic resolution; Controls: GEHC MR750, 2mm isotropic resolution).

T1 scans were registered to MNI152 space using FLIRT and FNIRT, and diffusion-weighted scans were processed using DiPy and FSL. Procedures included LPCA denoising, Gibbs ringing correction, brain extraction, and distortion correction via TOPUP and EDDY functions. White matter partial volume maps were generated via FAST and registered to DTI space. Tract masks were generated by using regions of interest (ROIs) associated with key auditory brainstem nuclei, such as the superior olivary complex (SOC), inferior colliculus (IC), and medial geniculate body (MGB) as key landmarks.

Average MNI space masks were obtained from Brainstem Navigator, registered using DiPy into both T1 and DTI space for all subjects, and averaged within population to create landmarks for

tract mapping. Probabilistic tractography was used on a subject specific basis and fit to the Constrained Spherical Deconvolution model, individually, for the left and right hemispheres. Streamlines that passed through all three ROIs were preserved.

A set of ROIs was generated from each population (Control and Patient) for the SOC, IC, and MGB. Group-specific ROIs were generated to account for variable partial volume averaging in the T1-weighted scans, ensuring preserved tractography would reside in the tissue.

Results: White matter bundle similarity was compared between the Patient and Control populations using DiPy's Bundle Analysis (BuAn) framework. No statistically significant differences were observed for these groups, but a modest linear relationship (r -squared = 0.45) was observed between the bundle similarity measure and age in the Patient population.

Conclusions: A small-sample pilot suggests a potential relationship between brainstem white matter fiber tract integrity and size and age of a prospective cochlear implantee. Further data collection is ongoing to expand the sample size and develop more uniform anatomical targets for group comparisons.

SU30. Detecting Individual Auditory Brainstem Responses (ABRs)

Malcolm Slaney¹, Emily Kuo^{*1}, Daibhid O Maoileidigh¹

¹*Stanford University*

Background: The Auditory Brainstem Response (ABR) is a measure of neural activity in response to sound stimuli. It is widely used for diagnosing hearing loss in humans and other animals. Current practice estimates hearing thresholds by identifying peaks in the mean ABR over hundreds of trials. However, thresholds based on the mean ABR alone decrease without bound as the number of trials used to estimate the mean increases.

We propose to score the similarity of each ABR trial with the population of ABR trials using covariance. By comparing the score distributions of stimulus-present and stimulus-absent trials, we define an ABR threshold based on the discriminability index d' . We show this measure converges as the number of trials increases.

Methods: We build a model to assess our new method, compare our new method with conventional methods, and confirm the theoretical basis for our method with a simple model and simulations.

We simulate ABR trials by generating deterministic waveforms with added Gaussian white noise. Increasing the amplitude of the deterministic waveform mimics responses to sounds of increasing stimulus level.

We then filter the simulated trials and calculate their mean for each stimulus level. At a given level, each individual trial is assigned a score equal to its covariance with the mean. The score distribution quantifies similarity between the trials.

Lastly, we compute the discriminability index d' value between the score distributions of a stimulus-present condition (non-zero waveform amplitude) with that of a stimulus-absent condition (no deterministic waveform). Because d' is the distance between the distributions, a stimulus is detected when d' is sufficiently large (for example, $d' > 1$). The stimulus level at which stimulus is detected is defined as the ABR threshold.

Results: We show that d' converges to a constant value as the number of trials increases. Consequently, ABR thresholds based on d' no longer decrease without bound as the number of trials increases. Using our simple model, we show how d' is related to the signal-to-noise ratio.

Conclusions: Previous ABR methods use the mean ABR waveform alone, causing the ABR threshold to depend on the number of stimulus trials. In this study, we introduce an alternative approach that uses covariance and d' to detect ABRs. This method defines an ABR threshold that becomes independent of the number of trials as the number increases. Future work will assess the utility of this approach using human and animal ABR data.

SU31. Enkephalin Regulation of Cochlear Nucleus Neuronal Function After Noise Exposure

Sidi Liu^{*1}, Ruijie Cai¹, Yiwei Du¹, Yaqiong Chen¹, huihui liu¹, Lei Song¹, Dian Jing¹, Hao Wu¹

¹*Shanghai Ninth People's Hospital, Shanghai Jiao Tong University School of Medicine,*

Background: While molecular and functional changes in inner ear cells post-noise exposure have received extensive attention, auditory brainstem alterations remain poorly understood. The cochlear nucleus receives signals from cochlear spiral ganglion neurons, processes/integrates them, and transmits to higher auditory centers. We show that single intense noise exposure induces pronounced molecular and functional changes in the cochlear nucleus as early as 1 day post-exposure, enriched in processes including synaptic transmission, ion channel activity, and cytoskeletal regulation. Notably, these changes persist to at least 3 days post-exposure. Concurrently, we found enkephalin plays an intriguing role here and investigated its potential cochlear nucleus protective function post-noise exposure.

Methods: We exposed 7-8-week-old C57BL/6J mice to 8-16 kHz noise at 109 dB SPL for 2 hours. The mice were then euthanized and dissected at 24 hours and 72 hours post-exposure to harvest cochlear nuclei, which were used for transcriptome sequencing or other molecular biology experiments. The results of RNA sequencing (RNA-seq) were validated using quantitative PCR (qPCR) or Western blotting (WB). Additional techniques employed included immunofluorescence staining, in situ hybridization, anterograde monosynaptic viral tracing, tissue clearing, whole-cell patch clamp recording, and auditory brainstem response (ABR) testing.

Results: Profound alterations in cochlear nucleus gene expression were observed at 1 day post-noise exposure. Enrichment analysis revealed the top enriched biological processes as synaptic reorganization, transsynaptic signaling, ion channel function, and cytoskeletal remodeling. Notably, proenkephalin (Penk) was the sole neuropeptide upregulated post-exposure, with sustained elevation through 3 days. Whole-cell patch clamp recordings localized Penk expression primarily to vertical cells of the dorsal cochlear nucleus (DCN). Via mWGA anterograde monosynaptic viral tracing, we demonstrated that Penk⁺ vertical cells innervate bushy and stellate cells in the ventral cochlear nucleus (VCN), which co-express δ - and μ -opioid receptors.

In vitro enkephalin perfusion induced hyperpolarization of resting membrane potential and reduced action potential firing in VCN neurons, suggesting a potential protective role against noise-induced hyperexcitability. Pretreatment with the δ -opioid receptor agonist SNC80 prior to noise exposure significantly ameliorated ABR threshold elevations, along with improved wave II latency and amplitude at 3 days post-exposure. Transcriptome sequencing and WB validation further revealed that δ -opioid receptor activation exerts neuroprotective effects—including anti-inflammatory and anti-apoptotic actions—via pathways including PI3K-AKT, MAPK, and NF- κ B.

Conclusions: A single intense noise exposure induces profound changes in gene expression in the mouse cochlear nucleus and upregulates proenkephalin (Penk) expression in vertical cells of the DCN. This upregulated Penk, via axonal innervation, modulates the electrophysiological properties of neurons in the VCN that express enkephalin receptors, including δ - and μ -opioid receptors. Prior to noise exposure, intraperitoneal administration of the δ -opioid receptor agonist SNC80 exerts neuroprotective effects in the cochlear nucleus—including anti-inflammatory and anti-apoptotic actions—and improves ABR metrics at 3 days post-exposure.

SU32. Triple AAV Vectors Enable Efficient and Safe Cochlear Gene Delivery for Large Genes in Adult Mice

Hidekane Yoshimura^{*1}, Mariko Kasuga¹, Yutaka Takumi¹

¹*Shinshu University School of Medicine*

Background: Several reports have demonstrated auditory restoration after intra-cochlear gene therapy in patients with OTOF-related hearing loss. However, as nearly 200 causative genes have been identified in hereditary deafness, expanding the scope of target genes for cochlear gene therapy is necessary. Most studies of hereditary hearing loss employ adeno-associated virus (AAV) vectors, but their carrying capacity is limited to ~4.7 kb. Because some deafness genes exceed this size, packaging into a single AAV capsid is unfeasible, and splitting the transgene into two or three parts may be required. While successful dual-AAV-vector approaches have been reported, no study has yet demonstrated the feasibility of triple-AAV delivery. We therefore aimed to establish a triple-AAV cochlear delivery strategy that achieves apex-to-base transduction with high efficiency and minimal cochlear damage.

Methods: Enhanced green fluorescent protein (EGFP) was divided into three parts and packaged separately into AAV2/2 vectors (each titer > 10¹³ GC/ml; VectorBuilder, construct patent pending). C3H/HeNjcl mice (5–6 weeks old) were used. In the left ear, 1 μ l of the triple AAV mixture was co-injected into the cochlea using the round window membrane + canal fenestration (RWM+CF) method we previously described. Auditory thresholds were assessed by auditory brainstem response two weeks post-injection. Cochleae and vestibular organs were then harvested and dissected to evaluate transduction efficiency.

Results: Robust transduction (40–50%) was observed in inner hair cells (IHCs) across all cochlear turns (apex, middle, and base). In contrast, outer hair cells (OHCs) and vestibular hair cells (utricle, saccule, semicircular canals) were not transduced. Importantly, auditory thresholds did not differ between injected and uninjected ears, indicating that the procedure did not affect hearing.

Conclusions: This study is the first to demonstrate that cochlear gene delivery using triple-AAV vectors is both efficient and safe for transducing IHCs in the adult murine cochlea. These findings suggest that triple-AAV strategies could be broadly applicable to the development of gene therapies for hereditary hearing loss caused by large deafness genes, such as CDH23, MYO15A, and USH2A that exceed the packaging limit of a single or dual AAV vector.

SU33. GJB2 Gene Therapy-Response of Two Pre-Clinical Mouse Models of the Most Frequent Form of Human Deafness, DFNB1

Anne Heritier*¹, Andrea Lelli², Amrit Singh-Estivalet³, Nawel Mekdad², Solène Roux², Jeanne Rakotopare², Muriel Sudres², Nicolas Michalski⁴, Rafik Boudra⁵, Arnaud Giese⁵, Laurent Désiré⁵, Christine Petit⁶

¹*Institut Pasteur*, ²*Institut de l'Audition/ Institut Pasteur*, ³*Université Paris Cité, Institut Pasteur, AP-HP, INSERM, CNRS, Fondation Pour l'Audition, Institut de l'Audition, IHU reConnect*,

⁴*Institut de l'Audition, Institut Pasteur, INSERM, Université de Paris, Paris, France*, ⁵*Sensorion*,

⁶*Institut de l'Audition, Institut Pasteur, INSERM, Collège de France, Université Paris Science et Lettres, Université de Paris*, 7

Background: More than 1.5 billion people worldwide live with hearing loss (HL). Sensorineural HL affects one new-born in 700-1000 and approximately one child or young adult in 500 before the age of 20. Approximately 70% of congenital severe to profound deafness cases are hereditary due to monogenic defects, thus potentially treatable by gene therapy (GT).

GJB2-related autosomal recessive non syndromic HL (also referred as DFNB1) is the most common genetic cause of congenital sensorineural HL in many human populations, frequently accounting up to half cases. In addition, it is also responsible for late onset deafness, occurring even after 40 years of age. GJB2 encodes gap-junction channel protein connexin-26 (Cx26), involved in metabolites and ions homeostasis in the cochlea, necessary for cochlear development and sensory hair cell function and survival. Notably, Cx26 contributes to the endocochlear potential, the driving force of the sensory mechanotransduction. Hundreds of pathogenic GJB2 variants including large deletions, loss-of-function, and missense variants have been reported which outcomes spanning from mild to profound deafness.

Methods: To develop GT approaches for deafness caused by Gjb2 defects, we generate two conditional knockouts mouse models (as Gjb2 inactivation results in embryonic mouse lethality) crossing transgenic Gjb2loxP mice with Cre mice which display strong and wide Cre recombinase cochlear expression (i.e. in almost all Gjb2-positive cells). Both models display profound congenital deafness, severe cochlear architecture abnormalities and reduced endocochlear potential

Results: ear delivery of a GT-Gjb2 recombinant adeno-associated virus (AAV) results in a strong and long lasting (at least 6 months) Cx26 expression in most of Cx26 expressing cells of the cochlea especially in Hensen's cells, Deiters' cells, inner and outer pillar cells, inner phalangeal cells, inner border cells and inner sulcus. Importantly, no Cx26 was detected in hair cells in any of the 2 models. In both models, GT-Gjb2 improves ABR threshold up to 3 months post administration and preserve cochlear structure in almost 90% of mice. Furthermore, GT-GJB2 strongly reduce hair cells degeneration and neurons loss.

Conclusions: Thus, GT-GJB2 improves audition in these preclinical models of Gjb2 defects

SU34. High-Throughput Screening Uncovers the Hair Cell-Specific Promoter for Gene Therapy

Ziting Chen^{*1}, Xiren Yuan¹, Shao-wei Hu¹, Mengzhao Xun¹, Yilai Shu¹

¹*ENT institute and Otorhinolaryngology, State Key Laboratory of Brain Function and Disorders and MOE Frontiers Center for Brain Science, Shanghai Key Laboratory of Gene Editing and Cell Therapy for Rare Diseases, Fudan University*

Background: Hearing loss is the most common sensory disorder globally, affecting over 400 million people, including 34 million children. Approximately 1 in 500 newborns suffer from hearing impairment, with genetic factors accounting for about 60% of cases. Adeno-associated virus (AAV)-mediated gene therapy has emerged as a promising treatment strategy for genetic hearing loss. However, the complexity of the cochlea—particularly its diverse cell types such as hair cells, supporting cells, and spiral ganglion neurons—poses significant challenges to precise gene delivery targeting. This study focuses on the systematic screening and identification of specific promoters for inner ear hair cells. By combining AAV vectors with high-throughput promoter screening, we achieved targeted delivery and precise expression in different types of cochlear hair cells, effectively overcoming previous issues such as off-target effects, low safety, and high dosage requirements in viral delivery. This work provides critical technical support for the clinical translation of genetic therapies for hereditary hearing loss.

Methods: Utilizing cochlear single-cell sequencing data, we conducted bioinformatic analysis and molecular cloning to construct a diverse hair cell promoter library encompassing various subtypes. A two-phase screening strategy was employed: high-throughput primary screening with a fluorescent reporter system identified candidate promoters, followed by precise secondary evaluation of their strength and specificity. An AAV-based gene therapy system was microinjected into *Pjvk*^{-/-} mice inner ears. Auditory function was assessed using ABR and DPOAE measurements, while immunohistochemistry evaluated protein expression and cell survival to determine system efficacy and safety.

Results: Through systematic screening, specific promoters for different types of hair cells were identified, enabling highly efficient and specific EGFP expression in hair cells. Based on one of these hair cell-specific promoters, HCpro, an AAV-mediated gene therapy system targeting hair cell-related deafness gene was designed. This system was delivered via microinjection into the inner ear of *Pjvk*^{-/-} mice. Auditory function was evaluated at multiple points post-treatment, revealing significantly reduced response thresholds compared to the untreated control group. Furthermore, no obvious adverse effects were observed in the cochleae of the treated mice, demonstrating the favorable safety and efficacy of this AAV-based gene therapy system. Ultimately, the treatment successfully restored auditory function in this genetic model of hearing loss.

Conclusions: Distinct from conventional promoter screening approaches, this study established an efficient and systematic strategy for identifying hair cell-specific promoters and successfully identified HCpro. This work not only provides a novel promoter option for the design of gene therapies targeting hair cell-related deafness genes but also opens avenues for extending

treatment strategies to other cochlear cell types, such as supporting cells and spiral ganglion neurons.

SU35. A Directed Evolution Novel Aav Mediated Gene Therapy Restores Hearing in Otof Mutant Mice and Patients

Hao Wu*¹, Ying Chen¹, Yong Tao¹, Guisheng Zhong²

¹*Shanghai Ninth People's Hospital, Shanghai Jiao Tong University School of Medicine,*

²*ShanghaiTech University; Shanghai Weimei Gene Technology Co., Ltd*

Background: OTOF commonly causes non-syndromic auditory neuropathy, that affects 2.3-10% of patients with hereditary hearing impairment. OTOF only expresses in inner hair cells (IHC), crucial in synaptic vesicle cycling. Dual AAV mediated gene therapy has successfully restored hearing in patients with OTOF mutations. AAV is a single-stranded linear DNA defective virus with multiple serotypes targeting different tissues or cells. IHC-specific AAV vector still remains a major challenge.

Methods: In this study, we developed a platform to engineer novel AAV vectors through capsid mutation, peptide insertion, DNA shuffling, and promoter modification. A novel AAV vector, AAV-WM04, was engineered, which exhibits extremely high specificity for IHC in both mice and non-human primates (NHPs). Based on this vector, a dual-vector OTOF expression system was designated as EA0010.

Results: EA0010 was injected into inner ear through round window in adult wild type mice and NHPs for safety verification. EA0010 rescued hearing of humanized adult OTOFQ829X/Q829X mice. To evaluate the effectiveness of EA0010 in patients with severe-to-profound hearing loss caused by OTOF gene mutations, we designed a single-center, single-arm, open-label, dose-escalation study. From Dec 2024, nine patients have been enrolled in this study.

Conclusions: Preliminary clinical results demonstrate that EA0010 effectively restores auditory function, especially in restoring high-frequency hearing, with no serious adverse event. Detailed results will be presented.

SU36. A Novel AAV Vector-Based Gene Therapy for Two Adult Rodent Models of DFNB1

Hao Wu*¹, Yong Tao¹, Guisheng Zhong²

¹*Shanghai Ninth People's Hospital, Shanghai Jiao Tong University School of Medicine,*

²*ShanghaiTech University*

Background: GJB2-related autosomal recessive nonsyndromic HL (DFNB1) is the most common genetic cause of congenital sensorineural HL worldwide, accounting for up to half of all cases in some populations. It can also cause later-onset HL, even after 40 years of age. GJB2 encodes connexin-26 (Cx26), a gap-junction channel protein critical for metabolite and ion homeostasis, cochlear development, and sensory hair cell function and survival. Hundreds of pathogenic GJB2 variants have been identified, ranging from large deletions to missense and loss-of-function mutations, with clinical outcomes spanning mild to profound deafness.

Methods: We developed AAV-DS1, an AAV vector optimized for DFNB1, designed for broad coverage of Gjb2-expressing cells in the inner ear of mouse, rat and minipig, while minimizing transduction of hair cells. AAV-DS1 with GJB2-specific promoter to drive the expression of wild-type GJB2 (AAV-DS1-GJB2) was delivered into the inner ears of adult Gjb2-mutant mice and rats via round window (RW) injection. Ongoing studies investigated efficacy, dose-response, correlation between ABR responses and transduction efficiency, early biodistribution, and toxicology in mice. In parallel, AAV-DS1-GJB2 was administered to minipigs using a clinically relevant surgical approach and medical device. Tolerability and biodistribution were assessed, and AAV tropism was characterized by immunoconfocal analysis and in situ hybridization on cochlear whole mounts and cryosections.

Results: A single intracochlear injection of AAV-DS1-GJB2 in adult Gjb2-mutant rats and mice resulted in a significant, dose-dependent improvement in auditory thresholds as early as 2 weeks post-injection. In minipigs, ABR thresholds and DPOAE amplitudes remained within the normal range 6 months post-surgery, confirming local tolerability. Biodistribution was largely restricted to injected ears. In WT mice, AAV-DS1-GJB2 was well tolerated, with no ABR threshold shifts up to 6 months and evidence of long-term transgene expression. Across rodents and minipigs, anti-HA labeling confirmed broad targeting of nearly all GJB2-expressing cell types without adverse functional impact.

Conclusions: AAV-DS1-GJB2 efficiently targets endogenous GJB2-expressing cochlear cells, with demonstrated efficacy and favorable safety in rodents and minipigs. These findings provide strong support for advancing AAV-DS1-GJB2 into clinical translation—enabling studies as a novel gene therapy for GJB2-related hearing loss.

SU37. Triple Antisense Oligonucleotide-Mediated Exon Skipping Targeting a Large Deletion in USH2A

Katerina Anamisis^{*1}, Stephanie Mauriac¹, Gwenaelle Geleoc¹, Jeffrey Holt¹

¹*Boston Children's Hospital, Harvard Medical School*

Background: Usher syndrome is an inherited autosomal recessive condition that accounts for about 50 percent of all hereditary deaf-blindness cases. There are three types of Usher syndrome, of which Type 2 is the most common. USH2 is characterized by moderate to severe sensorineural hearing loss, nyctalopia, and progressive loss of vision. The most common form, USH2A is caused by mutations in the USH2A, a 15.7 kb gene, that encodes for the protein usherin, expressed in cochlear hair cells and photoreceptor cells.

A patient at Boston Children's Hospital was diagnosed with USH2A. Genetic testing revealed two pathogenic mutations: an in-frame deletion of exons 61-63 that results in improper protein folding and a single base-pair deletion leading to the production of a truncated protein. Using Alpha Fold, we structurally analyzed the protein harboring the three-exons deletion and determined that skipping an additional three exons upstream of the deletion may restore proper protein folding and function. As such, we propose to develop antisense oligonucleotides (ASOs) that target these three exons and lead to removal of the region encoded by six consecutive exons, exons 58 to 63. This shortened protein excludes part of fibronectin (FN) domain FN22, all of FN23 through FN30, and part of FN31. The objective of this project is to determine whether the larger USH2A truncation restores function.

Methods: Exon skipping is a method in which ASOs are used to prevent the interaction between mRNA and the ribosome to elude translation. We designed several ASOs targeting splice sites in USH2A exons 58, 59, and 60, and assessed their skipping in retinoblastoma cells at a concentration of 200 nM for 48 hours. Skipping was evaluated by RT-PCR and sequencing. Patient-derived induced pluripotent stem cells (iPSCs) have also been generated using blood sample from the proband. USH2A expression and splicing in the USH2A iPSCs line is being assessed via RT-PCR.

Results: Primers were designed and validated in RB1 cells. RB1 cells were transfected with ASOs at 200 nM for 48 hours and subsequently harvested. RT-PCR was performed with the different primer sets. We validated skipping of exons 58 and 59 and are currently assessing other ASOs targeting exon 60. We are also assessing multiple exon skips combining different ASOs. Additionally, we are assessing mutant iPSC lines by RT-PCR to confirm splicing in absence of ASOs. We are also developing iPSCs derived inner ear and retinal organoids to test validated ASOs in the context of the three exons deletion.

Conclusions: This strategy is novel in that we are assessing skipping of 3 exons in the presence of another 3-exon deletion. We predict that removal of a large portion of the protein encoded by USH2A will lead to expression of a shorter, yet functional protein.

SU38. AAV Delivery of Cib2 Restores Hearing and Vestibular Function in Cib2 Ko Mice

Evan Ratzan^{*1}, Cristobal Von Muhlenbrock¹, Zubair Ahmed², Gwenaëlle Géléoc¹, Jeffrey Holt¹
¹*Boston Children's Hospital/Harvard Medical School*, ²*University of Maryland*

Background: Calcium and integrin-binding protein 2 (CIB2) binds to TMC1, the pore forming complex of the mechanotransduction channel (MET) and is essential for hearing. Mice lacking both Cib2 and Cib3 double knockout mice also show impaired vestibulo-ocular reflexes, head bobbing, and poor balance. Cib2 and Cib3 single knockout mice appear phenotypically normal; however, some reports of subtle progressive balance phenotypes have been reported in single KO mice by 9 months of age, along with stereocilia disorganization that may be associated with progressive degeneration. Patch clamp recording from vestibular hair cells suggest that Cib2 and Cib3 are functionally redundant in regulating MET. However, RNA expression of Cib2 is predominantly in striolar hair cells whereas Cib3 in extrastriolar hair cells.

Methods: Here we use vestibular evoked myogenic potentials (VsEP), rotarod, open field, and infrared palm reader analysis of Cib2 and Cib3 single KO mice to assess balance phenotypes in mice. We also used auditory brainstem response (ABR) to examine restoration of auditory function in injected mice. Hairpin chain reaction fluorescent in situ hybridization was used to assess Cib2 and Cib3 expression relative to the Ocm⁺ striolar domain and quantify in cellular resolution. RT-qPCR was completed to assess the relative distribution of Cib2 and Cib3 separately in utricles, saccules, crista, and cochlea to compare to HCR quantitative analysis. Functional assessment of mechanotransduction in Cib2 KO and Cib3 KO tissue was completed using FM1-43 labeling of acutely dissected tissues.

Results: Here we show that Cib2 KO and Cib2/3 DKO mice fail to produce VsEP responses to head jerk stimuli, whereas Cib3 KO mice have normal VsEP responses under the same conditions. Unilateral neonatal utricle injection of AAV is sufficient to restore Cib2 KO VsEP

and ABR responses to near WT thresholds in both ears. Similar to other groups, we identify no significant behavioral balance phenotype in Cib2 or Cib3 single KO mice. HCR-FISH shows non-redundant expression patterns of Cib2 in the striola and Cib3 in the extrastriola in the utricle and saccule. Similarly, Cib2 KO tissue shows FM1-43 dye absent in the striola of the vestibular maculae.

Conclusions: Taken together, these data indicate that Cib2 expression in the striola is necessary for VsEP generation. Additionally, despite its expression in vestibular organs, Cib3 it cannot compensate for loss of Cib2 when it comes to VsEP generation or striolar MET function. These results suggest that Cib2 and Cib3 are not functionally redundant in the vestibular system. Despite the regional differences in their expression, our behavioral phenotyping does not indicate a definitively distinct role for Cib2 versus Cib3 in balance. Thus, the underlying reasons for the non-overlapping expression and function of Cib2 and Cib3 remain an interesting area for future study.

SU39. Investigation of Vestibular Dysfunction Requires Renewed Research Enthusiasm

Evan Ratzan^{*1}, William Davis¹, Jacob Brodsky¹

¹*Boston Children's Hospital/Harvard Medical School*

Background: Hearing, balance, ocular gaze, head position, baroreflexes, and spatial memory all depend on functional input from structures of the inner ear to the brain. Close examination of scientific research output based on anatomical search terms of peripheral inner ear structures shows an obvious lag in areas of vestibular research progress in areas of academic publication, grant funding, and clinical trial development.

Methods: We utilized data mining of publicly available records (PubMed, NIHReporter, and ClinicalTrials.gov) to assess the rate of inner ear research output quantitatively. PubMed and NIHReporter searches included keyword terms separated by Boolean operators to focus on either auditory or vestibular anatomical peripheral structures with suffixes excluded for more inclusive output metrics. Similarly, we queried clinicaltrials.gov with additional search terms included pertaining to symptoms of inner ear dysfunction and names of syndromes. Query results were categorized into either vestibular (e.g. dizziness, vertigo, imbalance, etc.) or auditory (e.g. hearing, deafness, presbycusis, etc.). We combined these computational approaches with systematic review of published literature including patient survey data to understand the prevalence of hearing loss versus dizziness. We also reviewed reported cost estimates from multiple studies regarding unexplained falls to understand the relative cost of untreated vestibular dysfunction.

Results: PubMed data show that the expansive growth period of inner ear research by publication output from 1950 to 2024, particularly in cochlear research. In contrast, fewer publications contain peripheral vestibular anatomical terms ranked by frequency: saccule > utricle > otolith > semicircular canal > vestibular labyrinth > crista ampullaris > vestibular macula. Publications containing auditory terms ranked by frequency: cochlea > organ of corti > spiral ganglia > basilar membrane > stria vascularis > tectorial membrane > Reissner's membrane. NIHReporter queries from 1990-2024 reveal thousands less grants are awarded to projects focused on vestibular research compared to auditory/cochlear research. Unsurprisingly,

the total dollars spent on auditory/cochlear research surpasses vestibular research investment by a significant margin. Interestingly, our review of various patient survey studies show prevalence estimates between dizziness and hearing loss to be comparable.

Conclusions: Vestibular research consistently receives less public attention in the form of published research output, grant funding, and clinical trial development. While there are unique challenges associated with diagnosing patients with vestibular dysfunction, our prevalence estimates of dizziness appear comparable to hearing loss. During literature review, it became clear that vestibular dysfunction had far worse impacts on patients' quality of life and may have higher diagnostic and treatment costs than hearing loss as well. Despite a substantial need for clinical diagnostic and therapeutic interventions for vestibular dysfunction, research in this area is severely limited. A renewed enthusiasm among the next generation of trainees to investigate the vestibular system may help facilitate broader understanding of the inner ear and produce interventions for patients.

SU40. Catalyzing Hearing Research With the Gene Expression Analysis Resource (umgEAR.org)

Joshua Orvis¹, Ricky Adkins¹, Seth Ament², Carlo Colantuoni³, Brian Herb², Daniel Lesperance¹, Beatrice Milon⁴, Kevin Rose⁴, Joseph Receveur⁵, Christopher Shults⁴, Yang Song⁵, Anup Mahurkar¹, Ronna Hertzano⁴

¹*Institute for Genome Sciences*, ²*University of Maryland School of Medicine*, ³*Johns Hopkins University School of Medicine*, ⁴*NIDCD*, ⁵*University of Maryland, Baltimore*

Background: The gene Expression Analysis Resource (gEAR, umgear.org) is an online portal for multi-omic data visualization, sharing, and discovery, and continues to be an invaluable public resource for the hearing research community. gEAR allows for visualization, investigation, and reuse of sequencing datasets in a user-friendly web interface. The availability of hearing datasets in gEAR continues to grow with 1,299 datasets, 2,557 unique users, and over 3.75 trillion individual datapoints.

Methods: The proliferation of single cell/nuclei, epigenomics, multiome, and spatial transcriptomics techniques in the hearing research field has led us to incorporate additional visualization and analysis tools which provide users the ability to explore and analyze these datasets using only a web browser with no coding required. Expanded epigenomic tools allow users to quickly visualize open chromatin regions and methylation data alongside gene expression and other dataset displays.

Results: In addition to the range of visualization and search functionality offered via gEAR's new Epigenetic Explorer tools, epigenetic datasets in gEAR now dynamically link to the popular UCSC genome browser for even more analysis options. New spatial tools allow for the upload and interactive exploration of data from all major commercially available spatial platforms (e.g. 10X Visium and Xenium, CosMx and Curio, and more). Similar to other tools in gEAR, the spatial layouts now can be viewed within a dataset collection allowing for correlated views with other popular datasets.

Conclusions: In contrast with other online data visualization tools, a major strength of the gEAR platform is the ability to visualize, curate, and explore multiple datasets and data types side-by-

side. New options for publication landing pages (new pages with custom content to highlight your manuscript and link to all your data), dataset collection customization, and easily implementable transfer learning tools help researchers dramatically increase the visibility, interpretability, and reuse of their sequencing datasets and explore them alongside other cutting-edge hearing datasets. For users visiting gEAR for the first time, gEAR now includes interactive walkthroughs introducing users to the major functionalities of the platform and use of individual tools. gEAR is supported by the National Institute on Deafness and Other Communication Disorders (NIDCD), Hearing Health Foundation (HHF), and the Hearing Restoration Project (HRP) to promote discovery in hearing research.

SU41. Data-Driven Subtyping of Tinnitus Patients Using Deep Embedded Clustering

Min-Chae Jeon¹, Minyu Ko¹, Ye Lin Kim¹, Kyusun Park¹, Chan Mi Lee¹, Ji hyung Lim¹, Jae Sang Han¹, Shi Nae Park¹

¹*Seoul St. Mary's Hospital, College of Medicine, The Catholic University of Korea,*

Background: Tinnitus is a heterogeneous auditory disorder characterized by diverse clinical manifestations and variable therapeutic responses. While Tinnitus Retraining Therapy (TRT) has been widely implemented, its outcomes differ substantially among patients, reflecting the multifactorial nature of tinnitus involving auditory, psychological, and neurobiological dimensions. Conventional classification systems often fail to capture this complexity, limiting the precision of diagnosis and the prediction of treatment outcomes. Deep learning, particularly deep embedded clustering, provides an opportunity to identify latent structures within multidimensional clinical data and uncover novel subtypes of tinnitus that may guide personalized therapy. The present study aimed to utilize a deep embedded clustering approach to stratify tinnitus patients undergoing TRT into data-driven subtypes, characterize their clinical and audiometric profiles, and examine differential therapy outcomes across subgroups.

Methods: A retrospective dataset of patients treated with TRT was analyzed, including tinnitus handicap inventory (THI) scores, visual analogue scale (VAS) ratings of loudness and annoyance, audiometric thresholds across frequencies, tinnitus psychoacoustic features, psychological stress (BEPSI) and depression (BDI) indices, and therapeutic histories. Representation learning was performed using an autoencoder to reduce high-dimensional inputs into latent features, which were subsequently clustered using k-means in the embedded space. Subgroup characteristics were examined using descriptive statistics and visualized in latent manifolds. Longitudinal treatment responses, assessed through serial THI and VAS scores, were modeled to evaluate the clinical validity of the identified clusters.

Results: Deep embedded clustering revealed three clinically distinct patient subtypes. The first cluster was defined by frequency-specific hearing loss with moderate tinnitus severity, the second by high psychosocial burden with elevated stress and depression indices, and the third by predominantly tonal tinnitus with relatively preserved hearing. These subgroups demonstrated differential TRT trajectories: patients in the psychosocially burdened cluster exhibited slower recovery and higher residual symptoms, whereas those with tonal tinnitus and minimal hearing impairment showed more rapid and sustained improvement. Feature importance analyses further indicated that baseline THI, stress levels, and high-frequency hearing thresholds were the strongest predictors of subgroup membership and therapeutic outcomes.

Conclusions: This study demonstrates that deep embedded clustering can uncover hidden subtypes of tinnitus patients beyond conventional diagnostic categories. By integrating heterogeneous clinical, audiometric, and psychological features, this data-driven approach provides mechanistic insights into tinnitus heterogeneity and offers a framework for personalized management. Importantly, the identification of subgroups with distinct TRT outcomes underscores the clinical utility of artificial intelligence in guiding patient-specific therapy. These findings highlight the potential of AI-driven diagnostic and therapeutic platforms to bridge complex clinical data with translational neuroscience, advancing the precision of tinnitus care and contributing to a deeper understanding of its underlying pathophysiology.

SU42. Minipig Model Development for Hearing Research

Amanda Henton^{*1}, Stormy Sonneborn¹, Maza Tomhave¹, Adam Porter², Jared Hartsock¹, Jennifer Artis¹, Cole Vonder Haar³, Alec Salt¹, Jeremy Turner¹

¹Turner Scientific, ²Illinois College, ³Ohio State University

Background: The inner ear drug, biologics, and device development field has been limited by the lack of large-animal models to effectively bridge the gap between rodents and humans. Here we propose the miniature pig (Sinclair NanoPig) as an alternative large animal model in translational hearing research. Compared to commonly used large animal models such as dogs, cats, and some NHPs, the minipig cochlea dimensions are more similar to humans, enabling preclinical studies that use human-relevant dose volumes for studying drug distribution in the cochlea as well as human-sized implantable devices. Further, use of minipigs as a large animal model in biomedical research is cost-effective and in accordance with recent regulatory guidance to limit the use of NHPs in preclinical research. The minipig holds great promise as a better translational model for hearing research, but in order to expand their use in preclinical hearing research studies, there is a need for refining surgical access for delivery and sampling as well as development of normative audiometric datasets and behavioral audiometry methods that mirror clinical outcome measures of sound perception and audibility.

Methods: We used minipigs to develop an operant sound detection task utilizing a custom touchscreen device. Animals were trained to press illuminated boxes on a touchscreen in response to sound or silent stimuli in a two-alternative forced choice task. In addition to behaviorally assessed hearing thresholds, we have generated normative datasets for both bone- and air-conduction ABRs. Preliminary pharmacokinetic studies attempted perilymph sampling from the cochlear apex but found the approach technically difficult. Simulations showed that sequential perilymph sampling from the lateral semi-circular canal, as used extensively in guinea pigs, provides sufficient detail to document drug distribution.

Results: Through this method development study, we have demonstrated the feasibility of a touchscreen sound detection task in the minipigs and have refined local surgical access surgical approaches for drug delivery and sampling. We have also optimized key parameters for DPOAE and ABR measurement in mini pigs.

Conclusions: The minipig is an alternative large animal model that can effectively bridge the translational gap between rodents and humans due to the similarity in cochlear dimensions and anatomy to the humans. Optimizing perilymph sampling procedures and ABR and DPOAE measures in the minipig and developing behavioral assays that closely approximate outcome

measures in humans such as the audiogram or speech-in-noise tests, further aids in the translational validity of the minipig in auditory preclinical research.

SU43. Universally Controversial Stimuli Reveal That Adversarial Robustness Improves DNN Prediction Accuracy Across the Entire Human Auditory Cortex

David Skroll^{*1}, Jenelle Feather², Samuel Norman-Haignere¹

¹*University of Rochester Medical Center*, ²*Flatiron Institute*

Background: Sensory neuroscientists seek to develop models that replicate the computations of sensory systems and predict responses to complex stimuli. A key challenge is that distinct computational models often make similar predictions for complex natural stimuli, such as speech, masking potentially important computational differences. Prior research found that artificial deep neural networks (DNNs) trained on challenging auditory tasks learn features that predict much of the human cortical response to natural sounds. However, the decisions of DNNs can diverge sharply from human behavioral decisions. For example, standard DNNs make confident categorization judgments for noise-like sounds that are completely unrecognizable to a human observer. Training DNNs to be robust to adversarial attacks better aligns model decisions with human judgments. Despite this behavioral difference, standard and robust DNNs make nearly identical predictions for human cortical responses to natural sounds. Here, we develop a new approach for model comparison to investigate these seemingly contradictory results.

Methods: We developed a method to synthesize sounds that generate universally controversial predictions across the entire human auditory cortex and leveraged this method to compare standard and adversarially robust DNNs. Using fMRI data from 30 participants listening to 165 natural sounds (2 seconds each), we fit voxel-wise encoding models by linearly mapping DNN layer activations to fMRI voxel responses, separately for a standard and robust DNNs trained to recognize spoken words. We then developed a synthesis algorithm that generated a single set of 60 sounds that produced uncorrelated predictions across all auditory voxels. Our synthesis procedure successfully generated perceptually diverse, complex sounds—some speech-like, others tonal or noise-like. We then measured fMRI responses to these controversial sounds along with 120 natural sounds from 9 new participants.

Results: We found that standard and robust DNNs predicted fMRI responses to natural sounds with nearly identical accuracy. Moreover, the predictions from standard and robust models were themselves very similar for natural sounds, virtually guaranteeing similar neural prediction accuracy. In contrast, we found that controversial sounds produced uncorrelated model predictions throughout the entire human auditory cortex, even in participants whose data was not used to synthesize the sounds. We found that the robust model maintained high prediction accuracy for measured fMRI responses to the universally controversial sounds, while the standard model's accuracy dropped to near zero. We also found that natural and controversial sounds share a low-dimensional neural manifold along which standard and robust DNNs make highly controversial predictions.

Conclusions: We provide a general-purpose method to synthesize stimuli that distinguish competing sensory models. It is applicable to virtually any model, modality, or recording

technique. Our results demonstrate that adversarial robustness substantially improves neural prediction accuracy and enables more effective population control along the neural manifold.

SU44. A Multi-Channel Integrated Auditory Function Test System

Fangyi Chen^{*1}, Shijie Xiao¹, Yihang Zheng², Lei Song², Guanting Lin³

¹*Southern University of Science and Technology*, ²*Shanghai Ninth People's Hospital, Shanghai Jiao Tong University School of Medicine* ³*Giant Technologies Co., Ltd*

Background: ABR is the gold standard for objective hearing assessment of animals and people. The extensive use of genetically engineered mice in hearing research has created an urgent demand for the ability of ABR high-throughput testing.

Methods: We developed a four-channel ABR system enabling simultaneous testing of four subjects, integrating distortion product otoacoustic emission (DPOAE), cochlear microphonic (CM) and endocochlear potential (EP) detection functions.

Results: The system adopts high-speed ADC chip, which can obtain DPOAE and CM data above 32kHz. For the detection of various peak parameters (amplitude and latency) of mouse ABR, the performance is equivalent to that of the industry standard equipment TDT, and the test efficiency is improved by three times

Conclusions: This multifunctional test platform meets the current high-throughput ABR testing requirements, and provides excellent efficiency and expanded functional evaluation for the scalable high fidelity auditory phenotype in the next generation research.

SU45. Irregular Afferent Pathways Associated With the Striola Are the Peripheral Origin of Motion Sickness

Fangyi Chen^{*1}, Shijie Xiao¹

¹*Southern University of Science and Technology*

Background: At present, the pathological mechanism of motion sickness (MS) focuses on the mismatch between the real sensory input and the self-motion estimation predicted by the "internal mode". Drugs for the treatment of MS have obvious side effects due to a wide range of central action targets. Basic medical evidence shows that the pathological origin of MS can be traced to the abnormal signal input of vestibular receptors. Can we establish an interpretation model of the mechanism of MS through the analysis of the regulation path of peripheral vestibular input?

Methods: In this project, we studied the vestibulo-ocular reflex (VOR) of CIB2^{-/-} and CIB3^{-/-} transgenic mice expressed in the striola and extra-striola zone of otoliths, including VOR-SPN (Slow phase nystagmus) and VOR-FPN (Fast phase nystagmus). After that, MS in mice was induced by biaxial rotation, and the severity of MS was evaluated using real-time body temperature monitoring (core body temperature and tail temperature), VOR decline after rotation, and swimming posture control after rotation.

Results: (1) VOR-SPN mainly reflect the function of extra-striatal zone, which shows that the slow phase eye movements of aVOR (angular VOR) and OVAR (Off-vertical axis rotation) in

CIB3^{-/-} mice are significantly reduced. CIB2^{-/-} mice have no obvious vestibular dysfunction symptoms, including VOR and VSR.

(2) Compared with the control group C57 BL/6J mice, CIB2^{-/-} mice don't show significant thermoregulatory response during rotational stimulation, and their VOR efficacy was higher than that of the control group after rotation, with normal swimming posture.

Conclusions: The irregular afferent pathway associated with hair cells in the striola zone is the main vestibular peripheral source of MS. This discovery precisely locates the origin of MS from the macroscopic vestibular system to the sub organ structure - the striola zone. Thus, we will shift the targeted diagnosis and treatment of MS from the central system to regulating specific peripheral signaling pathways.

SU46. Resurgent Sodium Currents and Nav1.6 Expression in Vestibular Calyx Afferent Terminals

Nesrien Mohamed¹, Frances Meredith¹, Tim Benke², Anna Dondzillo¹, Katie Rennie*³

¹University of Colorado Denver, ²University of Colorado Children Hospital, ³University of Colorado Anschutz

Background: Vestibular afferent neurons relay signals from hair cells to the brain. Calyx-only afferents innervate type I cells, bouton afferents target type II cells, and dimorphic afferents contact both hair cell types. Firing characteristics vary by zone, with dimorphic afferents in the peripheral zone (PZ) showing highly regular repetitive activity. Ionic conductances, including sodium currents—transient (INaT), persistent (INaP), and resurgent (INaR)—may shape firing properties. INaR, generated by an open-channel block mechanism supports repetitive firing in select neurons, but its role in vestibular afferent signaling is unclear. We therefore used whole-cell patch-clamp to investigate INaR in vestibular calyces and modeling and immunohistochemical approaches to investigate underlying channels.

Methods: Cristae were extracted from Mongolian gerbils (P30-42), embedded in agarose, and sliced at 100 μ m. The central zone (CZ) and PZ regions were identified, and calyx terminals distinguished by their cup-shaped morphology. Whole-cell patch-clamp was used with K⁺- or Cs⁺-based intracellular solutions. A series of voltage protocols was applied to characterize INaT and INaR in voltage clamp. Action potentials were recorded in current clamp using K⁺-based electrode solutions. Na⁺ currents were modeled with a Markov kinetic scheme (Hong et al. 2018). For immunohistochemistry, slices were fixed and stained with anti-CASPR1 and anti-Nav1.6 antibodies and fluorescent images viewed on a confocal microscope.

Results: In whole-cell recordings all calyces expressed INaT. INaR was present in a subset of calyces, with 19 out of 38 PZ calyces (50%) and 4 out of 16 CZ calyces (25%) exhibiting INaR. Both current components were blocked by tetrodotoxin (500 nM). Preliminary data demonstrate that INaT in calyces expressing INaR activate at more negative potentials compared to those lacking INaR suggesting different underlying subunits. INaR amplitude depended on the duration and voltage of the preceding depolarizing step: brief (10 ms) or larger (+30 mV) depolarizing prepulses enhanced INaR compared to longer (50 ms) or smaller (−10 mV) steps, consistent with open-channel block and slow inactivation dynamics. INaR⁺ calyces exhibited more depolarized half-inactivation potentials for the INaT ($V_{1/2} = -72.4$ mV) than INaR[−] calyces

($V_{1/2} = -85.7$ mV). INaR facilitated faster recovery from both open-channel block and inactivation, and our computational model replicated voltage clamp findings. In current clamp, calyces with INaR displayed multiple spikes whereas those without INaR typically showed single evoked spikes. Anti-CASPR1 stained calyces and heminodes adjacent to anti-Nav1.6 staining below the neuroepithelium.

Conclusions: We found that INaR is prevalent in PZ calyces of the crista. Calyces with INaR exhibit faster recovery from inactivation and open-channel block, more depolarized half-inactivation of INaT, and repetitive firing. Nav1.6 channels may contribute to the generation of INaR within dimorphic calyx afferents. Understanding the heterogeneity of Na⁺ channels and firing mechanisms in vestibular afferents could guide treatment for vestibular dysfunction.

SU47. Effect of Modulus Presentation on the Magnitude Estimates of Angular Velocity

Jesus Gomez^{*1}, Erin Piker¹, Kristal Riska², Hannah Martin², Erin Hernon², Brandy Hollins¹

¹*James Madison University*, ²*Duke University*

Background: Magnitude estimation is a psychophysical method in which participants assign numerical values to physical stimuli. This method can be used to measure the perceived intensity of vestibular sensory experiences, such as angular motion. A reference stimulus, or modulus, is commonly used as an initial reference to which a specific number is assigned. Subsequent stimuli are then assigned numbers that reflect the participant's perceived magnitude relative to the modulus. While use of a modulus during magnitude estimation of various sensory experiences was used in the original method by S.S. Stevens in the 1950's, not all applications of magnitude estimation use a modulus in the same way. To date, the effect of modulus presentation on magnitude estimation of vestibular stimulation is not understood. The purpose of this study was to examine whether the scaling of a sinusoidal harmonic acceleration stimulus presented at varying peak velocities changed with the presentation of the modulus.

Methods: Twenty-one healthy adults (mean age = 20.5 years) estimated the magnitude of a single cycle sinusoidal harmonic acceleration stimulus presented at .16 Hz in 9 randomly presented peak velocity conditions (10-90 dps). A modulus was presented to all participants and assigned a value of 50. Participants were randomly assigned to one of three modulus groups: (1) modulus presented once at the beginning, (2) modulus presented at the beginning and again at midpoint, or (3) modulus presented before each condition. The dependent variable was the slope of the psychophysical function.

Results: Across groups, perceived angular velocity followed a log-linear function consistent with Stevens' Power Law. The exponents of perceived angular velocity varied between .72 and .81. Statistical analyses revealed no significant group differences.

Conclusions: The psychophysical function obtained by the method of magnitude estimation was not significantly influenced by the modulus presentation as a compressive scaling function was observed regardless of modulus presentation frequency. The results support the use of a single modulus, presented at the beginning. Future work should examine conditions without a modulus (i.e. "free modulus" where participants choose their own reference numbers) and whether there are interactions between the magnitude of the modulus and the psychophysical function. Future work should also examine if these results hold true in different participant cohorts, particularly

older participants or those with vestibular loss. Key take-away: The frequency in which a modulus was presented did not significantly affect the psychophysical function obtained by the method of magnitude estimation of angular motion.

SU48. Fall Risk in Underserved Populations

Jesus Gomez*¹, Erin Piker¹

¹*James Madison University*

Background: Falls are a leading cause of morbidity among older adults, yet disparities in fall risk remain poorly understood in underserved populations. Standardized tools such as the CDC STEADI (Stopping Elderly Accidents, Deaths, and Injuries) provide a validated framework for community-based screening but do not incorporate audiologic or vestibular risk factors. In the Harrisonburg, VA community, approximately 20% of residents identify as Hispanic, a proportion nearly double the statewide average, making the inclusion of this population especially important for fall risk screening. The proposed study will enhance the STEADI model by integrating vestibular and hearing assessments along with social determinants of health, including health literacy, using materials available in both English and Spanish. Specific aims are to: (1) assess the prevalence of fall risk among Hispanic and non-Hispanic White adults ≥ 40 years old, (2) determine the prevalence of previously undiagnosed benign paroxysmal positional vertigo (BPPV) in underserved communities, and (3) construct a predictive model of fall risk incorporating auditory, vestibular, and social determinants of health with a focus on falls risk among Spanish-speaking Hispanic adults over age 40.

Methods: Participants from the Harrisonburg, VA community completed the CDC STEADI screener, pure-tone audiometry, tympanometry, vestibular assessments (Dix-Hallpike, vHIT, VEMPs, Rotary Chair), and health literacy/social determinants questionnaires. Recruitment occurred through local community centers, churches, and the university.

Results: Data collection is ongoing and expected to wrap up fall 2025 with a sample size of 80. Preliminary pilot data (N = 14; mean age = 54.6 years) suggest that fall risk prevalence is higher among Hispanic participants compared to non-Hispanic White adults. The CDC STEADI identified 43% of Spanish-speaking Hispanic participants as at risk, > the national average. BPPV prevalence in the Hispanic participants was higher than national estimates (14% vs. 3%). Logistic regression analyses indicated that participants with BPPV were approximately five times more likely to be classified as at risk for falls compared to those without BPPV, and participants with low health literacy had 1.5 times greater odds of being at risk relative to those with adequate health literacy. These findings suggest that both vestibular dysfunction and health literacy are important contributors to fall risk and may be underrecognized in underserved populations.

Conclusions: Early findings suggest that using audiologic measures such as BPPV screenings and social determinants of health such as measuring health literacy, can add predictive value to determining who is at risk of falls. Incorporating audiologic and vestibular assessments improved detection and revealed disparities in risk factors. These preliminary results support larger-scale studies to validate predictive models integrating sensory and social determinants of health.

SU49. The VGluT1-Cre Mouse Targets a Subpopulation of Central Zone Afferents in the Mouse Vestibular Epithelia

Daniel Bronson^{*1}, Katherine Regalado Núñez¹, Radha Kalluri¹

¹*University of Southern California*

Background: In the vestibular nerve, the temporal precision needed to code rapid head movements is determined by neurons firing at irregular intervals, whereas the ability to detect slow head movements sensitively is determined by neurons firing at regular intervals. The dendritic terminals of irregular afferents are predominantly located within the central zones of the sensory epithelia while the terminals of regular afferents are within the peripheral zones (Fernández et al. 1988; Lysakowski et al. 1995). Because afferent firing patterns are tightly linked to central versus peripheral zones, we tested whether ion channel composition contributes to this diversity by using a Vglut1-Cre driver mouse crossed with an Ai14 TdTomato reporter to selectively label and record from ganglion neurons originating in the central zones of vestibular epithelia. Here we report the peripheral innervation pattern of the fluorescent neurons, their co-expression with Calretinin, and their biophysical properties. This work extends our previous report of central-zone innervation by providing an updated account of their molecular and biophysical features.

Methods: The prevalence of Vglut1-Cre positive (TdTomato positive) neurons was quantified in immunolabeled samples of whole-mount epithelia and cryo-sectioned vestibular ganglia from adult (post-natal day (P)60-P70) mice. We used antibodies against Beta-III tubulin (most somata) and Calretinin (sub-population of central zone somata) to evaluate the overlap between fluorescent somata and other sub-populations. Cross-sectional area of each cell was inferred by the boundaries of the Beta-III tubulin signal. Finally, we recorded using perforated patch-clamping methods from disassociated and cultured ganglion somata at two age ranges (P16±1 days) and adult (P60-P140).

Results: In epithelial whole-mounts, TdTomato positive neurons contacted the central zone of vestibular epithelia with both bouton and calyx terminals. In ganglion sections, TdTomato positive somata were found amongst the medium and large somata and constituted approximately 6% of the total population. Approximately two-thirds of the TdTomato positive somata also co-labeled with the central zone marker Calretinin. Patch-clamp recordings demonstrated that the fluorescent neurons have both transient and intermediate firing patterns. They also responded to simulated synaptic noise with irregular responses, qualitatively support the hypothesis that ion channel properties of central-zone fibers account for irregular firing.

Conclusions: The Vglut1-Cre^{*}Ai14 mouse line effectively targets vestibular afferents, with a bias toward irregularly firing central-zone fibers. The biophysical properties of these neurons support their role in generating irregular firing. Ongoing work is characterizing regional variations in ion channels (KCNQ, HCN, and Kv1) that may underlie differences in quantal versus nonquantal transmission. This line offers a promising tool for testing the functional contributions of central-zone neurons through genetic manipulation.

SU50. PROVIDE: Patient-Centered Care for Vestibular Disorders

Sonja Pyott^{*1}, PROVIDE Doctoral Network Consortium Various²

¹Carl von Ossietzky University of Oldenburg, ²Various

Background: Vestibular disorders extend far beyond dizziness and imbalance. They encompass a spectrum of symptoms, ranging from nausea and a loss of equilibrium to cognitive impairments, depression, and reduced quality of life. Current treatments remain limited in both effectiveness and personalization. The PROVIDE Doctoral Network (<https://provide-dn.eu/>), funded under the Marie Skłodowska-Curie Actions (MSCA) within the Horizon Europe framework, addresses this pressing clinical challenge. The goal of the network is to advance patient-centered care for vestibular loss by integrating various methodologies and expertise across disciplines and bridging scientific research with innovative solutions.

Methods: PROVIDE's research activities are integrated across three complementary work packages (WPs) identifying the underlying etiology (WP2), improving characterization (WP3), and bringing innovative treatments of vestibular loss to home use (WP4). Through an interdisciplinary approach, PROVIDE unites expertise from pre-clinical animal models and organoids to novel diagnostic tools to clinical interventions using haptic biofeedback, neuromodulation, and vestibular implants. In total, 22 partners from 12 countries are involved in the training and scientific development of 10 doctoral candidates.

Results: PROVIDE is generating scientific insights that advance the pathway from identification of the individual vestibular disorder etiology to providing personalized treatment. It is also developing new tools and methods that are freely available to all researchers. In addition, PROVIDE is creating openly accessible educational resources and training materials through an online learning platform as well as opportunities to participate in training events.

Conclusions: By promoting equitable and inclusive practices in training, research, and healthcare, PROVIDE is advancing interdisciplinary vestibular research and contributing to the development of sustainable tools to transform the management of vestibular loss and foster knowledge exchange and outreach beyond the network.

SU51. Effects of Prosthesis Stimulation on Compensatory Saccades During the En-Bloc Head Impulse Test in Vestibular-Impaired Monkeys

Yoshiko Kojima^{*1}, Leo Ling¹, James Phillips¹

¹*University of Washington*

Background: The vestibulo-ocular reflex plays a critical role in gaze stabilization. Patients with vestibular loss cannot maintain gaze on a target during head movements because the eyes move with the head. The head-impulse test (HIT) detects this instability by having patients fixate on a target while the head is rapidly and unpredictably rotated to stimulate the semicircular canals. Patients make two types of compensatory saccades during HIT: covert saccades, which occur during head rotation, and overt saccades, which occur after head movement stops. Patients who acquire covert saccades show improved Dizziness Handicap Inventory scores, higher visual acuity, and reduced oscillopsia, likely because retinal slip is minimized and vision is suppressed during the saccade. Learning to generate covert saccades is therefore important for quality of life. To study the neural basis of these movements, we developed a vestibular-impaired monkey model and confirmed use of a saccadic strategy during en-bloc HIT, in which head and body rotate together.

A vestibular neuroprosthesis has been used to replace missing sensory motion information. Although significant progress has been made in surgical implantation techniques and waveform optimization over the past two decades, functional restoration remains incomplete. Novel approaches are therefore needed to achieve full recovery. As a supplement to current strategies, one approach is to understand how the brain integrates and adapts to artificial stimulation delivered alongside natural neural activity, including residual vestibular function and saccades. In this study, we test whether vestibular prosthesis stimulation facilitates saccades during en-bloc HIT and assess its long-term effects.

Methods: One bilaterally vestibular-impaired monkey was tested during en-bloc HIT at a peak velocity of 100°/s. The right horizontal semicircular canal was stimulated with a vestibular prosthesis delivering biphasic pulses at 250 pps.

Results: Vestibular neuroprosthesis stimulation facilitated leftward saccades. Repeated sessions enhanced performance in both stimulation and no-stimulation conditions, and this effect persisted for several days.

Conclusions: Right-ear stimulation drives activity in the right vestibular nucleus, which in turn enhances activity in the left abducens nucleus through excitatory projections and reduces right abducens nucleus activity via inhibitions. During leftward saccades, the right abducens serves as antagonist whereas the left abducens as agonist. As stimulation depressed antagonist activity and enhanced agonist activity, the balance shifted toward easier saccade initiation. Furthermore, the long-lasting effects suggest that stimulation also induces adaptation or plastic changes in neural circuits that control gaze stabilization.

These findings indicate that vestibular prosthesis stimulation may facilitate recovery by enhancing covert saccade initiation.

SU52. Defining Contributions of the Vestibular Nuclear Complex (VNC) to Vestibular Short Latency Evoked Potentials (VsEPs) of the Rat

Danial Naqvi¹, Mamiko Niwa¹, Rod D. Braun¹, Avril Genene Holt¹

¹*Wayne State University School of Medicine*

Background: The vestibular system is crucial for posture, gait, and the perception of head and body position in space. Our lab has shown that linear jerk stimulation of irregular vestibular afferents activates central vestibular pathways and is measurable with vestibular-short latency evoked potentials (VsEPs; Holt et. al, 2025). Previous lesion studies in chickens have shown that P2 and later peaks of the VsEP waveform reflect activity of central pathways (Nazareth and Jones, 1997). However, the contribution of the vestibular nuclear complex (VNC) to mammalian VsEP waveform peaks is not well understood. Designer receptors exclusively activated by designer drugs (DREADDs) are genetically engineered receptors used to modulate neuronal activity. These receptors are only activated upon administration of an exogenous ligand. We expressed inhibitory DREADDs in the VNC to initially determine whether the VNC contributes to later VsEP peak(s).

Methods: Sprague-Dawley rats received bilateral VNC injections of an inhibitory DREADD viral vector (AAV2-CAG-hM4Di-P2A-mCherry-WPRE) via stereotaxic surgery. Craniotomies were sealed with dental cement, and a ceramic nut was fixed at Bregma to allow attachment to

the shaker arm for jerk stimulation. Three - 4 weeks after the surgery, VsEPs were recorded across two sessions, at least one week apart. Each session included two blocks of 2,000 jerks (1,000 up, 1,000 down, ~3,300 g/s). During session one, animals received saline (IP) before block one and deschloroclozapine (DCZ; DREADD agonist) before block two. During session two, saline was given prior to both blocks to control for the potential effect of repeated stimulation. VsEP amplitudes and latencies (P1, P2, P3) in each session were analyzed and compared across blocks. To determine which brain regions expressed the fluorescent DREADD receptors, animals were transcardially perfused. Brains were postfixed, cryoprotected, serially sectioned (40 μ m), and imaged.

Results: During the first session, P3 amplitude was significantly reduced in the block following DCZ administration compared to the saline block ($p < 0.05$, paired T-test). There were no significant differences in P1, P2, and P3 amplitudes between blocks in session 2. Administration of DCZ also increased P2 response latencies compared to the saline block in session one ($p < 0.05$). No significant differences were found between the saline blocks in session two. To confirm DREADD expression, we imaged histological sections through the VNC.

Conclusions: Our data show that partially inhibiting rostral VNC activity reduces P3 neuronal synchrony and delays P2 and P3 response times. The changes observed in synchrony and process speed reflect VNCs contribution to later VsEP waves. These results advance the interpretation of VsEPs as a tool for assessing both peripheral and central vestibular function. Future studies should assess the effects of rostro-caudal position and VNC subdivisions to the VsEP waveform.

SU53. Characterization of Auditory and Vestibular Consequences in a Preclinical Single and Repetitive Blast Model

Yuan Gao^{*1}, Federica M. Raciti¹, Pavan Krishnan², Maria Camila Salazar³, Hunter Rosenzweig³, Curtis King⁴, Michael Hoffer¹, Suhrud Rajguru⁵

¹*University of Miami Miller School of Medicine*, ²*University of Miami/Jackson Health System*,

³*University of Miami*, ⁴*Restor-Ear Devices LLC*, ⁵*University of Miami, Bruce W. Carter Department of Veterans Affairs Medical Center*

Background: Blast explosions can inflict significant damage on the auditory and vestibular systems. Acute symptoms following even mild blast exposures can include tinnitus, hearing loss, dizziness, and disorientation, whereas high rates of chronic sensorineural hearing loss and vestibular dysfunction are reported in the military population. In this study, we directly compare outcomes following single vs repetitive exposures to investigate progressive inner ear functional loss caused by low-intensity blasts.

Methods: Brown Norway rats (n=8; 14-18 weeks) were randomized to single-blast (8–12 psi), repetitive blast (10 total blasts, once daily) or sham (no blast). Anesthesia for the blast was achieved with isoflurane supplemented with O₂. Auditory brainstem response (ABR; 4, 8, 16, 24 kHz) and cervical vestibular evoked myogenic potential (cVEMP; 1,8 kHz) amplitude, latency and thresholds are collected at baseline, blast day (BD) 5 and BD10, post-blast day (PBD) 7, PBD14, and PBD 28. Tympanic-membrane integrity was examined prior to electrophysiological recordings. Gait kinematics, including fine movement and posture were analyzed across the groups.

Results: Both single-blast and repetitive-blast groups exhibited a significant shift in ABR and cVEMP thresholds compared with sham controls. The elevation in thresholds was accompanied by changes in amplitudes and latencies consistent with acute auditory and vestibular dysfunction. By PBD28, animals in the single-blast group demonstrated recovery, with ABR and cVEMP thresholds returning toward baseline values. In contrast, the repetitive-blast group exhibited persistent ABR and cVEMP threshold elevations at PBD28 compared to both sham and single-blast animals.

Conclusions: These findings indicate that, while both single and repetitive mild blast exposures disrupt peripheral auditory and vestibular function, recovery diverges across these groups over time. Single-blast animals show transient deficits that are partially resolved within 28 days, whereas repetitive-blast animals exhibit sustained auditory and vestibular dysfunction. This suggests that cumulative blast exposure potentially impairs endogenous functional recovery and produces long-lasting sequelae, highlighting the importance of further investigation of its mechanism.

SU54. Identifying Neurons in the Vestibular Nuclei Responsive to Vestibular Evoked Potentials

Alice Yen^{*1}, Hyun Jae Lee¹, Doris Wu¹

¹*National Institute on Deafness and Other Communication Disorders, National Institutes of Health*

Background: The peripheral vestibular system consists of two otolith organs that detect linear accelerations and three cristae which detect angular accelerations. These sensory organs are innervated by the vestibular ganglion that relays peripheral inputs to the vestibular nuclei (VN) located within the brainstem, as well as to the cerebellum. However, the circuitry and identity of the VN neurons are still largely unknown; specifically, how peripheral vestibular information from the end-organs is relayed and processed centrally is poorly understood. An important functional assessment of the striola of the otolith organs is the initiation of compound action potentials known as vestibular-evoked potentials (VsEP), in response to jerk stimuli to the head. Understanding how the VN respond and process inputs from the striola will provide insight into central processing of vestibular information in general. To identify VN neurons responding to VsEP, we examined the expression of c-Fos, an immediate early gene induced during neuronal activation, following jerk stimulation in mice. To further validate that the observed c-Fos expression is associated with VsEP, we performed the same jerk stimuli on Tmie knockout mutants, in which all hair cells lack mechanotransduction and consequently, VsEP is absent.

Methods: We applied a modified VsEP protocol to stimulate the utricle and saccule in anesthetized adult mice using maximum, repetitive linear jerk stimuli continuously for 20 minutes. Control animals also received anesthesia but were not stimulated. Thirty minutes after the end of stimulations, transcardiac perfusion was performed. Then, the brain was dissected, fixed, and cryopreserved. During processing, coronal cryosections of the brainstem at the level of VN were collected. Multiplex RNAscope was performed using probes for c-Fos, paired with Calbindin-II and Neurofilament for VN identification. In WT animals, comparisons were made between stimulated and unstimulated controls. In Tmie^{-/-} experiments, comparisons were made

between stimulated Tmie^{-/-} mutants against unstimulated Tmie^{-/-} and stimulated Tmie^{+/-} littermates.

Results: Stimulated WT mice showed an increase in c-Fos labeled neurons in caudal medial vestibular nuclei (MVN) and descending vestibular nuclei (DVN), compared to unstimulated controls. This increase in c-Fos expression is consistent with the role of striola in mediating postural control. Congruently, such increase of c-Fos⁺ neurons in DVN of Tmie^{+/-} stimulated controls was strongly reduced in stimulated Tmie^{-/-} mice. By contrast, an increase in c-Fos⁺ neurons in the rostral MVN was observed in both stimulated and unstimulated Tmie^{-/-} animals, compared to Tmie^{+/-} littermates.

Conclusions: Results of the Tmie^{-/-} mutants support the conclusion that the increased c-Fos expression found in caudal MVN and DVN after jerk stimuli is associated with VsEP. Currently, we are investigating whether these c-Fos⁺ neurons are excitatory or inhibitory in nature using known molecular markers. We are also characterizing the upregulated c-Fos expression in rostral MVN of Tmie^{-/-} mutants, which is independent of jerk stimuli.

SU55. Dexamethasone-Eluting Cochlear Implantation Reduces Intracochlear CX3CR1⁺ Cellular Infiltration and Foreign Body Response in Long-Term Follow-Up in Mice

Bryce Hunger^{*1}, Aditya Alluri¹, Brian Mostaert², Md Fahad Hossain¹, Muhammad Rahman², Shakila Mahmuda Fatima¹, Razu Ibrahim², Ya Lang Enke³, Robert Gay³, Marlan Hansen², Alexander Claussen²

¹The University of Iowa, ²University of Iowa Hospitals and Clinics, ³Cochlear Limited

Background: Cochlear inflammation and foreign body response following cochlear implant (CI) surgery may impact clinical outcomes by contributing to delayed loss of residual acoustic hearing and increasing CI electrode impedance. We have previously reported that a dexamethasone-eluting CI (DexCI) reduces macrophages infiltration and the foreign body response when assessed up to 112 days post-CI in mice and reduces CI impedance values in humans in a similar time-frame. It is not known whether these anti-inflammatory and anti-fibrotic

effects persist at clinically relevant longer-term follow-ups. This study aims to assess the effect of the DexCI in reducing the post-CI foreign body response at longer time-points beyond when dexamethasone elution is anticipated to be diminished.

Methods: 10-12-week-old CX3CR1⁺/GFP Thy1⁺/YFP mice (n=6 per group at each timepoint) on

C57Bl6 background with normal hearing, were implanted with a standard or dexamethasone-eluting mouse CI (standard CI, DexCI, respectively) in the left ear via the round window; with the

right ear being an unoperated control. Cochleae were harvested at 224- or 336-days post-CI

and prepared for immunohistochemistry to assess macrophages (CX3CR1), spiral ganglion neurons (Thy1), fibrotic tissue (α -SMA) and nuclei (DAPI). Subsequent Movat's Pentachrome staining was performed to further characterize cochlear fibrosis and neo-ossification and assess for cochlear trauma. The density of CX3CR1+ macrophages was measured in the scala tympani (ST), Rosenthal's canal (RC) and lateral wall (LW) as well as the spiral ganglion neuron (SGN) density and volume of α -SMA-positive fibrotic tissue in the ST for each cochlear turn.

Results: All cochleae implanted with a Standard CI showed robust cochlear fibrosis and neo-ossification at 224- and 336-days. However, DexCI cochlea showed minimal to no foreign body response, except in 2/6 cases at 224-days where basilar membrane translocation of the CI was identified. CX3CR1+ macrophage density and α -SMA-positive fibrotic tissue was significantly reduced in the ST, LW and RC of the basal turn in the mice implanted with DexCIs when compared with standard CIs at both 224- and 336- days post-CI. The qualitative degree of neo-ossification and fibrosis was most pronounced in cases of translocation in the Standard CI group, with the FBR spanning all three scala in instances of translocation versus being confined to the ST in cases without CI translocation.

Conclusions: DexCI reduced macrophage infiltration and fibrosis relative to Standard CI over the long-term (224- and 336- days post-CI), except in cases where basilar membrane translocation was identified. Further, we observe that insertion trauma in the form of CI translocation may amplify the CI foreign body response. These findings show that in a mouse model, DexCI reduces fibrosis well beyond the expected dexamethasone elution window, suggesting the foreign body response mitigation to be a durable effect long-term.

SU56. Systemic Treatment With Antisense Oligonucleotides Restores Vestibular Function in Usher 1C Mice

Jake Harthcock^{*1}, Jessica Landry², Raven Riley¹, Bhagwat Alapure², Zelma Iriarte-Oporto¹, Ian McNeill¹, David Huang¹, Jennifer Lentz³, Wu Zhou¹, Hong Zhu¹

¹University of Mississippi Medical Center, ²LSU Health-New Orleans, , ³Neuroscience Center of Excellence, LSU Health Sciences Center

Background: Usher syndrome (USH) is a rare genetic disorder characterized by the multi-sensory loss of hearing, balance, and vision. Approximately 2.5% of USH is caused by mutations in the USH1C gene, encoding the protein harmonin expressed in hair cells. While assistive devices such as cochlear implants help manage hearing loss, no therapies exist to restore vestibular function. Here, we studied the therapeutic effects of antisense oligonucleotides (ASO-29) to treat balance dysfunction in an Ush1c c.216G > A knock-in mouse model of USH1C. The ASO-29 targets the 216A mutation to redirect aberrant Ush1c splicing and promote full-length harmonin expression.

Methods: A single dose of ASO 29 was delivered to USH1C mice by intraperitoneal injection at postnatal day 2 (P2) and aged to 6 months. Vestibular function was assessed in ASO-treated and

untreated USH1C mice and wild-type (WT) littermate controls by measuring the vestibulo-ocular reflex (VOR) responses. Eye movements were recorded using a high-speed eye tracking system. Rotational VOR (rVOR) and translational VOR (tVOR) were measured to assess semicircular canal and otolith function, respectively. Gains, phases, and distortion indexes were calculated by performing a fast Fourier transform (FFT) analysis. General motor behavior was assessed by open-field, rotarod, and balance beam analyses. Hearing function was assessed by auditory-evoked brainstem response (ABR) analyses.

Results: At six months of age, untreated USH1C mutant mice had significantly reduced rVORs compared with WT littermates, indicating severe canal function deficits. TVOR gains remain comparable to WT mice. Additionally, untreated USH1C mice showed circling behavior, and significantly increased latency-to-fall on the rotarod and time-to-traverse the balance beam, and significantly elevated hearing thresholds at all frequencies tested compared with WT littermates. ASO-29-treated USH1C mice showed robust rVOR responses corresponding to 56 to 65% of WT levels across the tested frequency range. ASO-treated USH1C mice also showed improved latency-to-fall on the rotarod and time-to-traverse on the balance beam compared with untreated USH1C littermates. ABR analyses showed improved of hearing thresholds in ASO-treated USH1C mice compared with untreated USH1C mice.

Conclusions: Systemic ASO-29 treatment in USH1C mutant mice led to a significant restoration of vestibular canal function, vestibular behavior, and hearing function. These results demonstrate the therapeutic potential of ASOs to treat balance deficits associated with Usher syndrome. (supported by NIH R01 DC020243-01A1, 1P20GM156708-01) (JH and JL: co-presenter, JL, WZ, HZ co-correspondents)

SU57. Postnatal Role of Jagged1 in the Hair Cells and Supporting Cells of the Vestibular System

Olusegun Jimoh¹, Brandon Cox¹, Olusegun Jimoh^{*1}

¹*Southern Illinois University School of Medicine*

Background: The vestibular system, composed of the utricle, saccule, and semicircular canals, is essential for balance and spatial orientation. Sensory function within this system relies on two types of hair cells (HCs) (type I and type II), which detect head motions and gravity. Supporting cells (SCs) encase HCs, providing structural support and protecting HCs from damage, much like glial cells support and protect neurons in the central nervous system. Jagged1 (Jag1), a Notch ligand, is crucial for inner ear development, guiding progenitor cell formation, while other Notch ligands mediate the differentiation of progenitor cells into HCs and SCs. While Jag1's role in early cochlear and utricular development is well-established, its continued postnatal expression suggests an additional function during maturation. Prior research demonstrated that deleting Jag1 from SCs of the cochlea at birth led to the loss of a SC subpopulation, called Hensen cells, caused a mild hearing loss, and stereocilia deficits in inner HCs (Chrysostomou et al., 2020; Gilels et al., 2022). Previous studies have shown that Jag1 is expressed in the utricle after birth and into adulthood, suggesting its potential involvement in other processes such as postnatal HC addition, maturation, turnover or survival. Here we deleted Jag1 from utricular HCs or SCs at birth to understand its function.

Methods: We generated mouse models to delete Jag1 specifically from HCs or SCs at postnatal day (P) 1 using: Atoh1-CreER:Jag1^{f/f}:Rosa26Tom^{+/f} mice for HC-specific Jag1 deletion, and Plp-CreER:Jag1^{f/f}:Rosa26Tom^{+/f} mice for SC-specific Jag1 deletion. Utricles were immunostained with myosin VIIA to label HCs, SOX2 to label SCs and type II HCs, and Phalloidin to visualize phagosomes and stereocilia bundles. We quantified the number of each cell type at 2 and 4 weeks after the Jag1 deletion using confocal microscopy.

Results: Our preliminary results suggest a decrease in the number of SCs following Jag1 deletion from SCs, suggesting that Jag1 plays a role in maintaining SC survival postnatally. Additionally, when Jag1 was deleted from utricular HCs, we observed an increase in the number of phagosomes that target HCs at both 2 and 4 weeks post-deletion compared to controls. However, our preliminary results showed that there is no significant difference in the number of type I or type II HCs in HC-specific deletion of Jag1. This lack of change may be due to endogenous cellular turnover mechanisms that compensate for the loss of Jag1, preserving the overall HC population. However, a larger sample size and analysis at longer post-deletion periods are needed.

Conclusions: Our findings suggest that Jag1 plays a role in maintaining the survival of SCs in the postnatal utricle. The increase in phagosomes when Jag1 was deleted from HCs also suggests a role for Jag1 in the natural HC turnover process.

SU58. Effects of Tmie Deletion on Vestibular Hair Cells in Mice

Zelma Iriarte Oporto*¹, Sumana Ghosh¹, Raven Riley¹, Ian McNeill¹, Andy Lu², Bradley Walters¹, Hong Zhu¹, Wu Zhou¹

¹Head and Neck Surgery, University of Mississippi Medical Center²SURE Program, University of Mississippi Medical Center

Background: Tmie gene encodes a protein that is crucial for the mechanoelectrical transduction (MET) channel complex in the hair cells in the inner ear (Zhao et al., 2014). In a prior investigation, we characterized the vestibular phenotypes of spinner, a mouse model with a Tmie deletion for human hearing loss DFNB6 (Iriarte Oporto et al., 2025). Vestibulo-ocular reflex (VOR) tests showed that Tmie KO mice exhibited no eye movement responses to head rotation (rotational VOR, rVOR) and substantially reduced responses to head translation (translational VOR, tVOR). Additionally, single vestibular afferent recording showed that substantial reduction in the spontaneous firing rates of both canal and otolith afferents, a decrease in the population of regular canal afferents, and diminished sensitivity of otolith afferents to translation. In this study, we further examined whether loss of vestibular hair cells may underlie the functional deficits we observed.

Methods: Temporal bones were collected from 4 to 7-month-old male and female C57 BL/6 wild-type (WT), Tmie^{+/-}, and Tmie^{-/-} mice. Animals were perfused transcardially with 4% paraformaldehyde, and temporal bones were post-fixed, decalcified in 0.25 M EDTA, and microdissected to isolate cristae and maculae for whole mount processing. Immunolabeling was performed using primary antibodies against Myo7a, Sox2, and OCM. Myo7a specifically labels all hair cells, Sox2 identifies both supporting cells and type II hair cells, and OCM highlights the striolar region of the utricle and saccule and the central region of the cristae. Imaging was

conducted utilizing a Zeiss LSM 880 confocal microscope and image analysis was carried out with Zen Blue software and Fiji/ImageJ.

Results: Preliminary analysis showed no significant differences in overall hair cell density in the saccules and horizontal canals between control and Tmie KO mice. Similarly, OCM-positive cells in the utricle, saccule, and horizontal cristae did not differ between control and Tmie KO mice. Sox2 immunostaining showed increased proportion of Type II hair cells in the central region of the horizontal cristae, and the extrastriolar region of the saccule in Tmie KO mice.

Conclusions: Although preliminary, our morphological analysis indicates that vestibular hair cells are preserved in Tmie KO mice, suggesting that the observed vestibular functional deficits are not attributable to hair cell loss. This contrasts with the auditory system, where Tmie KO mice exhibit clear hair cell degeneration. Ongoing studies are focused on examining the structural integrity of vestibular hair cell hair bundles in Tmie KO mice to further clarify the basis of the functional impairments.

Supported by NIDCD R01 DC018919, 1P20GM156708-01.

SU59. (Micro)structure of the Brainstem-Cortical Pathways and Their Relation to Auditory Categorization and Speech-In-Noise Performance

Rose Rizzi*¹, Jack Stirn¹, Zara Eisenhut¹, Gavin Bidelman¹

¹*Indiana University*

Background: Successful speech perception requires listeners to bin continuous acoustic information into discrete phonetic categories. Categorization skills vary among listeners; some maintain within-category acoustic information (gradient) while others discard category-irrelevant information (discrete) during perception. Listeners also vary in how consistently they label speech sounds and more gradient/consistent labeling has been linked with better speech-in-noise (SIN) perception. How gross brain anatomy and microstructure (i.e., white matter tract density) of the brain's major speech-language and auditory pathways relates to individual differences in speech categorization and SIN processing has not been explored.

Methods: We assessed individual differences in categorization and SIN comprehension via phoneme labeling and QuickSIN tasks. Diffusion-weighted imaging (DWI) with probabilistic tractography estimated axonal density (quantitative anisotropy – QA) of bilateral arcuate fasciculi and the acoustic radiations. Anatomical segmentation provided estimates of surface area, gray matter volume, and thickness of important frontotemporal auditory-linguistic brain areas (Broca's area) and the midbrain.

Results: Behaviorally, we found QuickSIN scores were correlated with changes in the slope of listeners' identification curves suggesting a more stable categorization listening strategy yielded better (lower) SIN thresholds. DWI data showed that listeners with greater white matter density in bilateral arcuate fasciculus and the left acoustic radiation performed better on the QuickSIN. Further, morphometric results revealed more perceptually consistent listeners had reduced surface area and gray matter volume in left Broca's area. Behaviorally, we found QuickSIN scores were correlated with changes in the slope of listeners' identification curves suggesting a more stable categorization listening strategy yielded better (lower) SIN thresholds. DWI data

showed that listeners with greater white matter density in bilateral arcuate fasciculus and the left acoustic radiation performed better on the QuickSIN. Further, morphometric results revealed more perceptually consistent listeners had reduced surface area and gray matter volume in left Broca's area.

Conclusions: These findings support the notion that individual differences in phonetic categorization account for variance in SIN comprehension and are at least partially explained by differences in anatomical properties of the auditory-linguistic brain. Closer association between structures of the left cerebral hemisphere (surface area, gray matter volume) and behavioral response consistency in phoneme labeling suggests listeners with more stable phonetic perception make more efficient use of frontal language areas. Higher density in the acoustic radiations further suggests that the subcortical auditory pathways also contribute to better SIN understanding. This may involve afferent but also corticofugal efferent pathways.

SU60. Subcortical Speech Coding Predicts Perceptual Consistency in Phoneme Categorization and Improved Speech-in-Noise Perception

Rose Rizzi*¹, Jack Stirn¹, Zara Eisenhut¹, Gavin Bidelman¹

¹*Indiana University*

Background: Listeners discretize the speech signal by assigning sounds to phonetic categories, though there is variability between individuals in how they accomplish categorization. Retaining more within-category acoustic information (gradiency) and having more consistent perception of sounds may be advantageous for understanding speech-in-noise (SIN). It is unclear how different levels of neural processing in the auditory system reflect these perceptual differences. In particular, whether subcortical speech-evoked responses drive perceptual consistency and gradiency in acoustic- mapping has not been thoroughly explored.

Methods: We recorded brainstem frequency-following responses (FFRs) while listeners actively labeled vowels along an acoustic-phonetic continuum using a visual analog scale. We measured individual differences in gradiency and consistency via phoneme labeling and SIN comprehension via the QuickSIN. We computed intertrial consistency of FFRs to index the stability of listeners' neural speech representation across stimulus presentations. We also assessed how faithfully midbrain responses represented stimulus acoustics using representational dissimilarity matrices (RDMs) computed across all token pairs. Neural RDMs were then compared with acoustic RDMs to estimate neuro-acoustic correlation (NAC) and thus whether FFRs carried gradient vs. discrete information of the speech signal.

Results: Greater behavioral consistency during phoneme labeling was correlated with improved SIN scores. Neurally, we found listeners with greater behavioral consistency also had more consistent subcortical representations of speech sounds in their FFRs. Likewise, more consistent listeners and more gradient listeners had higher NAC in subcortical RDMs, suggesting a more accurate and detailed encoding of the speech continuum.

Conclusions: Our findings reveal important benefits of perceptual consistency (and to a lesser extent gradiency) to several domains of speech perception. We find perceptual consistency is driven by more faithful stimulus feature encoding at a surprisingly early, subcortical level of the auditory system. More consistent sensory processing could provide a more stable readout of the

speech signal to higher cortical brain areas. This could in turn confer advantageous to later perceptual processes downstream, including understanding speech in noise.

SU61. Comparison of Speech in Noise Processing in Hearing Impaired Populations Using [15O]Water Pet

Phillip Gander^{*1}, Laura Kiskunas², Joel Berger², Bob McMurray², Inyong Choi², Laura Ponto¹, Timothy Griffiths³

¹*University of Iowa Hospitals and Clinics*, ²*University of Iowa*, ³*Newcastle University*

Background: Difficulty with speech in noisy real-world environments remains a primary complaint in hearing impaired (HI) listeners despite successful use of amplification devices. Research in normal hearing listeners indicates that auditory cortex is active while abstracting speech objects from noise and provides input to fronto-temporal networks for further perceptual, attentional, and semantic analysis. We want to understand whether these are the same neural mechanisms across hearing impaired listeners with different devices (CI and hearing aid) and configurations, and how these mechanisms relate to successful hearing outcomes.

Previously we demonstrated in a proof-of-concept study that we could robustly and reliably measure brain [15O]Water positron emission tomography (PET) blood flow activity to speech in noise in cochlear implant users at a single subject level. We observed activity in a fronto-temporal network to speech in noise in each single subject. Here we expand our investigation to include a broad range of hearing impairment (CI and hearing aid users) and device configurations to capture variability that may be different to that of a matched control population.

Methods: We measured brain blood flow using [15O]Water PET in a group of 44 cochlear implant subjects, 20 hearing aid users, and 20 age-matched normal hearing controls while they performed a word-in-noise identification or noise-control task (matched on RMS sound level). Six runs were performed for each condition. On a given 3-min run for speech in noise (+15 dB SNR), word tokens were presented in multi-talker babble, and at random intervals subjects were prompted to perform a 4-alternative forced choice task. The control condition was a noise level detection task matched for response demands. PET data were analyzed in SPM12 using a flexible factorial model.

Results: We found robust activations in single subjects for the contrast speech in noise vs control noise in auditory cortex and inferior frontal cortex. Group level activation regions of interest in auditory cortex and inferior frontal cortex were significant, along with activations across a network of areas involved in language processing ($p < 0.05$, corrected). Group comparisons highlighted differences in the involvement of frontal cortex which may relate to the existence of acoustic hearing. A regression analysis including speech in noise task performance indicated the involvement of brain regions for attention and object analysis.

Conclusions: Our results show that speech in noise processing in different hearing impaired populations may depend on the availability of residual acoustic hearing, and the use of brain networks for language similar to that of the normal hearing population.

SU62. Intelligibility Modulates Early Attentional Filtering of Competing Speech

Benjamin Richardson¹, Merri Rosen², Christopher A. Brown³, Barbara Shinn-Cunningham*¹

¹*Carnegie Mellon University*, ²*NEOMED (Northeast Ohio Medical University)*, ³*University of South Florida*

Background: The intelligibility of competing speech influences how it interferes with perception of target speech. However, most previous studies have failed to equate local spectrotemporal statistics; thus, observed differences in performance may reflect differences in low-level acoustic features. Also, few measured underlying neural responses. Here, listeners performed a selective attention task, detecting target color words amidst competing, spectrotemporally matched intelligible or unintelligible maskers. We measured simultaneous electroencephalography (EEG) to gain insight into underlying mechanisms.

Methods: Twenty different normal-hearing listeners participated in each of two Experiments. Listeners were asked to attend to a target stream comprising color and object words spoken by a male talker, while ignoring a masker stream spoken by the same or a different male talker. Target words were randomly presented in time, while the masker stream was ongoing. The masker stream comprised either words drawn from the same set (Words masker), or a spectrotemporally scrambled version (Scrambled masker). Target and masker streams were also filtered in adjacent non-overlapping frequency bands to reduce energetic masking. Listeners were asked to detect target color words by pressing a button. We simultaneously measured evoked responses using EEG. In Experiment 1, the scrambling procedure resulted in a flat amplitude envelope masker. Experiment 2 served as a control, where the Scrambled masker stream was amplitude modulated with a Words masker envelope to match isochronous acoustic onsets.

We computed hit rates (responses to color words in the target stream), within-stream false alarm rates (responses to object words in the target stream), and between-stream false alarm rates (responses to color words in the masker stream in the Words condition). From the EEG, we computed the amplitude of onset sensory P1-N1 responses and P300 target recognition responses.

Results: Results replicated across experiments. A Scrambled masker yielded higher hit rates and lower within-stream false alarm rates than a Words masker. Participants performed better with a different talker than a same talker masker, but only with a Words masker. Between-stream false alarm rates with a same talker Words masker were significantly higher than with a different talker. Evoked responses mirrored behavioral performance. Onset (P1-N1) responses evoked by target color words were larger for a Scrambled masker than a Words masker. This effect was larger when the target and masker were spoken by the same talker. Target recognition (P300) was greater for target color than object words, but did not vary with masker type or talker.

Conclusions: Our results demonstrate that auditory attention is more strongly disrupted by intelligible speech than by unintelligible speech, even when their spectrotemporal properties, and thus the degree of energetic masking, are closely matched. Furthermore, intelligibility and talker differences were reflected in early sensory (P1–N1) responses, but not target recognition (P300) responses, implicating an early-latency attentional filtering mechanism.

SU63. Evaluation of Aided Speech Intelligibility, Listening Effort, and Subjective Sound Quality With Real-Time Deep Neural Network-Based Noise Reduction

Nathan Higgins*¹, Carrie Secor¹, Ashley Wright², Matthias Keller², Jason Galster², Erol Ozmeral¹

¹*University of South Florida*, ²*Sonova US Corporate Services*

Background: Hearing loss affects many aspects of daily life, yet deficits in speech understanding are especially detrimental to professional productivity, social engagement, and quality of life. As a result, improvement in speech intelligibility, notably in noisy environments, is a primary goal of hearing aid design. Strategies to improve speech understanding include use of directional microphones, and signal processing to emphasize speech-content and reduce noise. Despite these innovations, hearing aid users still frequently report difficulty hearing speech in noise. Recent advancements in computational hardware and deep learning have now made it possible to include a real-time deep neural network (DNN) noise reduction system within the physical form factor of commercial hearing aids. Initial tests of the DNN noise reduction showed up to 10 dB SNR improvement for speech in noise based on acoustic measures (Raufer et al., 2024), and behavioral results show significant improvement in speech intelligibility and reduction in listening effort (Wright et al., 2024).

Methods: Here, to further evaluate this new technology, behavioral measures in the presence of speech-shaped noise tested speech intelligibility, listening effort, and subjective measures of sound quality for the DNN-capable device (with DNN-on and DNN-off), as well as comparable commercial devices from other manufacturers. Participants (N=29) had documented hearing loss and were experienced hearing aid users. The intelligibility task used materials adapted from the coordinate response matrix (CRM; Bolia et al., 2000), with sentences presented in the free field from a range of target-azimuth locations. Listening effort was measured using the adaptive categorical listening effort scaling task (ACALES; Krueger et al., 2017). The subjective listening task presented a 4-minute two-talker conversation, followed by a questionnaire assessing elements of speech clarity, naturalness, loudness, and separation from noise.

Results: Results from the CRM experiment showed significantly higher accuracy by listeners with the DNN-on device configuration compared to DNN-off, notably for target locations at the periphery (+/- 120°) with improvement in accuracy up to 30%. Participant ratings of listening effort were significantly lower for comparable SNRs (-2.9 dB) for the DNN-on configuration compared to DNN-off. Finally, subjective measures of speech quality were significantly better with the DNN for measures of clarity, naturalness, separation from noise, and overall satisfaction compared to alternate devices.

Conclusions: The DNN-capable device tested in this experiment represents the next technological advancement in the search for optimal listener performance by providing real-time noise reduction and subsequent improvement in speech understanding. Quantitative results consistently showed better performance with the DNN-on, as measured by speech intelligibility in the CRM task and reduced listening effort in the ACALES task, without compromising the subjective sound quality provided by the device. Future studies on device-performance in multi-talker environments and real-life listening situations will need to be done to further evaluate this new technology.

SU64. Effects of Listening Effort Demands on Cortical Tracking of Attended and Ignored Narrative Speech

Juraj Mesik*¹, Michael Phelan¹, Magdalena Wojtczak¹

¹*University of Minnesota*

Background: Aging and hearing loss are associated with increased prevalence of speech perception difficulties in the presence of background noise. To maintain high comprehension performance in such challenging situations, listeners tend to exert greater amounts of cognitive resources, such as selective attention and context-based filling-in and predictive processes, which are collectively referred to as listening effort (LE).

While LE is increasingly recognized as an important factor in speech perception, it is relatively unknown how changes in LE manifest at the level of acoustic, linguistic, and semantic neural representations of speech. Multiple studies have previously reported that aging is associated with amplified cortical representations of continuous speech (e.g., Presacco et al., 2016; Decruy et al., 2019, Mesik et al., 2021), with increases in reliance on LE with age being one of the hypothesized causes of these changes. However, as LE was not directly manipulated in these studies, the extent to which cortical tracking of different speech features is affected by LE remains unclear.

Methods: In the present, ongoing study, we test whether varying the LE demands in a speech comprehension task modulates cortical processing of speech using a large sample of participants (target $n = 60$) spanning a wide age range (18-80 years). While undergoing EEG recordings, participants listen to pairs of audiobooks narrated by different male speakers, instructed to attend to one of the stories and ignore the other. On a trial-by-trial basis (i.e., every ~1 min of the story), LE demands are manipulated by pitch-shifting the ignored story such that the median F0 of the narrator either matches that of the target narrator, making them more difficult to distinguish (higher LE), or they differ by 4 semitones, making them easier to separate (lower LE). Following each trial, participants respond to several comprehension questions about the target story and rate their subjective LE.

Results: The EEG data from each LE condition are analyzed using temporal response function (TRF) analyses, which are used to decompose the EEG signal into contributions from the processing of attended and ignored speech at multiple levels of the processing hierarchy (acoustic, linguistic, and semantic). Effects of LE demands on cortical tracking of speech are evaluated by comparing the prediction accuracies of TRF models from each of the two conditions, and by directly comparing pairs of TRFs for the corresponding speech features between the LE conditions. The outcomes of these analyses will be used to explore how these TRF measures are related to age and cognitive status of the participants (working memory capacity, attentional inhibition, and fluid intelligence).

Conclusions: The results will help elucidate how recruitment of additional cognitive resources in effortful listening shapes cortical processing of speech at multiple levels of the speech processing hierarchy [Supported by NIH grant R21DC020788].

SU65. A Novel Algorithm for Estimating Psychometric Functions in the Matrix Speech-In-Noise Test With Automatic Speech Recognition

Stefan Stenfelt*¹, Hoda Jalalkamali¹

¹*Linköping University*

Background: The matrix speech-in-noise test was first developed in Sweden in the early 1980s and is now available in more than 15 languages. Each sentence consists of five words with a fixed syntax: name, verb, number, adjective, and noun. Test material is organized into lists of 10 sentences, each containing unique words. The primary goal is to determine the signal-to-noise ratio (SNR) at which a listener achieves a predefined level of speech intelligibility, typically 50% of words correctly identified. Traditionally, two lists (20 sentences) are required to obtain this threshold. Here, we present a novel adaptive algorithm that uses all SNR–intelligibility data to estimate the full psychometric function. In addition, participant responses are scored automatically using speech recognition, allowing the test to be performed without a tester.

Methods: The procedure consists of three iterative phases. Phase 1 begins with an SNR where no words are recognized (0% intelligibility). The same sentence is then repeated with SNRs increased in 2 dB steps until 100% intelligibility is reached. All SNR–intelligibility pairs are stored, and a sigmoid psychometric function is fitted. From this curve, SNRs corresponding to 20%, 40%, 60%, and 80% intelligibility are extracted and used in Phase 2 with four new unique sentences. The resulting data are combined with Phase 1 to refine the psychometric function. Phase 3 repeats this procedure with updated SNRs and additional new sentences. The final psychometric function incorporates all data, enabling estimation of SNR thresholds at any intelligibility level.

Results: The new method was evaluated in 20 native Swedish speakers with normal hearing. Performance was compared between the classical algorithm (20 sentences, threshold at 50% intelligibility) and the new adaptive algorithm. The adaptive approach typically required fewer than 15 sentences to estimate the full psychometric function, compared with 20 in the classical method. Threshold SNRs at 50% intelligibility differed by < 1 dB between the two approaches. Automatic speech recognition, implemented with OpenAI’s Whisper, achieved nearly perfect accuracy in scoring participant responses.

Conclusions: The proposed adaptive scoring algorithm for the matrix test yields faster results while providing the entire psychometric function, rather than a single threshold value. The 50% SNR thresholds were nearly identical to those obtained with the classical method, confirming its validity. Automatic speech recognition proved highly reliable, enabling fully autonomous administration of the test without a human tester.

SU66. The Consistency of Spectral Contrast and Auditory Enhancement Effects at Higher Frequencies in Speech Perception

Christian Stilp*¹, Matthew Winn²

¹*Marquette University*, ²*University of Minnesota*

Background: Perception of any sound is influenced by the spectrum of its preceding context. In spectral contrast effects (SCEs), a spectral peak in the preceding context stimulus promotes

perception of spectrally adjacent information in the target sound. In auditory enhancement effects (EEs), a spectral notch in the preceding context stimulus promotes perception of that same spectral region in the target sound (i.e. pop-out effect). SCEs and EEs have long been studied in isolation without much examination of a potential link between them. Stilp and Winn (2025 ARO) reported strong consistency in SCE and EE magnitudes affecting normal-hearing (NH) listeners' categorization of mid-frequency /d/-/g/ targets ($r = 0.76$). However, this consistency did not extend to perception of noise-vocoded speech ($r = 0.05$), possibly due to reduced access to fine spectral details distinguishing /d/ from /g/. Here we assessed the consistency of SCEs and EEs in wider-band, higher-frequency speech cues that distinguish /s/ (as in "seat") from /ʃ/ (as in "sheet"). We predicted the magnitudes of SCEs and EEs would be consistent in how they affected listeners' categorization of spectrally intact and degraded speech. We also predicted that spectral smearing would broaden spectral peaks (increasing SCEs) and make spectral notches less shallow (decreasing EEs).

Methods: Nineteen NH hearing listeners categorized target words from a 10-step continuum ranging from "seat" to "sheet". The target word was always preceded by a context sentence filtered to elicit SCEs and EEs. To elicit SCEs, a bandpass filter amplified energy from 2200-4500 Hz or 4500-8200 Hz to facilitate contrastive perception of "seat" and "sheet", respectively. A bandstop filter attenuated energy in these same frequency regions to elicit EEs.

Results: Both SCEs (more high-frequency "seat" responses when the context sentence had the lower-frequency range amplified) and EEs (more "seat" responses when the context sentence had the higher-frequency range attenuated) influenced perception of both spectrally intact and degraded speech. Data showed consistency among SCE and EE effect magnitudes in spectrally intact speech ($r = 0.45$) but not degraded speech ($r = 0.19$), showing that spectral degradation disrupts the symmetry between these auditory effects even when the target does not demand fine resolution. We observed larger SCEs than EEs in noise-vocoded speech ($p < .001$), consistent with predictions based on spectral smearing.

Conclusions: The consistency of EE and SCE magnitudes in NH listeners' speech perception extends to higher-frequency speech contrasts, but is disrupted with spectral degradation, indicating another fundamental aspect of hearing that is likely affected by CI processing.

SU67. Simulated Peripheral Adaptation Accounts for Spectral Context Effects in Speech Perception

Braden Maxwell*¹, Matthew Winn¹, Christian Stilp²

¹University of Minnesota, ²Marquette University

Background: Perception of any sound is influenced by the spectrum of its preceding context. In spectral contrast effects, a spectral peak in the preceding context stimulus promotes perception of spectrally adjacent information in the subsequent target sound. For example, when perceiving a sound that could be "da" or "ga", a precursor context sentence with prominent energy in low-F3 frequencies (1700-2700 Hz) encourages perception of the high-F3 target "da"; a context sentence with prominent energy in high-F3 frequencies (2700-3700 Hz) encourages perception of the low-F3 target "ga" (Stilp and Assgari, 2017). Here, we used computational modeling to evaluate the hypothesis that adaptation of auditory nerve fibers underlie these perceptual shifts.

Methods: Neural responses to stimuli from Stilp and Assgari (2017) were simulated using a model of the auditory nerve that takes peripheral nonlinearities into account (Zilany et al., (2014). Center frequencies of high-spontaneous-rate fibers spanned 2300-3000 Hz to cover F3 regions of interest. Average neural rates were calculated over a 50-ms window that began at the start of the formant transition. Then, rates were normalized by subtracting the mean of the population response to obtain the population-response shape. Following Maxwell et al. (2020), a decision variable was implemented for the model to mimic behavioral responses. On each trial, if the shape of the model's population response to the target syllable more closely resembled its response to the "da" endpoint of the target continuum (smaller Mahalanobis distance), the model selected a "da" response, and vice versa for "ga". This process was repeated 100 times to yield percent correct for each context sentence/target syllable pair.

Results: Simulated neural responses captured essential characteristics of listener data from Stilp and Assgari (2017). The model's "ga" responses monotonically increased as the frequency of F3 onset in the target syllable decreased (became more "ga"-like). Critically, neural responses showed evidence of a spectral contrast effect: more high-F3 "da" responses followed precursor sentences with amplified low-F3 frequencies, and more low-F3 "ga" responses followed sentences with amplified high-F3 frequencies.

Conclusions: Modeling results supported the hypothesis that neural adaptation in the auditory periphery can explain spectral contrast effects in speech perception. Shifts in simulated neural responses accounted for shifts in behavioral responses to the same stimuli. Future work will explore additional experimental paradigms and contributions by later stages of neural processing.

SU68. Subcortical Responses to Connected Speech: The Role of Language Experience

Zilong Xie*¹, Zhiying Qian¹

¹*Florida State University*

Background: Prior studies have shown that both long-term language experience and short-term training can enhance subcortical auditory encoding of speech sounds. However, these investigations often rely on frequency-following responses elicited by repetitive, isolated speech stimuli (e.g., single syllables), which do not reflect the dynamic and continuous nature of everyday speech. The present study aims to examine the extent to which language experience influences subcortical processing of connected speech.

Methods: Participants included four groups of normal-hearing adults with varying levels of Mandarin Chinese proficiency: native English speakers with no exposure to tonal languages (n = 11), beginner-level Mandarin Chinese learners (n = 21), advanced Mandarin Chinese learners (n = 14), and native Mandarin Chinese speakers (n = 20). They listened to synthesized Mandarin sentences, each composed of four syllables, with an additional one to three syllables appended at the end of each trial. During the task, they engaged in cyclic syllable counting from 1 to 4 and reported the final count. To assess subcortical auditory processing, temporal response functions (TRFs) were used to model EEG responses using speech features estimated from auditory nerve models. TRF metrics—including model prediction accuracy, peak latency, and peak amplitude—were compared across groups to evaluate the influence of language experience on subcortical encoding of connected speech.

Results: TRFs across all groups showed a prominent peak around 8 ms, resembling the wave V of auditory brainstem responses, indicating subcortical involvement in processing connected speech. No significant group differences were observed in the latencies or amplitudes of this wave-V-like peak, nor in the model prediction accuracy.

Conclusions: These preliminary findings did not provide evidence for an effect of language experience on subcortical processing of connected speech. Further research is warranted to examine subcortical responses to more naturalistic, continuous speech stimuli.

SU69. Effect of Reverberation and Interruptions on Listening Effort

Victoria Figarola*¹, Wusheng Liang¹, Sahil Luthra¹, Matthew Winn², Christopher A. Brown³, Barbara Shinn-Cunningham¹

¹*Carnegie Mellon University*, ²*University of Minnesota*, ³*University of South Florida*

Background: Everyday listening often occurs in complex environments that include distractions and distortions. Prior work on factors that disrupt spatial selective attention have been conducted in anechoic settings (Liang et al., 2023), but realistic settings involve reverberation that would affect the clarity of both the target signal and the distractors. Although reverberation increases difficulty of target perception, it could also reduce salience of distractors; furthermore, listeners can adapt to stable reverberation in the environment. The impact of reverberation on disrupted auditory attention is therefore unknown. This study tested whether reverberation amplifies or reduces the disruptive impact of interrupters on recall of a target, and whether pupil dilation can index these effects.

Methods: Participants (N=60, normal hearing) heard two competing, temporally interleaved streams of syllables with and without interruptions. Both streams consisted of syllables from the same male talker; they differed only in their location, with one stream spatialized to 30° left and the other to 30° right of center. All syllables and interrupters were spatialized using binaural room impulse responses (BRIRs).

At the start of each trial, a spatialized /ba/ cued the listener to the target stream. Streams comprised 4 syllables randomly drawn with replacement from [/ba/, /da/, /ga/]. Syllable onsets were 600 ms apart; the target began 300 ms before the distractor. At the end of the trial, subjects reported the target syllables in order. In 50% of trials, a novel interrupter occurred 125ms before the onset of the 2nd target syllable. Syllable recall accuracy was compared across conditions. The time course of pupil diameter was baseline-corrected, z-scored, and analyzed using cluster-based permutation tests; peak pupil size latency and amplitude were extracted as summary measures.

Results: Reverberation and interruption each significantly reduced syllable recall accuracy, with the strongest effects for syllables after the interrupter. Interrupters decreased accuracy by ~8%, and reverberation by ~6%. Pupil time courses showed significant clusters of increased dilation for interrupted trials in both environments. Peak amplitude analyses revealed larger dilation for interrupted versus uninterrupted trials, with a marginal effect of reverberation and a significant interaction: The reverberant, uninterrupted condition elicited the smallest peak amplitude despite

being behaviorally most difficult. Peak latency occurred earlier under both reverberation and interruption, with additive effects but no interaction.

Conclusions: Unexpected interrupters reliably increase cognitive effort, amplified under reverberation. Uninterrupted reverberation produced both the lowest accuracy and smallest pupil response, which may reflect reduced salience of syllable onsets and energetic masking from reverberant tails. These findings extend adaptation theories by demonstrating that although listeners may perceptually adjust to reverberation, working memory and attentional demands remain vulnerable to interference.

SU70. Optimized Feature Gains Explain and Predict Successes and Failures of Human Selective Listening

Ian Griffith*¹, Preston Hess², Josh McDermott²

¹*Harvard University*, ²*Massachusetts Institute of Technology*

Background: Attention enables communication in settings with multiple talkers, allowing us to select sources of interest based on their features. Decades of research have left two gaps in our understanding of feature-based attention. First, humans succeed at attentional selection in some conditions but fail in others, for reasons that remain unclear. Second, neurophysiology experiments implicate multiplicative gains in selective attention, but it remains unclear whether such gains are sufficient to account for real-world attention-driven behavior. To address these gaps, we optimized an artificial neural network with stimulus-computable feature-based gains for the task of recognizing a cued talker’s speech, using binaural audio input (a “cocktail party” setting).

Methods: We optimized a deep neural network to report words spoken by a cued talker in a multi-source mixture. The model received an excerpt of the cued talker’s speech in isolation, followed by a mixture of a different excerpt of the cued talker with other talkers and/or noise sources. Audio was spatialized within simulated reverberant rooms using human head-related transfer functions. Attentional gains were implemented via learnable logistic functions operating on the time-averaged model activations of the cue excerpt. The activations of the mixture were then multiplied by these gains. Gains could be high for features of the cue, and low for uncued features, as determined by parameters optimized to maximize correct recognition. Task performance was measured across a diverse set of diotic and spatial listening conditions for both models and human participants to quantify human-model behavioral alignment.

Results: The model successfully learned to use both spatial and vocal timbre cues to solve the word recognition task. Though not fit to human data, the model matched human performance, exhibiting selection based both on voice qualities and spatial location. The model also predicted novel attentional effects that we confirmed in human experiments. Finally, the model’s internal representations exhibited signatures of “late selection” like those seen in human auditory cortex.

Conclusions: We provide a framework to quantitatively model feature-based auditory attention by optimizing a deep neural network to perform an attentional word recognition task. The results suggest that human-like attentional strategies naturally arise from optimization of feature gains for selective listening, offering a normative account of the mechanisms and limitations of auditory attention.

SU71. EEG-Based Neurofeedback Training of Auditory Selective Attention: Toward Clinical Translation Across Languages and Listening Conditions

Jusung Ham*¹, Hyosung Joo², Jinhee Kim³, Seokhyeon Bae², Hyunju Hwang², Jukyung Lee², Barbara Shinn-Cunningham³, Inyong Choi¹, Jihwan Woo²

¹*University of Iowa*, ²*University of Ulsan*, ³*Carnegie Mellon University*

Background: Speech comprehension in noisy environments presents significant cognitive challenges, particularly for individuals with hearing impairments. While conventional hearing aids amplify sound, they often fail to improve listening in noisy settings, underscoring the importance of central auditory processing. Auditory selective attention modulates neural representations to enhance target signals over background noise, and individual variations in this ability correlate with speech-in-noise performance. Previous neurofeedback training (NFT), designed to enhance this attentional modulation, improved word-in-noise perception in normal-hearing English speakers. Building on this, the present work investigates two critical extensions for a step forward to a better clinical viability: 1) whether the training benefits generalize to speakers of a different language (Korean) and to more complex sentence-in-noise (SiN) tasks, and 2) whether the training is effective in a diotic condition, where the target and masker sounds are co-located, which is more representative of real-world listening and a crucial step for application in hearing-impaired populations.

Methods: Two groups of normal-hearing participants were recruited: ten Korean speakers and eight English speakers. All participants underwent weekly NFT sessions for three to four weeks. During training, participants attended to one of two simultaneous speech streams ("Up" with a female voice vs. "Down" with a male voice), presented either dichotically (to the Korean group) or diotically (to the English group). The target speech was visually indicated by coins placed above or below a center line. Based on the attentional state, decoded from single-trial EEG, a rocket icon moved up or down, either collecting or missing the coins. To evaluate the efficacy of training, the strength of attentional modulation and SiN perception were assessed before and after the training period. The strength of attentional modulation was measured by the magnitude of entrainment of the EEG to the attended vs. unattended speech envelope. SiN was assessed using sentences presented against multi-talker babble at varying signal-to-noise ratios (SNRs) and spatial conditions.

Results: Following the training, both studies demonstrated a trend of strengthened attentional modulation. A significant increase was observed in the magnitude of entrainment for the English-speaking group in the diotic condition (Cohen's $d=1.19$, $p=0.012$), with a similar positive trend noted for the Korean-speaking group (Cohen's $d=0.97$, $p=0.091$). Correspondingly, SiN performance showed trends of improvement when the two groups were combined (Cohen's $d=0.76$, $p=0.064$), particularly under challenging SNR conditions.

Conclusions: These complementary preliminary findings demonstrate the potential of this NFT paradigm to enhance sentence-based speech-in-noise perception across different languages and in a clinically relevant diotic listening condition. Further research involving larger populations, including individuals with hearing loss, will validate these results and advance the development of evidence-based rehabilitation strategies to improve communication in noisy environments.

SU72. Neural Correlates of One-Shot and Generalized Recognition Learning of Degraded Speech Signals

Yunkai Zhu^{*1}, Amy Garcia¹, Cameron Grier¹, Dylan Pearson¹, Andrew Dykstra¹

¹*Communication Sciences and Disorders, University of Central Florida*

Background: Separating neural correlates of conscious perception from sensory processing is a fundamental goal of cognitive neuroscience. Auditory stimuli that can help dissociate such neural correlates include degraded speech signals such as sine-wave speech (SWS) and noise-vocoded speech. Classic tasks using such stimuli often use "one-shot learning", utilizing the fact that while naive listeners hear SWS as noise or whistles, a single exposure to corresponding original speech (OS) can render SWS word-like. This permits the comparison of different percepts (before and after one-shot learning) despite identical stimuli, effectively separating stimulus processing from conscious perception. However, few studies have examined the neural plasticity associated with such learning or how such effects change across longer timescales (e.g. the course of a one-shot learning SWS experiment).

Methods: 19 participants listened to 60 pre-selected SWS tokens or phonetically similar foils, each taken from a previously curated dataset. Each subject was asked to listen to SWS both before and after hearing corresponding OS and in each case to select the word they perceived in a two-alternative forced-choice (target word or phonetically similar foil). Electroencephalography (EEG) was measured throughout and binned based on whether the word occurred before or after OS (i.e. pre- versus post-OS) and whether the word occurred early or late (i.e., in the first or second half of the experiment, respectively).

Results: Listeners were more accurate at recognizing target words after versus before OS. However, this effect was weakened as the experiment progressed, reflecting the fact that participants' accuracy on pre-OS SWS recognition also increased as the experiment progressed, suggesting generalized SWS learning. Slow cortical responses showed a one-shot learning effect at posterocentral electrodes after 500 ms as well as above-chance pre- versus post-OS decoding, particularly between ~200 and 600 ms post-stimulus. Reflecting generalized learning of SWS, this decoding effect weakened as the experiment progressed. However, this early-versus-late effect was only significant in the alpha band, consistent with time-frequency analysis showing significant early-versus-late differences in the alpha and beta bands from ~50-350 ms after stimulation.

Conclusions: Consistent with previous studies, our results show that listeners can both utilize immediately preceding context to help them recognize otherwise unintelligible SWS tokens, and that they can learn to perceive SWS more generally (i.e., without cues) on a relatively slower timescale, perhaps engaging a novel, learned listening mode for SWS. The neural plasticity underlying both effects is reflected in both the slow cortical potential and higher-frequency (e.g., alpha- and beta-band) EEG signals. Such longer-term learning effects should be considered in one-shot learning experiments.

SU73. Predicting Speech-In-Noise Performance and Noise-Reduction Outcomes With Electrophysiological and Subjective Measures

Subong Kim^{*1}, Susan Arzac¹, Natalie Dokic¹, Jenn Donnelly¹, Nicole Genser¹, Kristen Nortwich¹, Alexis Rooney¹

¹*Montclair State University*

Background: Individuals with similar clinical hearing profiles have varying tolerance to background noise, which is an inherent individual trait that may affect their reaction to noise-reduction (NR) processing commonly implemented in digital hearing aids. The present study evaluated such individual characteristics using electrophysiological measures and subjective noise-tolerance profiles to examine their relationship with speech-in-noise performance and NR outcomes.

Methods: The neural signal-to-noise ratio (SNR), an amplitude ratio between auditory evoked responses to target speech and noise onset, was calculated for each individual as a cortical index of noise tolerance from a cohort of 42 individuals with normal hearing. Further, noise-tolerance profiles were derived using k-means cluster analysis to assign participants into distinct subgroups based on their performance on a noise-tolerance domain test, which evaluates the relative importance of three criteria, including noise annoyance, speech interference, and listening effort, in judgment of noise tolerance.

Results: The neural SNR significantly correlated with speech-in-noise performance and NR outcomes with varying processing strengths. However, noise-tolerance profiles did not show any differences in such outcomes among different clusters of participants. The neural SNR and noise-tolerance profiles also did not show any meaningful relationships.

Conclusions: While the neural SNR showed a robust relationship with speech-in-noise performance and NR outcomes, and subjective noise-tolerance profiles were comparatively less sensitive, subjective measures remain one of the most accessible options in the clinic. Thus, we must continue to investigate ways to incorporate both electrophysiological and subjective measures to understand better individual characteristics that determine their noise tolerance levels and hearing outcomes.

SU74. Modeling the Effects of Temporal Incoherence Within Speech on Sentence Intelligibility

Jaeeun Lee^{*1}, Cathrina Veigel², Helia Relaño-Iborra³, Torsten Dau², Andrew J. Oxenham¹

¹*University of Minnesota*, ²*Technical University of Denmark*, ³*Eriksholm Research Centre*

Background: Temporal coherence—the synchronized timing of acoustic events across frequency channels—is considered a core cue in auditory scene analysis, supporting the perceptual grouping of components from a common source. While its importance has been demonstrated extensively with synthetic and non-speech stimuli, its role in speech perception remains unclear. In particular, introducing temporal incoherence into speech by desynchronizing frequency bands does not appear to make it harder to segregate a target speaker from a competing speaker than when listening to speech in steady noise (Lee and Oxenham, 2024, J. Acoust. Soc. Am. 156, 3285–3297). It is unknown how current computational models of speech intelligibility handle speech whose onset of the frequency bands are asynchronized, or whether their predictions would depend solely on the type of background masker. This study compared

model predictions to existing behavioral data to provide new insights into the relationship between model mechanisms and human performance.

Methods: We employed the sCASP model of speech intelligibility (Relaño-Iborra et al., 2019, J. Acoust. Soc. Am. 146, 3306–3317) to predict the behavioral results of Lee and Oxenham (2024). In that study, 25 normal-hearing listeners heard speech filtered into eight contiguous frequency bands and temporal coherence was disrupted by introducing delays between bands. The target speech was presented with either speech-shaped noise or a single competing talker as the masker. Both target and masker could be temporally coherent or incoherent, with the degree of incoherence varying across conditions. The sCASP simulated peripheral auditory processing and generated speech intelligibility predictions by correlating the modulation spectrograms of the clean target speech and the degraded stimulus.

Results: The model predicted a decrease in intelligibility as across-band delays increased, consistent with the general behavioral trend. However, sCASP overestimated the severity of this decline, particularly at larger delays. The model also predicted strong masker type effects, with greater degradation in the speech-in-speech condition. By contrast, human listeners showed relatively similar performance across masker types.

Conclusions: The study examined how temporal coherence affects intelligibility of speech in complex auditory environments, employing a well-established model of speech intelligibility (sCASP) to interpret behavioral data. Our preliminary results reveal mismatches between model predictions and human performance, highlighting limitations in current modeling approaches. These findings provide insights into the mechanisms underlying auditory scene analysis with speech and point to directions for further model development.

SU75. Neural Correlates of Spectro-Temporal Modulation Sensitivity

Madhurima Patra*¹, Alexandra Hustedt-Mai¹, Michael Heinz¹

¹*Purdue University*

Background: The ability to detect spectro-temporal modulation (STM) cues is closely linked to improved speech-in-noise perception, an ability particularly compromised in individuals with sensorineural hearing loss (SNHL). Impaired STM sensitivity has often been attributed to broadened cochlear tuning and is increasingly being considered a potential early indicator of SNHL.

A new clinical measure, the Audible Contrast Threshold (ACT), adaptively manipulates modulation depth to quantify STM sensitivity. This test has been validated across both normal-hearing and impaired listeners, showing promise as a practical and, importantly, language-independent tool for assessing auditory function. By avoiding linguistic confounds, ACT allows assessment in diverse populations and may support clinical decision-making regarding amplification strategies.

While behavioral studies highlight the real-world relevance of STM sensitivity, less is known about its neural correlates. Cortical responses to acoustic changes, measured as the Acoustic Change Complex (ACC), provide a physiologically grounded metric related to intelligibility. Using electroencephalography (EEG), we seek to characterize how cortical dynamics track STM changes and whether these signatures align with psychophysical markers such as ACT.

Methods: Human EEG recordings were collected while participants listened to STM blocks embedded in broadband noise. Stimulus design alternated between spectrally structured and unstructured sequences, with energy carefully equated across conditions. EEG was acquired using a 32-channel BioSemi system. Post-change neural features, including auditory steady-state responses (ASSR), band-limited power, root-mean-square amplitude, and global field power were analyzed. Logistic regression with stratified five-fold cross-validation was applied to decode modulation depth and classify clean versus noisy conditions. ACT scores were also obtained for all participants, serving as a complementary behavioral reference.

Results: Spectral decomposition revealed that the neural representation of STM stimuli varied across frequency bands. In particular, delta and theta phase coherence following stimulus change increased systematically with modulation depth, consistent with theories of neural entrainment in speech tracking. However, classification accuracy for modulation depth was marginally above chance, suggesting subtle cortical distinctions. In contrast, clean versus noise-added conditions were robustly classified, with area under the ROC curve well above chance, largely driven by ASSR contributions, suggesting that noise-related envelope coding elicits stronger cortical signatures than modulation depth encoding.

Conclusions: Our findings suggest distinct cortical signatures of STM encoding in the human brain, aligning neural entrainment with behavioral measures of modulation sensitivity. By combining EEG with ACT, this work bridges psychophysical and neural levels of analysis, offering a stronger framework for assessing auditory deficits in SNHL. Parallel EEG studies are ongoing using several pre-clinical chinchilla models of SNHL to garner more direct mechanistic insight. Overall, these cross-species insights further support the translational use of STM measures for precision clinical diagnostics and intervention planning.

SU76. External Validation of an Acoustic Change Complex Prediction Model for Speech Perception in Adults With Sensorineural Hearing Loss

Lana Biot¹, Laura Jaxsens², Emilie Cardon¹, Huib Versnel³, Annick Gilles¹, Vincent Van Rompaey¹, Marc J.W. Lammers²

¹*University of Antwerp*, ²*Antwerp University Hospital*, ³*University Medical Center Utrecht*

Background: The acoustic change complex (ACC) is a cortical neural response to changes in an ongoing sound, recorded via electroencephalography. Previous work by our group (Vonck et al., 2022) presented an ACC-based prediction model to predict the behavioral speech reception threshold (SRT), which explained 87% of the variance in SRT in normal-hearing and hearing-impaired individuals. This model suggests that the ACC could serve as an objective tool for assessing auditory performance, especially in populations with limited language or cognitive abilities. Our research aims to externally validate the ACC-based prediction model in a broader population with varying degrees of sensorineural hearing loss (SNHL).

Methods: Eighty adults aged 18-65 years (35 men, 45 women) with varying degrees of SNHL participated in this study. ACCs were evoked using acoustic change stimuli consisting of a 3000 ms reference tone at 1000, 2000, or 4000 Hz, gliding to a 300 ms target tone with a 12% higher frequency (i.e. 1000-1120 Hz, 2000-2240 Hz, 4000-4480 Hz). Each participant underwent pure-tone audiometry to determine normal hearing or the degree of SNHL. The SRT was obtained

using the Leuven Intelligibility Sentences Test (LIST). To assess test-retest reliability of the ACC, 52 participants completed a second ACC recording 1-4 weeks after the initial session.

Our aim is to validate the ACC prediction model by Vonck et al. (2022): $SRT = -6.4 + 0.071 \cdot HL + 0.083 \cdot (ACC_{latency} - 100)$, with HL being the pure-tone average at 500, 1000, 2000, and 4000 Hz and ACClatency the average latency of the three ACC recordings.

Results: While the Spearman correlation between predicted and behavioral SRT was strong ($\rho = 0.750$, $p < 0.001$), Bland-Altman analysis revealed poor agreement with increasing discrepancies at higher mean values. Intraclass correlation further confirmed limited reliability of the model across the full range of hearing loss ($ICC = 0.266$, $p = 0.004$). However, ACC test-retest reliability was excellent ($\rho = 0.834$, $ICC = 0.952$, both $p < 0.001$).

Conclusions: External validation revealed that the current ACC prediction model performs adequately only in individuals with normal hearing to mild hearing loss. To generalize across broader SNHL profiles, model refinement is necessary. Further refinement of the model is currently ongoing to improve its applicability. Nonetheless, the high test-retest reliability of the ACC supports its potential as a robust objective measure.

SU77. Estimating Speech Recognition Reference Curves Using Audiometric Measurements

Elisabeth Al*¹, Niek Versfeld¹, Cas Smits²

¹*Amsterdam UMC - location VUmc*, ²*VU Medical University*

Background: In clinical practice, audiometric tests—including tone and speech audiometry—are essential for assessing hearing acuity. Tone audiometry measures the softest perceptible sounds per frequency, establishing individual hearing thresholds, while speech audiometry evaluates word recognition across sound levels, producing a speech recognition curve. Comparing an individual's curve to a normal-hearing reference provides insight into speech intelligibility loss and helps optimize hearing aid settings.

Proper calibration is critical for reliable measurements. ANSI and ISO standards define procedures and allowable deviations, enabling consistency across equipment and locations. However, unlike pure-tone audiometry, broadband speech calibration lacks standardized methods. Previous studies have explored different procedures, but changing audiometers or transducers can still affect speech recognition outcomes, even with standard calibration. For example, improved intelligibility of 4.6 dB was reported for Sennheiser HDA200 headphones compared to free-field expectations.

Differences between free-field and headphone listening arise from anatomical acoustic effects and technical characteristics of transducers (e.g., Telephonics TDH39 vs. Sennheiser HDA200). Establishing new reference curves requires many participants and is resource-intensive, while multiple curves increase error risk. This study aims to identify and quantify these differences and develop a predictor to estimate reference curves from technical parameters, eliminating the need for repeated subject testing in the future.

Methods: Thirty-two native Dutch-speaking adults (18–25 years) with normal hearing participated. Eligibility was confirmed via history taking, pure-tone audiometry, bone conduction thresholds, and tympanometry. Audiometric testing was conducted in a sound-insulated room

using an Otometrics Astera2 audiometer under five conditions: free-field (Yamaha MP5S loudspeaker), DD450 headphones, and TDH39 headphones, both with and without audiometer-applied frequency filtering. Calibration followed ISO and IEC standards, and inverse filtering was applied to create unfiltered test material. Speech stimuli consisted of 30 Dutch word lists (Bosman and Smoorenburg, 1995). Speech recognition was assessed monaurally in the better ear, starting at 30–40 dB SPL and decreasing in 5 dB steps over six lists per condition. SRTs and slopes were derived by fitting a Gaussian function using maximum likelihood optimization.

Results: Despite careful calibration and comparable pure-tone thresholds, the DD450 consistently yielded higher speech recognition scores than the TDH39. These differences persisted across filtered and unfiltered conditions, indicating that headphone choice significantly influences speech intelligibility. Although variations in the headphones' frequency response may partly account for these discrepancies, the response characteristics alone do not fully explain the observed effects. Revisions to the calibration procedures in current standards may therefore be recommended to ensure that speech recognition results are independent of the transducer used.

Conclusions: Even when calibration standards are met and hearing thresholds are equivalent, headphone selection can alter measured speech recognition. These findings highlight the necessity of transducer-specific reference curves and motivate the development of predictive models for speech recognition thresholds, enabling reliable clinical assessments across varying audiometric setups.

SU78. The Effect of Spectral Degradation, Level, and Noise on Discourse Comprehension and Listening Effort

Gerald Tabe*¹, Natalie Field², Matthew J. Goupell², Samira Anderson², Chengjie Huang²

¹*The Hearing Brain Lab and Auditory Modeling and Perception Lab at the University of Maryland, College Park*, ²*University of Maryland College Park*

Background: Speech is often masked or distorted by background noise, with communication in background noise often occurring at increased sound levels. Speech perception often decreases at these higher levels, in a phenomenon known as “Rollover.” Hearing loss increases communication difficulty through decreased recognition of single words to impacts of comprehension of longer passages of discourse. One of the best available treatments for moderate-to-profound hearing loss is the cochlear implant (CI), but CI users struggle to communicate in noisy environments. Vcoded speech is used to simulate reduced spectral resolutions experienced by CI users. We investigated communication difficulties in noise under conditions that typically produce rollover, then measured discourse comprehension and listening effort in young normal-hearing adults when they listened to clear unprocessed or vocoded speech under quiet or background noisy conditions at different stimulus levels. We hypothesized that behavioral performance will be maximum in unprocessed speech but will significantly decline at 85 dB SPL in unprocessed and vocoded noisy speech, with this decline followed by increased listening effort at higher sound levels under noisy conditions.

Methods: Nine young normal-hearing adults between the ages of 18-30 years with no neurological or visual impairments listened to 1-1.5-minute-long literary passages, either unprocessed or vocoded. Passages were presented over headphones at sound levels of 35, 55, 65, 75, and 85 dB SPL, in quiet and in background noise at a +10-dB SNR. While listening,

participants focused on a red cross displayed at the center of a screen so an eye tracker could record their pupil dilation as a measure of listening effort. After each passage, participants answered comprehension questions to assess how well they understood the material.

Results: Behavioral performance decreased at the highest sound levels (85 dB SPL) for both unprocessed and vocoded speech in noise, which is consistent with the presence of rollover. Pupillometry revealed that listening effort peaked during unprocessed speech at 75 dB SPL in noise, suggesting that even with non-vocoded acoustic signals, increased intensity in noisy conditions forced subjects to exert more effort while listening to passages. For vocoded speech in noise, pupil dilation was lower than that of unprocessed speech at 75 dB SPL and steadily declined, possibly indicating participants' disengagement with increased task difficulty.

Conclusions: Findings suggest rollover is present during speech in noise but is not correlated with increased listening effort. In young normal-hearing adults, listening effort remained consistent across unprocessed and degraded speech, with no significant relationship with rollover as performance decreased. Additionally, listening effort peaked at a lower level than behavioral performance, indicating that listeners can compensate for a degraded, louder signal with increased effort to maintain behavioral performance. For future research applications, we would maintain challenging auditory conditions while exploring how listening effort is impacted by time-of-day effects.

SU79. Tuning In: Effects of Low-Frequency Allocation and Fine-Structure Timing on Pitch Perception in Cochlear Implant Users

Marisol Castellanos*¹, Ravinder Singh¹, Raymond Goldsworthy¹

¹*University of Southern California*

Background: Conventional cochlear implant (CI) coding strategies, such as the Advanced Combination Encoder (ACE), primarily transmit slow-varying temporal envelope cues while discarding acoustic temporal fine structure (TFS). Although effective for speech in quiet, this limits access to pitch-relevant cues—especially in the low-frequency range crucial for music perception and tonal language comprehension. This study examines whether enhancing low-frequency access and/or reintroducing TFS timing can improve pitch sensitivity in CI users. Using a within-subject psychophysical design, we compare pitch perception across four coding strategies that systematically vary low-frequency allocation and TFS encoding.

Methods: Adult CI users (data collection ongoing) are tested using the Cochlear NIC research interface, which bypasses clinical processors. Four coding strategies are evaluated: (1) ACE-NMT: Baseline ACE implementation from Cochlear's Nucleus MATLAB Toolbox, (2) ACE-LF: Custom ACE variant with expanded low-frequency channel allocation to improve access to fundamental frequency (F0) cues,

(3) HD-ACE: High-definition ACE variant (similar to HDCIS) with increased pulse density to support TFS encoding, and (4) Peak-Derived Timing (PDT): Novel strategy that introduces low-frequency-biased timing by placing pulses at waveform peaks.

Results: All strategies are loudness-balanced, with consistent mapping parameters where possible. Each participant completes three psychophysical protocols, presented in randomized order: (1) Electrode Psychophysics: Discrimination of place, rate, and combined cues to assess

baseline pitch sensitivity, (2) Pure-Tone Pitch Perception: Frequency-difference limens (FDLs) at 110, 220, and 440 Hz, and (3) Musical Pitch Perception: F0-difference limens (F0DLs) for piano tones matched in fundamental frequency.

Stimuli are processed through each coding strategy. Thresholds are estimated using adaptive procedures targeting 75% correct. Linear mixed-effects models (with subject as a random factor) evaluate strategy effects. Secondary analyses assess whether individual baseline sensitivity predicts benefit from enhanced coding.

Conclusions: We hypothesize that ACE-LF will improve FDLs at low frequencies (110–220 Hz) relative to ACE-NMT; HD-ACE and PDT will yield additional improvements by reintroducing TFS timing, especially at lower F0s; and that individual benefits will correlate with sensitivity to place and/or rate cues.

This study provides a systematic, psychophysically grounded comparison of conventional and novel CI coding strategies using both synthetic and ecologically valid stimuli. Findings will guide future CI sound coding aimed at enhancing pitch perception in music and complex listening environments. Preliminary results will be presented.

SU80. The Elusive Bilingual Inhibitory Control Advantage and Its Role in Suprathreshold Hearing: An Investigation

Stephanie Bronfman¹, Tomo Curran¹, Chloe Danley¹, Julia Gallagher¹, James Lawler¹, Xingyu Zhang¹, Hari Bharadwaj¹, Aravindakshan Parthasarathy¹

¹*University of Pittsburgh*

Background: As multilingual populations grow, it is important to understand how bilingualism influences systems that support speech perception in noise (SPIN). Selective attention and working memory are two cognitive processes that are crucial for filtering task-irrelevant sounds in noisy environments. However, the effect of multiple language exposures on these cognitive processes is still unclear. Here, we hypothesized that bilinguals would outperform monolinguals on auditory tasks that require distraction suppression but show comparable performance on tasks with minimal cognitive demands.

Methods: We recruited 153 participants (ages 18-40) through the online platform Prolific - 65 individuals whose first language (L1) is English and 88 others who are bilingual in English (L1) and Spanish (L2). All participants were right-handed, living in the U.S. or Canada, and had normal hearing. They completed four tasks designed to measure different cognitive abilities related to speech perception and working memory. The matrix sentences task evaluated informational masking by testing participants' ability to filter through multiple speakers while focusing on a target speaker. The auditory Stroop task assessed distraction suppression by having participants respond to prompts while ignoring conflicting auditory information. The Modified Rhyme Task assessed energetic masking by having participants identify a target word masked by inharmonic tones. The n-back test measured working memory by requiring participants to recognize stimuli presented earlier in a sequence.

Results: Bilingual participants showed a decreased Stroop cost, suggesting a bilingual advantage in distraction suppression. However, no group differences were observed in working memory, or the informational masking task. Surprisingly, monolinguals outperformed bilinguals in the energetic masking task, indicating that bilingualism may come with a greater cost of lexical recovery when retrieving words presented without linguistic context. Overall, findings support a conditional bilingual advantage confined to tasks with inhibitory control demands.

Conclusions: Bilingual listeners showed enhanced distraction suppression and inhibitory control. Ongoing analyses are focused on examining duration and degree of bilingualism in explaining variance on SPIN performance. Future work will test additional language pairings, broader age ranges, and real-world outcomes (e.g., listening effort, fatigue, device use) to identify when bilingual experience confers benefit, or cost, for everyday listening. Clinically, this condition-specific bilingual advantage has implications for personalized counseling and diagnostic testing.

SU81. Differential Effects of Masker Type on Speech-In-Noise Perception in ADHD

James Lawler*¹, Tomo Curran¹, Julia Gallagher¹, Stephanie Bronfman¹, Chloe Danley¹, Xingyu Zhang¹, Hari Bharadwaj¹, Aravindakshan Parthasarathy¹

¹*University of Pittsburgh*

Background: Attention Deficit Hyperactivity Disorder (ADHD) is associated with impairments in working memory and cognitive control, which are critical for goal-directed sensory behavior. These deficits may make it difficult for individuals with ADHD to selectively attend to speech in complex acoustic environments. Prior work suggests adults with ADHD experience increased cognitive load and expend more effort than neurotypical peers during speech perception-in-noise (SPIN) tasks. This effort is likely tied to limitations in working memory and attentional control, which are necessary for separating target speech from competing sounds. We hypothesize that individuals with ADHD will show lower accuracy on a SPIN task with informational masking compared to controls. We further expect that working memory and distraction suppression ability will predict SPIN task performance.

Methods: This study compared SPIN processing in individuals with and without ADHD in energetic and informational masking conditions. The Modified Rhyme Test with an inharmonic tone complex served as an energetic masker, while the Matrix Sentences task was paired with a non-overlapping informational masker to probe auditory processing at higher levels. The signal-to-noise ratio (SNR) between target and masker was varied to determine thresholds. Working memory was assessed via an n-back task ($n = 1-3$). Distraction suppression was measured using an Auditory Stroop task, calculating Stroop cost as the difference in reaction times between incongruent and congruent trials.

Results: Participants with ADHD demonstrated significantly higher SNR thresholds on the informational masking task relative to neurotypical peers, but no group difference emerged for the energetic masking condition. Initial group comparisons of distraction suppression via Stroop cost were not significant; however, after controlling for age, gender, and baseline reaction time, the ADHD group performed significantly worse. No group differences were found in working memory as measured by the n-back task.

Conclusions: The observed SPIN deficit under informational, but not energetic, masking indicates that ADHD-related deficits in speech perception occur beyond the cochlear level. The significant Stroop cost difference supports the role of reduced distraction suppression in explaining poorer SPIN outcomes for ADHD individuals. These results suggest attentional control, rather than initial auditory encoding, underlies the group differences in SPIN performance. Ongoing analyses will include questionnaire data on self-reported ADHD symptoms and medication use, allowing exploration of relationships between symptom severity, medication, and SPIN perception.

SU82. Cross-Species Physiological Measures of Spectrotemporal Modulation Processing

Mary Pierce Barnes^{*1}, Madhurima Patra², Sofia Lall¹, Michael Heinz², Hari Bharadwaj¹

¹*University of Pittsburgh*, ²*Purdue University*

Background: Restoration of speech audibility through amplification is a cornerstone of current audiological practice. Yet, individuals with sensorineural hearing loss (SNHL) often struggle to understand speech, even when it is audible, particularly in noisy environments. Psychophysical measures of sensitivity to spectro-temporal modulations (STM) have emerged as language-independent assays of suprathreshold auditory fidelity that can reliably predict speech-in-noise performance. However, behavioral testing is impractical in infants and other difficult-to-test groups and the neural correlates of this predictive power remain unknown. The acoustic change complex (ACC), an EEG response to modulation onset, may provide an objective neural correlate of STM sensitivity. This project seeks to establish normative baselines and optimized testing parameters for the STM-based ACC by collecting data in both normal-hearing humans and chinchillas. These foundational measures will then provide the framework for subsequent application across the continuum of normal hearing and SNHL in both human listeners and preclinical chinchilla models.

Methods: Human participants undergo otoscopy and full audiometric evaluation to confirm normal hearing. Behavioral measures include word identification in noise using the Modified Rhyme Test (MRT) materials, and STM sensitivity for noise carriers as in Zaar et al., (2023; 2024). Electroencephalography-based (EEG-based) ACCs were acquired as neural metrics of STM processing. Stimuli for ACC measurements were 2 seconds long consisting of a 1-s unmodulated reference segment smoothly transitioning to a 1-s spectrotemporally modulated segment. Responses to both tonal and noise carriers were collected. ACC responses are analyzed for reference-to-STM transition as a function of modulation depth and will be compared directly to behavioral STM thresholds in human listeners. Analogous stimuli are also employed for chinchillas with ACC responses measured using both subdermal electrodes and a 32-channel mini-EEG cap. Specifically, because peripheral frequency tuning in chinchillas is known to be substantially broader than psychophysically measured frequency selectivity in human listeners (Temchin et al., 2008; Shera et al., 2010), measurements in chinchillas span a wider range of STM parameters.

Results: Preliminary data show that ACC responses are measurable in both species. In human listeners, preliminary data also show that behavioral STM thresholds are predictive of speech-in-noise outcomes, replicating the work by Zaar et al. (2023; 2024)

Conclusions: These results highlight the feasibility of using the ACC as a candidate neural marker of suprathreshold auditory processing relevant for speech-in-perception. Data collection in both species is ongoing with the goal of expanding the sample. Human ACC measures will be compared to behavioral STM measurement to evaluate the translational potential of this approach to populations and settings where behavioral testing is not feasible. Chinchilla ACC norms established through this work will be used in future studies in SNHL chinchilla models.

SU83. The Long-Term Impact of Childhood Mild Traumatic Brain Injuries on Adult Auditory Processing Abilities

Chloe Danley¹, Tomo Curran¹, Stephanie Bronfman¹, James Lawler¹, Julia Gallagher¹, Xingyu Zhang¹, Hari Bharadwaj¹, Aravindakshan Parthasarathy¹

¹*University of Pittsburgh*

Background: Mild traumatic brain injury (mTBI), or concussion, is highly prevalent in children yet long-term neural effects are still unclear. While many children appear to recover, prior studies suggest lasting deficits in auditory working memory, speech-in-noise perception, and increased listening effort that can persist into adulthood. Normal aging independently contributes to similar declines in auditory processing abilities causing everyday communication challenges. However, the interaction between early-life concussion and age-related auditory decline remains largely unexplored, leaving a critical gap in our understanding of long-term outcomes due to mTBI across the lifespan.

Methods: 252 North American English-speaking adults, aged 18-72, were recruited via an online platform, Prolific. All participants reported normal hearing, and passed a preliminary headphone check and hearing screening. A total of 104 participants self-reported a history of childhood mTBI, while 148 served as age- and sex-matched controls. Participants completed a concussion history questionnaire, post-concussion symptom survey, and the Hearing Handicap Inventory for Adults (HHIA). Auditory assessments included speech-in-noise perception (Matrix Sentences), auditory working memory (N-back), selective attention and inhibitory control (Auditory Stroop), and energetic masking (Modified Rhyme Test).

Results: Adults with childhood mTBI performed significantly worse in a speech-in-noise task emphasizing informational masking, while no differences were observed in energetic masking conditions. Additionally, a childhood history of mTBI was also significantly associated with decreases in auditory working memory assessed using an n-back task, and inhibitory control assessed using Auditory Stroop. While aging and mTBI each negatively impacted performance on the inhibitory control and the informational masking task, mTBI did not amplify age-related declines across the lifespan, suggesting the effects of concussion are long-lasting but largely independent of aging.

Conclusions: Childhood mTBI has persistent negative effects on auditory processing in adulthood, particularly in tasks requiring working memory, inhibitory control, and involving informational masking. These deficits appear independent of aging and separate from energetic masking, underscoring the long-term impact of pediatric concussion. Clinically, results emphasize the importance of considering concussion history when evaluating adults with speech-in-noise complaints despite normal audiometric thresholds, as these patients may present with central rather than peripheral deficits. Ongoing analyses will examine the role of injury

frequency, age of occurrence, and subjective hearing handicap in shaping outcomes. Together, this work highlights the need for proactive monitoring, patient counseling, and development of rehabilitation strategies to reduce the enduring consequences of childhood mTBI.

SU84. Using Mobile EEG for Tracking Auditory Attention in Realistic Scenarios: Introducing Attention Switches and Conversations

Johanna Wilroth^{*1}, Oskar Keding², Martin A. Skoglund¹, Maria Sandsten², Martin Enqvist¹, Emina Alickovic³

¹*Linköping University*, ²*Lund University*, ³*Eriksholm Research Centre*

Background: Auditory attention decoding (AAD) identifies which sound source a listener focuses on in multi-talker settings. This is key for future hearing aids (HAs), where neural signals could guide selective amplification of attended speech. Generally, there has been a heavy focus within AAD to use controlled lab setups with clean, audio-only stimuli and record brain activity via stationary equipment such as magnetoencephalography (MEG) or wired electroencephalography (EEG). While effective, these lack ecological validity, as real-world listening involves attention switching, visual cues, and eye gaze changes.

Recent work moves toward realistic scenarios with more complex tasks (e.g., switching attention, audiovisual stimuli), and mobile devices such as ear-centered EEG arrays (cEEGrids) and wireless EEG caps are important steps toward future brain-controlled HAs. Here, we recorded mobile EEG from 24 normal-hearing participants in a novel audiovisual (AV) multi-talker paradigm with three AV conditions: sustained attention, switching attention, and attending to a podcast conversation.

Methods: The participant sat in a sound-attenuated room with three monitors at azimuths 0 degrees and 30 degrees left/right, and four loudspeakers at 30 and 90 degrees left/right. Two AV stimulus sets were used: (1) single talkers speaking to the camera and (2) a two-person podcast conversation. Conditions included sustained attention, switching between talkers, and attending either the AV conversation or a side audio-only speaker.

EEG was recorded with a 44-channel scalp cap and 20-channel cEEGrids, eye movements with a static tracker, and sound with two ceiling microphones. Linear temporal response functions (TRFs) were applied forward (predicting EEG from speech) and backward (reconstructing speech from EEG). Analyses included TRF peaks (P1, N1, P2), reconstruction correlations, optimal lags, and classification, for comparison between speech features, attention, EEG setups, audio sources, and conversation settings.

Results: Scalp EEG revealed significant attention-related P2 peak differences between attended and ignored speech. cEEGrid data showed weaker correlations, highlighting the need to investigate optimal preprocessing settings further. Performance did not differ between sustained and switching conditions, suggesting robustness to attention shifts. Classification accuracy ranged from 55–70% across decision windows (1.1–35 s), supporting feasibility in varied listening tasks with mobile EEG.

Conclusions: This study extends mobile EEG beyond single-talker audio-only settings to AV sustained attention, switching, and conversations. While cEEGrids showed weaker attention modulation, scalp EEG provided robust results with clear TRF signatures and stable model performance. Backward models generalized across tasks, with classifiers exceeding chance in all conditions. These findings bring neural tracking closer to realistic applications and future brain-controlled HAs.

SU85. Speech Perception in Quiet and Noisy Environments in Mandarin-Speaking Cochlear Implant Users With Low Frequency Residual Hearing

Ruijie Wang¹, Lei Xu^{*1}, Jianfen Luo¹, Xiuhua Chao¹, Haibo Wang¹

¹*Shandong Second Provincial General Hospital*

Background: The residual hearing (RH) is important for the rehabilitation results after cochlear implant (CI) surgery.

Methods: Thirty-seven sensorineural hearing loss (SNHL) patients (41 ears) with different degree of low frequency residual hearing (LFRH) underwent CI at our department from June 2017 to July 2024 were enrolled. Speech recognition included the monosyllable and disyllabic word in quiet, the sentence in quiet, the consonant, vowel, and lexical tone in quiet, and sentence in noisy environment. Correlations between preoperative LFRH and improvement in postoperative speech recognition rate after surgery were analyzed.

Results: Patients enrolled included six ears implanted with SY28, five with F28, six with MS, two with 422, 10 ears 512, two with 622, five with CA, two with SJ, and two with 522 electrodes. The mean age at CI surgery was 18.9 years (range: 4-44 years). The mean threshold of 125, 250, and 500Hz was 52.0dB (5-80dB), 59.9dB (35-90dB), and 73.7dB (30-105dB) HL, respectively. The preoperative recognition rate was 16.5% in monosyllable, 18.0% in disyllabic, 27.8% in sentence in quiet. The postoperative (mean, 7.6 months) rates were 65.8% in monosyllable, 73.0% in disyllabic word, 85.5% in sentence in quiet, 64.8% in consonant, 67.3% in vowel, 84.0% in lexical tone, and 4.1dB signal noise rate (SNR) in sentence in noise. The speech recognition was significantly improved at nearly one year after CI surgery ($p < 0.05$). The preoperative threshold of 125 Hz was significantly correlated with the improvement of disyllabic word recognition post CI ($p=0.0382$, $r=0.1056$).

Conclusions: Patients with residual hearing experience a significant improvement in speech recognition approximately one year after CI, and the preoperative 125Hz threshold is correlated with the postoperative improvement in disyllabic word recognition.

SU86. Frontal Cortex Modulation of Frequency Tuning During Word Recognition in Noise in Middle-Age and Older Adults

Kenneth Vaden^{*1}, Mark Eckert²

¹*Medical University of South Carolina*, ²*Columbia University*

Background: Difficulties in understanding speech in noisy environments present a significant challenge for many older adults. Pre-stimulus frontal activity appears to support word recognition in noise, including for older adults with hearing losses. One potential mechanism for

this performance benefit is frontal modulation of auditory cortex, a hypothesis supported by evidence that inhibition of cingulate cortex diminishes auditory discrimination in animals. We tested the hypothesis that pre-stimulus frontal cortex activity modulates or alters frequency tuning in auditory cortex during a word recognition in noise task and examined the extent to which tuning effects interact with age-related hearing loss.

Methods: A retrospective analysis was performed with data from 45 middle-aged and older participants (average age = 64.7 ± 7.3 years) who had normal hearing to moderate hearing loss. Participants were asked to identify words presented in speech-shaped noise (speech: 88 dB SPL, noise: 73 dB SPL; +15 dB signal-to-noise ratio). The words and noise were presented in the relative quiet between sparsely collected functional magnetic resonance imaging (fMRI) data. Spectral power in one-third-octave bands was computed for each word. For each band, a GLM was fitted that modelled words on trials with higher vs. lower pre-stimulus frontal-cortex activity, as well as a parameter for spectral power in that band. Voxel-wise characteristic frequency (CF) in auditory cortex was then defined by the band with the strongest BOLD association. Frequency tuning was examined based on the strength of BOLD associations with spectral power for CF and non-CF bands. The strength of these associations was compared between high- and low-frontal activity trials.

Results: Elevated pre-stimulus frontal cortex activity was significantly associated with higher auditory cortex BOLD contrast for both CFs and non-CFs, across subjects and speech frequencies [paired $t(224) = 3.13$, $p = 0.002$]. Participants with more hearing loss also appeared to show smaller auditory cortex responses to spectral power for specific one-third octave bands. For example, elevated 0.5 kHz pure-tone thresholds were associated with significantly smaller increases in CF effects for trials that were preceded by high pre-stimulus frontal activity [$r(31) = -0.39$, $p = 0.02$].

Conclusions: The results suggest that frontal cortex modulates auditory cortex frequency tuning during word recognition in noise by increasing the responsiveness of auditory cortex to variation in spectral power, but to a lesser extent of listeners with more hearing loss. Together, these findings are consistent with frontal modulation of auditory cortex during word recognition in noisy conditions.

SU87. Analyzing Deep Learning and Classical Machine Learning Methods for Classifying Communication and Head Movement Behaviors in Live Multi-Participant Conversations

Alexis Earley^{*1}, Anshuman Chhabra¹, Erol Ozmeral¹, Angkana Lertpoompunya², David Eddins³, Nathan Higgins¹

¹University of South Florida, ²Mahidol University, ³University of Central Florida

Background: Head movements play a pivotal role while engaged in multi-talker conversation by providing non-verbal feedback to partners and enhancing a listener's ability to separate sound sources. Commercial hearing-aids with an on-board IMU (Inertial Measurement Unit, i.e., accelerometers) typically use that information for step-counting and activity levels. At least one device uses it as an input to their environment classifier and integrated directional microphone. None, however, use the IMU to detect specific patterns of head movements to predict behaviors such as nodding, head shaking, listening to a person versus a video, or talking. Training an

automatic classifier to accurately detect these behaviors first requires collecting head movement data during multi-person conversation and laboriously annotating each behavior-type for each participant with high temporal precision. From that point, with the goal of training the most accurate model and integrating with the hardware in the hearing aid to improve device performance, the question is how best to model the data. To address this gap, we collected accelerometer data during natural multi-person conversations and paired it with detailed human annotations of communication and head-movement behaviors.

Methods: Head-movement data was collected from three cohorts of young, normal-hearing individuals (three per cohort) in a controlled, conference-room setting during 50-minute multi-talker conversations. Participants wore hearing aids with on-board accelerometers, and audio-video was recorded for each talker. Videos were manually annotated for communication and head-movement behaviors, including conversational turns and nonverbal cues such as tilts and nods. Temporal and spectral features were extracted from the accelerometer data (windowed into 1-second segments) corresponding to roll and pitch movements. These features, combined with the annotated behaviors, were used to train and test machine learning models. Models were trained on data from all but one participant and then tested on the held-out participant, repeating this procedure across all individuals.

Results: Several deep learning and classical machine learning models were compared for classifying communication behaviors (e.g., talking, listening, watching video) and head orientations (e.g., turning left or right, facing down, facing forward). More specifically, various sequence-to-sequence models, a state-of-the-art deep learning technique, were utilized. These models incorporated modern architectural components such as transformer networks. Multiple performance metrics were used to evaluate models, and results suggest that modern deep learning models outperform classical machine learning methods by significant margins. Classification performance improved further when temporal sequence information was incorporated.

Conclusions: These results indicate that during multi-talker conversation, hearing-aid accelerometers can automatically classify stereotypical behaviors with high temporal resolution (1-second). Even when tested on unseen subjects, the models remained reliable. This establishes a foundation for more advanced approaches that combine behavioral and movement patterns, further integrate temporal dynamics, and incorporate additional inputs to improve accuracy and ecological validity.

SU88. Cortical Response Differences in Hearing-Impaired and Normal-Hearing Older Adults During Speech Perception in Noise

Alexis Earley*¹, Erol Ozmeral¹

¹*University of South Florida*

Background: At the neural level, auditory streams develop along a hierarchical pathway: primitive acoustic features are encoded as early as the auditory brainstem and continually refined up to the primary auditory cortex; from there, perceptual-feature representation and ultimately object and category-specific representations are formed along the ventral cortical pathway. To investigate how selective attention operates within this hierarchical pathway, we conducted an experiment using electroencephalography (EEG). Our previous studies with younger and older

listeners have shown prominent late-latency cortical responses to changes in spatial location for steady-state noise and speech targets. The present experiment specifically investigated how hearing impairment in older listeners affects these late-latency cortical responses.

Methods: Older, hearing-impaired adults ($n = 20$) and older, normal-hearing adults ($n = 18$) were tested in the free field. Listeners were presented with a speech stream either in quiet or in background babble at 6-dB signal-to-noise ratio (SNR). Speech materials were taken from a corpus of ~2500 monosyllabic words spoken by a male voice with an interstimulus interval of 100 ms, and babble consisted of non-English conversations from 10 talkers. Listeners either passively listened or responded by button press after the speech stream changed location among 5 possible locations in the front hemifield. Cortical responses were measured using a 64-channel EEG system. EEG preprocessing was performed using the Brainstorm analysis software, followed by custom signal processing and statistical analysis in MATLAB.

Results: The EEG global field power (GFP) was characterized by N1, N2, and P3 deflections. Notably, all components were observed in both active and passive tasks, consistent with prior findings in younger normal-hearing listeners. Preliminary results suggest that participants' P3 responses to speech occurred earlier in passive conditions compared with active attention ones. During passive listening, P3 activity was higher in normal-hearing subjects than those with hearing impairment; this difference was not observed during the later P3 peaks in the active attention tasks. Earlier components (N1 and P2) were also significantly larger in normal-hearing individuals, particularly during passive conditions. Additionally, hearing impairment was associated with differences in P3 amplitude across specific spatial angles.

Conclusions: Shorter latencies could reflect primarily bottom-up, stimulus-driven processes, whereas later responses might be associated with top-down, task-related processing. The fact that the prominence of these components diverge across the listening groups could be indicative of poor audibility, as well as possible compensatory effects. Future work may include effects of intervention (e.g., amplification) on emphasizing bottom-up processing effects in the hearing-impaired listener group

SU89. Central Encoding Deficits and Compensatory Behavioral Strategies After Peripheral Deafferentation in Guinea Pigs

Marianny Pernia¹, Manaswini Kar¹, Kayla Williams¹, Srivatsun Sadagopan*¹

¹*University of Pittsburgh*

Background: Exposure to moderate-to-intense noise can cause temporary threshold shifts and permanently decreased auditory brainstem response (ABR) wave I amplitudes. These decreases are thought to arise from the peripheral deafferentation (PD) of high-threshold auditory nerve fibers that encode sounds in loud listening conditions. However, the extent to which decreased ABR wave I amplitudes correlate with speech-in-noise perception deficits has been a subject of much debate, with recent studies yielding conflicting results. Resolving this question is critical for understanding the neural underpinnings of 'hidden' hearing loss and developing effective diagnostic and therapeutic strategies.

Methods: To help resolve this question, we developed a guinea pig model to investigate PD effects on a complex sound recognition task (vocalization-in-noise categorization). We induced

PD with noise exposure and confirmed that ABR wave I amplitudes were permanently decreased while thresholds recovered to ~5 dB of baseline.

Results: We found that local field potentials (LFPs) in the auditory cortex were altered after PD, indicating changes in central sound encoding. We expected this combination of peripheral and central deficits to significantly affect categorization behavior. Surprisingly, however, animals continued to perform well in the categorization task. Behavioral analyses revealed that the animals adopted different compensatory strategies, with a high degree of individual variability, to overcome the underlying encoding deficits. To determine whether the high performance after PD could be the result of engaging top-down mechanisms, we used pupillometry in passive listening animals to measure behavioral correlates of largely bottom-up processing. We found that vocalization-in-noise categorization thresholds were indeed affected at loud sound levels, consistent with high-threshold fiber loss.

Conclusions: These preliminary results suggest that top-down mechanisms can powerfully mask PD-induced deficits present in the ascending auditory pathway. We propose that taking these central compensatory mechanisms into account is essential for resolving the debate on the relationship between PD and speech perception deficits.

SU90. Dose-Dependent Ototoxicity Effects of Gentamicin and Ethacrynic Acid in a Chinchilla Model of Snhl

Arezou Rokhforouz*¹, Afagh Farhadi¹, Samantha Hauser¹, Michael Heinz¹

¹*Purdue University*

Background: In preclinical models, sensorineural hearing loss can be induced by targeting specific cochlear structures using controlled noise exposure or ototoxic drugs. In chinchillas, carboplatin exposure selectively targets inner hair cells. A mild noise exposure protocol causes reversible threshold elevations but permanent synaptic loss between auditory- nerve fibers and IHCs (cochlear synaptopathy), whereas a moderate noise exposure protocol produces permanent damage to IHCs, outer hair cells, and synapses. Additionally, previous studies have shown that high combined but single doses of ethacrynic acid and gentamicin lead to near-complete OHC destruction, though these reports have focused primarily on anatomical and histological outcomes. The goal of this research is to develop a dosing strategy that induces gentamicin-related OHC-based hearing loss with threshold shifts like those produced by the moderate noise exposure protocol, while preserving IHCs, and to investigate the associated physiological changes in cochlear function. Optimizing efficient gentamicin protocol will provide a reliable model for studying OHC-specific contributions to SNHL and for evaluating therapeutic strategies.

Methods: Two approaches were used to induce OHC damage in chinchillas. In the first, gentamicin was administered intramuscularly in combination with intravenous ethacrynic acid, which has been used in the past to achieve OHC damage with single doses. In the second, animals received only repeated systemic gentamicin dosing over several. Hearing function was evaluated at baseline and at multiple post-treatment time points using auditory brainstem responses, middle ear muscle reflexes, and otoacoustic emissions, including distortion-product, stimulus-frequency, and transient-evoked measurements.

Results: Gentamicin combined with ethacrynic acid produced dose-dependent effects on cochlear function in chinchillas. While lower doses caused only subtle increases in ABR thresholds and small reductions in OAEs, higher doses resulted in moderate-severe to severe threshold shifts and near-complete loss of OAEs, consistent with at least widespread OHC destruction. However, the extent of this damage exceeded what typically observed in the moderate noise exposure protocol, which produce more moderate threshold elevations and preserve some OAEs, suggesting only partial OHC dysfunction. The higher gentamicin dose with ethacrynic acid was also associated with systemic health complications. Together, these findings suggest that although gentamicin with ethacrynic acid reliably induces OHC-related hearing loss, its severity can surpass the moderate noise exposure model and highlights the need to optimize dosing to achieve moderate threshold shifts while preserving IHCs, which we are continuing to pursue.

Conclusions: These preliminary findings underscore the importance of carefully optimizing gentamicin–ethacrynic acid dosing strategies to selectively damage OHCs without affecting IHCs. Establishing such a protocol will provide a consistent and efficient experimental model of OHC-specific SNHL. Beyond its research value, this model will contribute to the development of more precise diagnostic approaches that can eventually be translated to clinical practice, improving the identification of cochlear pathologies, and guiding more effective therapeutic interventions.

SU91. Relationship Between Distorted Tonotopic Coding and Suprathreshold Spectrotemporal Modulation Perception in Sensorineural Hearing Loss

Shaina Wasileski¹, Olivia Flemm¹, Michael Heinz², Hari Bharadwaj¹

¹*University of Pittsburgh*, ²*Purdue University*

Background: Threshold audiometry and restoration of speech audibility through amplification are cornerstones of current audiological practice. Yet, individuals with sensorineural hearing loss (SNHL) often struggle to understand speech, even when it is audible, particularly in noisy environments. Psychophysical measures of sensitivity to spectro-temporal modulations (STM) have emerged as language-independent assays of suprathreshold auditory fidelity that can reliably predict speech-in-noise performance. However, the mechanistic basis underlying individual differences in STM sensitivity among patients with SNHL remains unknown. Emerging cross-species evidence from our team and others suggests that SNHL not only broadens auditory filter "tips," as traditionally recognized, but also distorts the fundamental tonotopic organization of the cochlea. Specifically, temporal responses of the cochlear base can be commandeered by "off-frequency" (lower frequency) sound fluctuations. Furthermore, chinchilla models reveal that the degree of distorted tonotopy varies according to the specific cochlear pathology underlying SNHL. For instance, suprathreshold tonotopy remains largely intact in metabolic hearing loss but is significantly distorted in noise-induced hearing loss, which is associated with outer hair cell damage. Consistent with animal models, human studies demonstrate that individuals with similar clinical hearing profiles can exhibit widely varying tuning-curve tip-to-tail ratios (TTRs) and associated degrees of distorted tonotopy. These individual variations in distorted tonotopy are a candidate mechanism to explain why patients with similar audiograms can differ markedly in their STM sensitivity and speech-in-noise

comprehension. This study directly tests whether individual variations in markers of distorted tonotopy predict individual differences in STM sensitivity and speech-in-noise performance.

Methods: To investigate the relationship between distorted tonotopy and STM sensitivity, we recruited individuals along the continuum of normal hearing to symmetric moderate SNHL (N=32 thus far) to participate in lab measurements to gather STM thresholds, speech-in-noise (SPIN) thresholds, and psychophysical tuning curves. Separately, anonymous participants (N=53 thus far) were recruited to participate in online web-based measurements where STM thresholds, SPIN thresholds, and tuning-curve TTRs.

Results: Linear modeling analysis of in-lab data revealed that TTRs, a correlate of distorted tonotopy, are predictive of aided SPIN scores, and online data replicated this association. Additionally, online STM thresholds predict SPIN replicating the results from Zaar et. al (2024). In turn, STM thresholds were predicted by TTRs.

Conclusions: These preliminary data showing associations between TTRs, STM sensitivity and SPIN scores are consistent with the notion that distorted tonotopy is a prominent contributor to suprathreshold hearing outcomes in SNHL. Further data collection is ongoing.

SU92. Fidelity and Validity of the French-Canadian Version of the Communication and Acceptance Scale (FR-CAS)

Léonie Therrien¹, Alexandra Tessier², Mathieu Houtton³, Ingrid Verduyck¹, Paméla McMahon-Morin⁴, Victoria Duda¹

¹*University of Montreal*, ²*Université de Québec à Trois-Rivières*, ³*Université Laval*, ⁴*Université de Sherbrooke*

Background: Hearing loss can significantly affect various aspects of daily life. Constantly needing to ask others to repeat themselves or having to explain one's hearing difficulties and coping strategies can lead to feelings of fatigue, frustration, or discouragement. Over the years, numerous questionnaires have been validated to assess the functional impacts of hearing loss. However, hearing care professionals in French-speaking regions of Canada have access to very few tools that have been validated in their language. The Communication and Acceptance Scale (Öberg and al., 2020) is a Swedish questionnaire that comprises 22 items, including 18 statements rated on a Likert scale ranging from "totally agree" (1 point) to "totally disagree" (5 points). This study aimed to 1) translate and culturally adapt the Communication and Acceptance Scale (FR-CAS), and 2) evaluate the metrological qualities of its French-Canadian version.

Methods: This study was conducted in two phases: the first involved cross-translation, and the second focused on validation. For the first phase, the questionnaire underwent a rigorous double-translation process, accompanied by consultations with French-speaking and Swedish-speaking individuals with knowledge in the field of communication disorder, as well as audiologists, to ensure linguistic, conceptual and cultural equivalence. For the second phase of the study, a total of 90 participants were recruited. All were aged 18 or older, fluent in French, and self-identified as living with hearing loss. Participants were asked to complete three instruments: the (FR-CAS), the Hearing Handicap Inventory for the Elderly- Screening version (HHIE-S), and the Échelle de mesure de difficultés d'audition (ÉMDA). To assess test-retest reliability, participants completed

the FR-CAS a second time following a two-week interval and intraclass correlation analysis was conducted. A Cronbach alpha was measured to assess internal consistency and Spearman correlations were conducted to assess concurrent validity between the questionnaires.

Results: The internal consistency of the overall scale was strong, with a Cronbach's alpha of 0.81. Test-retest reliability was also robust ($r = 0.810$, $p < 0.001$), indicating good temporal stability. Concurrent validity was moderate, but statistically significant, when comparing total scores from the FR-CAS with both the HHIE-S ($r = -0.682$, $p < 0.001$) and the EMDA ($r = -0.615$, $p < 0.001$). All correlations were similar to those reported for the original Swedish CAS.

Conclusions: The French version of the Communication and Acceptance Scale (FR-CAS) demonstrated strong validity and reliability, establishing it as a new tool for hearing professionals in French-speaking regions of Canada. It offers a meaningful way to assess individuals' acceptance of hearing loss and its effects on communication and emotional well-being.

SU93. Longitudinal Changes in Acoustic Absorbance in Cochlear Implant Recipients

Joshua Pinzour^{*1}, Nir Ben-Shlomo¹, Aseem Jain¹, Marlan Hansen¹, Gabrielle Merchant², Rachel Scheperle¹

¹University of Iowa Health Care, ²Boys Town National Research Hospital

Background: Patients often experience decrements in acoustic hearing sensitivity following cochlear implantation.

When hearing recovers, conductive hearing loss is suspected (Chole et al., 2014). When hearing loss persists, this is often attributed to cochlear trauma. Some post-surgical changes impacting sound transmission are transient (Racca et al., 2022), though permanent ones have also been suggested (Scheperle and Hajicek, 2020). Cochlear conductive hearing loss may also contribute (Banakis Hartl et al., 2016). Correctly identifying the mechanism(s) responsible for post-operative hearing loss is critical to improving hearing preservation outcomes and to identifying the most appropriate medical and audiological management for the individual patient.

This study focuses on evaluating middle ear sound transmission using longitudinal absorbance measurements in newly implanted CI recipients. The aims include (1) establishing the incidence of suspected conductive hearing loss, (2) describing the timeline and frequency characteristics of recovery, and (3) characterizing permanent changes to middle ear transmission. Individual variability is of interest as changes post implantation may arise from multiple factors impacting different frequency regions.

Methods: Fifteen cochlear implant (CI) recipients have participated to date with various lengths of follow-up post-surgery. Video otoscopy and wideband acoustic immittance measures are being performed serially: at surgery (prior to implantation) and at each post-operative visit (initial activation, 0.5-, 1-, 3-, 6-, and 12-months post activation.) Otoscopic images are evaluated post-hoc for evidence of hemotympanum, effusion, or other notable findings. Baseline absorbance measurements are compared to published normative data, and post-operative absorbance is compared to the subject's own pre-operative baseline.

Results: Pre-operative measurements were not always normal. Some ears had a history of previous ear surgery (e.g. myringotomy tubes) or external ear abnormalities (e.g. exostosis). No ear was excluded; each subject's pre-operative measurements served as their baseline for comparison with their post-operative results

Evidence of hemotympanum/effusion was seen frequently at initial activation (~2 weeks post-surgery). Absorbance for ears with abnormal otoscopic impressions will be compared with absorbance for ears with normal otoscopic impressions. Effusion was visually observed up to 2 months. The frequency patterns, direction, and magnitude of absorbance changes relative to pre-operative baselines were highly variable across subjects. Within a subject, the absorbance systematically changed over time, though resolution to baseline was observed in only a few cases. These patterns will be quantified further as more data are available.

Conclusions: Sound transmission through the outer and middle ear is impacted by cochlear implantation. The effects are observed immediately post-surgery and change over time. Otoscopy can help identify changes to the middle ear system visible through the tympanic membrane, while absorbance patterns provide insight into changes that are less visible and may persist beyond the acute healing phase.

SU94. A Multi-Biomarker Battery for Stratifying Complex Sensorineural Hearing Loss and Predicting Listening Outcomes

Samantha Hauser^{*1}, Andrew Sivaprakasam², Hari Bharadwaj¹, Michael Heinz³

¹*University of Pittsburgh*, ²*Indiana University School of Medicine*, ³*Purdue University*

Background: Complex sensorineural hearing loss (SNHL) can involve multiple components of the peripheral and central auditory pathways, but standard clinical measures of hearing like the audiogram are primarily sensitive to OHC dysfunction. Other pathologies, such as cochlear synaptopathy or inner-hair-cell dysfunction, can remain undetected despite their detrimental effects on neural coding of sound and perception. These hidden pathologies, with or without co-occurring OHC dysfunction, are likely to contribute to variability in perception and treatment outcomes. Non-invasive biomarkers that detect the diversity of cochlear pathologies potentially present in SNHL are needed to better understand and address the complaints of individuals with hearing difficulties. Pre-clinical animal models of SNHL provide mechanistic insight into the effects of specific pathology profiles on physiological biomarkers, and studies in humans improve our understanding of the perceptual consequences of hearing loss. In this cross-species study, we use a battery of biomarkers in both human and animal subjects to dissect the clinical category of SNHL, expanding previous work to investigate multiple subtypes of hidden and overt hearing loss.

Methods: Pre-clinical chinchilla models of four types of sensorineural injury were used to assess the sensitivity of each biomarker to isolated and co-occurring pathologies, induced either with noise or ototoxic drugs. Before and after exposure, animals completed a physiological battery including auditory brainstem response (ABR) thresholds, ABR to a high-level click, envelope following response (EFR), otoacoustic emissions (OAEs), and the middle ear muscle reflex (MEMR). Human participants with normal hearing or mild to moderate SNHL were also tested

with the same physiological measures. In addition, human subjects completed three speech-in-noise tasks to relate physiological measures of hearing to speech perception.

Results: In chinchillas, biomarkers showed changes after exposure in at least one group, but no single biomarker was sufficient to accurately classify animals by their exposure group. Classification accuracy significantly increased when a combination of biomarkers was used. The most accurate model included a combination of distortion product OAEs, MEMR strength, phase-locking value, pure-tone average, EFR magnitude, and ABR Wave I amplitudes. In human subjects, including physiological measures improved the identification of individuals with poor speech-in-noise performance. Specifically, MEMR and stimulus frequency OAEs were sufficient for identifying the poorest performing individuals with normal hearing thresholds.

Conclusions: This work highlights the critical need to consider biomarkers beyond the audiogram for diagnosing hearing loss. A combination of measures sensitive to both OHC and non-OHC dysfunctions is needed to improve the diagnostic specificity of SNHL. Additionally, a large, standardized dataset will be necessary for more detailed profiling that takes advantage of advances in machine learning based classification techniques. To effectively analyze the contributions of these factors to hearing impairment, a multi-metric physiological, cross-species profiling approach will be essential.

SU95. Predicting Profiles of Cochlear Pathology From Non-Invasive Physiological Biomarkers

Samantha Hauser¹, Jane Mondul², Andrew Sivaprakasam³, Hari Bharadwaj¹, Michael Heinz²

¹*University of Pittsburgh*, ²*Purdue University*, ³*Indiana University School of Medicine*

Background: Temporal-bone histology shows that damage to outer hair cells, inner hair cells, the stria vascularis, and the auditory nerve contribute to sensorineural hearing loss.

Physiological measures such as otoacoustic emissions, the middle ear muscle reflex, and the auditory brainstem response are used both in research and clinically to detect these pathologies and to aid in identifying the site of lesion. However, it remains difficult to establish a one-to-one correlation between physiological responses and histological profiles, especially when more than one pathology is present (as is typically the case with complex sensorineural hearing loss). In this study, we examined the relationship between individual histological profiles of cochlear pathology in several pre-clinical chinchilla models and responses on a battery of physiological tests sensitive to both OHC and non-OHC dysfunctions. Our goal is to identify individual profiles of sensorineural hearing loss through physiological biomarkers of cochlear pathology.

Methods: Chinchillas with and without experimentally induced hearing loss (noise or ototoxic drugs) were used. Distortion product otoacoustic emissions (DPOAEs), stimulus frequency otoacoustic emissions (SFOAEs), wideband middle ear muscle reflex (MEMR), auditory brainstem responses (ABR), and envelope following responses (EFR) to a rectangular amplitude modulated tone were collected on each animal. Pre- and post-treatment data were collected for exposed animals. After all testing was completed, animals were euthanized and perfused. Cochleas were harvested, post-fixed, and decalcified. Cochleas were then bisected through the modiolus, immunolabeled, and dissected into half turns. Specimens were labeled for hair cells (Myo7a), afferent neurons (NFH), hair cell presynaptic ribbons (CtBP2), and cholinergic efferent

neurons (ChAT). In a subset, stereocilia were also labelled (ESPN). Confocal z-stack images were obtained at .5, 1, 2, 4, and 8 kHz cochlear locations.

Results: The noise-exposure protocol resulted in a mild to moderate elevation of ABR thresholds and reduced DPOAE amplitudes. Most of these animals, however, showed intact hair cells at the tested cochlear locations. Gentamicin exposed animals showed profound elevation of ABR thresholds and complete loss of hair cells. Consistent with prior findings, hair-cell counts alone underestimated the effects on auditory physiology. Many animals with overt elevations in hearing sensitivity showed little to no loss of hair cells. Further image analysis will also quantify the contribution of stereocilia dysfunction to responses on physiological assessments in the absence of hair cell loss.

Conclusions: Profiling individual degrees of pathology across multiple components of the cochlea is critical to understanding the contribution of various pathologies to hearing and is necessary for precision diagnostics and ultimately pharmaceutical treatments for hearing loss. Hair-cell survival is not enough to explain the effect of noise on physiological assessments of hearing. These findings highlight the need for more nuanced understanding of the relationship between histopathology and physiology.

SU96. Auditory Neuropathy Associated with Kinase Suppressor of RAS2 Deficiency

Hongzhe Li¹, Alisa Hetrick¹, Subburaman Mohan¹

¹*VA Loma Linda Healthcare System*

Background: The kinase suppressor of RAS 2 (KSR2) plays a critical role in regulating energy intake, energy expenditure, and substrate utilization. In humans, mutations in the KSR2 locus are associated with severe early-onset obesity and insulin resistance. Studies in Ksr2-knockout (KO) mice demonstrate that Ksr2 expression and function in the hypothalamus are centrally regulated, leading to neuroinflammation, hyperphagia, altered metabolic rates, and consequently obesity and type 2 diabetes (T2D). Among the many mouse genes linked to obesity, Ksr2 deletion produces one of the most profound obese phenotypes, often resulting in early lethality. Obesity, in turn, is inconveniently associated with an elevated risk of sensorineural hearing loss (SNHL), with metabolically unhealthy obesity conferring an even greater risk. A recent meta-analysis confirmed that obesity correlates with a higher prevalence of hearing impairment in adults. In this study, we evaluated auditory function in Ksr2-deficient mice to determine whether obesity driven by Ksr2 deletion contributes to the development of SNHL.

Methods: Ksr2-KO mice on a C57BL/6J-Tyrc-Brd x 129SvEvBrd hybrid background were originally obtained from Lexicon Pharmaceuticals (Woodlands, TX) and transferred to the Veteran's Affairs Loma Linda Healthcare System (VALLHS). The colony was maintained using a heterozygous × heterozygous breeding strategy and housed in a modified Specific Pathogen Free (SPF) facility, without sound conditioning of ambient noise, with ad libitum access to food and water. After weaning, mice were provided a standard diet (Teklad #7001, Envigo) and weighed weekly, while breeders were maintained on a higher-energy diet (Teklad #8626). At approximately 20 weeks of age, hearing function in littermate mice of both genotypes, Ksr2-KO (Ksr2^{-/-}) and wild-type (Ksr2^{+/+}), was assessed using auditory brainstem response (ABR) and distortion product otoacoustic emission (DPOAE).

Results: As they entered adulthood, Ksr2-KO mice rapidly developed obesity, whereas sex-matched littermates gained weight more gradually and often reached a plateau. By 20 weeks of age, the body weight of Ksr2-KO mice was nearly double that of their littermate controls. DPOAE responses showed deterioration at high-frequency regions with substantial inter-animal variability; however, overall responses were comparable between Ksr2-KO and wild-type mice. Similarly, ABR thresholds did not differ significantly between genotypes. Notably, wave-I ABR amplitudes were markedly reduced in Ksr2-KO mice for both click ($p < 0.0001$) and tonal stimuli ($p < 0.001$, two-way ANOVA).

Conclusions: Although Ksr2-KO mice exhibited a severe obese phenotype, their DPOAE responses and ABR thresholds remained normal, indicating preserved outer hair cell function. In contrast, the significant reduction in wave-I ABR amplitude suggests impaired synaptic transmission between inner hair cells and spiral ganglion neurons, consistent with classic auditory neuropathy. Similar to peripheral neuropathy—which is common in obesity- and T2D-associated neuropathies and typically affects the hands and feet—auditory neuropathy also represents a prevalent form of neuropathy in obesity and T2D populations.

SU97. Sparse Labeling of Spiral Ganglion Neurons Reveals Differences in Spike Initiation Zone Distances by Synaptic Position

Nathaniel Nowak^{*1}, Zara Mubin¹, Daniel Bronson¹, Juan Llamas², Ksenia Gnedeva², Radha Kalluri¹

¹*University of Southern California*, ²*Keck School of Medicine University of Southern California*

Background: Cochlear hair cells transduce auditory stimuli and send this information to the central nervous system through spiral ganglion neurons (SGNs). The dendrites of type I SGNs are typically unbranched and contact a single inner hair cell. The position of the synapse along the inner hair cell is correlated with synaptic morphology, sound intensity sensitivity, transcriptional profile, and the ion channel properties of post-synaptic type I SGNs. However, the extent to which diversity in SGN output reflects contributions from presynaptic hair cell machinery, intrinsic neuronal properties, or dendritic attenuation remains unclear. To address the latter, we measured the distance between synaptic terminals and spike initiation zones and will present a preliminary model that integrates these measurements with our prior ion channel characterizations as a foundation for a whole-neuron model of Type I SGNs.

Methods: To identify the spike-initiation zone and dendritic length on individual neurons, SGNs were sparsely labeled through two viral transfection strategies. First, an AAV that drives the expression of Cre recombinase was delivered intracerebroventrically in postnatal day 1-3 (P1-3) Ai14 (floxed tdTomato) mice at doses that drive sparse neuronal expression of tdTomato. Second, to selectively label modiolar-contacting SGNs, a Cre-dependent GFP virus was injected into the posterior semicircular canals of P1–P3 NF107Cre mice. Four weeks after injection, cochleae from both ears were collected and immunostained for confocal imaging of fluorescent dendrites and Caspr, a paranodal structural protein marking spike initiation zones.

Results: Across 83 modiolar-contacting and 46 pillar-contacting type I SGNs, we found that modiolar-contacting neurons had significantly shorter dendrite lengths from the peripheral terminal to the Caspr-labeled spike initiation zone. On average, modiolar-contacting dendrites were around 20% shorter than their pillar-contacting counterparts. These findings were repeated

in mice where GFP was expressed only in NF107Cre-positive neurons. 59 out of 68 NF107Cre; GFP positive neurons synapsed on the modiolar side of the inner hair cell. Consistent with these neurons being ‘modiolar’ contacting, these results closely match the proportion of Calretinin-negative NF107Cre; Ai14 somata in the spiral ganglion (223 out of 242).

Conclusions: Whether a neuron successfully fires an action potential depends on many factors, including the expression of ion channels and dendritic morphology. Our goals are to disentangle how anatomical and biophysical factors jointly determine the functional output of SGNs. These results highlight sparse labeling and the NF107Cre line as valuable tools for tracking dendritic lengths and selectively targeting modiolar-contacting type I SGNs. Ongoing work will integrate these data with previous biophysical characterizations of ion channels to assess the relative contributions of dendritic morphology and ion channel properties to the cellular mechanisms underlying SGN subtype diversity.

SU98. Aberrant JAK2 Activation During Development Alters Auditory Thresholds, Neural Gain, and Postsynaptic Architecture

Jonathan Fleege^{*1}, Vijayprakash Manickam², Dinesh Gawande², Iman Ezzat¹, Marisa Zallochi¹

¹Creighton University School of Medicine, ²Creighton University

Background: The JAK-STAT pathway is a central regulator of cytokine and growth factor signaling, with well-established roles in hematopoiesis and inflammation. However, its role in auditory development remains largely unexplored. Aberrant JAK2 signaling is known to drive hematologic disorders and alter immune cell function, raising the possibility that it may also influence cochlear maturation and neural encoding. We investigated how constitutive activation of JAK2 (Jak2CA/WT Pax2Cre) impacts auditory function, outer hair cell (OHC) physiology, spiral ganglion neuron (SGN) subtypes, and synaptic organization.

Methods: Jak2CA/WT Pax2Cre⁺ (EXP) and Jak2CA/WT Pax2Cre⁻ (CTRL) mice were assessed at P28-30. Auditory brainstem responses (ABRs) measured thresholds, P1 latency, intensity, and P1-N1/P3-N3 amplitude intensity functions across 4 - 64 kHz. Distortion product otoacoustic emissions (DPOAEs) were used to evaluate outer hair cell function. Cochlear histology included spiral ganglion neuron (SGN) subtype labeling (Tuj1, Calb1, Calb2, Peripherin), synaptic ribbon - postsynaptic pairing (CtBP2/PSD95), and afferent innervation (neurofilament, myosin 7A).

Results: EXP mice exhibited elevated ABR thresholds across the frequency spectrum, indicating a broad deficit in auditory sensitivity. Latency intensity analysis revealed significant conduction delays at 16 and 32 kHz. Although P1-N1 amplitudes were preserved, higher-order P3-N3 amplitudes were reduced at 5.6-32 kHz, suggesting impaired central auditory gain. DPOAEs demonstrated elevated thresholds and diminished growth functions, particularly at mid-to-high frequencies, consistent with compromised OHC function. SGN analysis showed a significant reduction in Calb2-positive neurons in the apical turn, while Tuj1-, Calb1-, and Peripherin-positive subtypes were preserved, pointing to selective vulnerability of a neuronal population important for temporal encoding. Synaptic ribbon counts and CtBP2/PSD95 pairing were largely intact, but PSD95 puncta appeared globular and disorganized in EXP mice, suggesting altered postsynaptic maturation rather than frank synapse loss. Afferent fiber density and gross

innervation patterns were preserved, supporting the conclusion that functional deficits arise from subtle postsynaptic and neuronal subtype changes rather than widespread neurodegeneration.

Conclusions: Constitutive JAK2 activation disrupts early auditory development at multiple levels. Physiologically, EXP mice show global threshold elevation, conduction delays, impaired OHC function, and reduced higher-order amplitude growth, reflecting deficits in both peripheral sensitivity and central gain. Structurally, these deficits are accompanied by selective SGN subtype loss and altered postsynaptic organization, despite preservation of overall ribbon counts and afferent innervation. These findings identify JAK2 as a novel regulator of cochlear development and neural encoding. Importantly, they suggest that JAK2-targeted therapies, now widely used in hematologic disease, may have unanticipated consequences for auditory function.

SU99. Angiotensin Receptors as Targets for Protection From Noise-Induced Hearing Loss

Kiran Marla^{*1}, Sepehr Salehpour¹, Carolina Chu¹, Douglas Bennion¹

¹*Carver College of Medicine University of Iowa*

Background: The renin–angiotensin–aldosterone system is a ubiquitous endocrine system with significant contributions to inner ear physiology. In opposition to angiotensin II binding to its type 1 receptor (AT1R), which drives inflammation and fibrosis, binding of the type 2 receptor (AT2R) promotes vasodilation, anti-fibrotic, and neuroprotective effects. We hypothesized that AT2R antagonism would impair recovery of auditory function after noise-induced hearing damage, and that conversely, AT1R antagonism using losartan would protect against hearing loss.

Methods: Thirty-two mice (16 male, 16 female) were randomized into four groups of 8. AT1R antagonism was achieved with losartan-infused chow, while AT2R antagonist PD123319 was delivered via continuous subcutaneous infusion via osmotic mini-pump. Controls received standard chow and/or subcutaneous saline. Groups were as follows:

- A: AT1R and AT2R antagonism (losartan + subcutaneous PD123319)
- B: AT1R antagonism (losartan + subcutaneous saline)
- C: AT2R antagonism (control chow + subcutaneous PD123319)
- D: Control chow and subcutaneous saline

Surgical subcutaneous placement of Alzet osmotic mini pumps was performed 1 day prior to noise exposure, and losartan treatment was initiated immediately following noise exposure. Auditory brainstem responses (ABR) were measured at 8, 16, and 32 kHz from 90–10 dB in 5 dB steps at baseline and at 1-, 7-, 14-, and 30-days following noise exposure (8-16kHz octave band noise, 114dB SPL for males, 116dB SPL for females). Experimenters were blinded to group assignment. One-tailed Mann–Whitney U tests were performed to compare elevated post-noise ABR thresholds of select groups.

Results: As compared to baseline levels, noise overexposure resulted in permanently elevated ABR thresholds in all groups, as expected. By day 7, Group C (AT2R inhibitor drug alone) exhibited significantly worsened thresholds at 8 kHz compared with controls in Group D (median 85.0 vs 55.0 dB, $p = 0.0105$), with persistent differences at day 14 (82.5 vs 55.0 dB, $p =$

0.0177) and day 30 (75.0 vs 50.0 dB, $p = 0.01235$). In contrast, AT1R inhibition in Group A (Losartan plus AT2R inhibition) compared to Group C (AT2R inhibition alone) attenuated the noise-induced ABR shift in a protective manner at 8, 16, and 32 kHz across all time points after day 1, except for 8 kHz at day 30 and 32 kHz at day 14. For all comparisons, the magnitude of differences was diminished at higher frequencies.

Conclusions: Type 1 and Type 2 angiotensin receptors confer opposing effects in our mouse model of noise-induced hearing loss. Availability of AT2Rs for activation may provide endogenous protection against worse hearing outcomes during acoustic trauma. In the absence of AT2R signaling, pharmacologic AT1R inhibition with losartan results in significant levels of protection against severe noise toxicity. AT1R inhibition and AT2R activation may represent overlapping strategies for achieving hearing protection against loud noise.

SU100. Hair-Cell Degeneration in Hpsc-Derived Inner-Ear Organoids Carrying TMPRSS3 Variants

Pei-Ciao Tang¹, Diane Jung^{*1}, Xue Liu¹

¹*University of Miami Miller School of Medicine*

Background: Mutations in TMPRSS3 cause congenital or postlingual hearing loss (DFNB8/10), and defective Tmprss3 proteins are linked to hair-cell loss and altered endocochlear potential. Complex genotype–phenotype correlations in patients with TMPRSS3 variants, and poor cochlear-implant outcomes in some, have impeded our understanding of and treatment plan for TMPRSS3-associated recessive deafness. Since gene therapy has shown promise for treating hearing loss in aged mice with Tmprss3 mutations, we developed a human induced pluripotent stem cell (hiPSC)–derived inner-ear organoid model from TMPRSS3 patients to study the effects of patient-specific mutations on human hair cells.

Methods: hiPSC lines were reprogrammed from blood samples of patients carrying a) a homozygous c.208delC variant and b) compound heterozygous c.1333G > A and c.1273G > A variants; the former had congenital hearing loss, whereas the latter developed postlingual hearing loss. Inner-ear organoids were generated from mutant hiPSC lines and from their isogenic control lines.

Results: Organoid growth and hair-cell development were monitored by immunocytochemistry (ICC) using SOX2 and MYOSIN-7A antibodies. Hair-cell loss was assessed by ICC of cleaved caspase-3 to define the timepoint at which hair-cell degeneration occurs.

Conclusions: We established patient-derived inner ear organoids carrying TMPRSS3 variants for determining the timeline of hair cell degeneration, as well as the role of TMPRSS3 in the human inner ear. This model system will be critical for developing gene therapies for human inner ear disorders.

SU101. Single-Cell RNA Sequencing Reveals Hypoxia-Mediated Transcriptomic Alterations in Vestibular Schwannoma

Diane Jung^{*1}, Pei-Ciao Tang¹, Bryan Souza¹, Olena Bracho¹, Michael Ivan¹, Yan Guo¹, Mengsheng Zha¹, Christine Dinh¹

¹*University of Miami Miller School of Medicine*

Background: Vestibular schwannomas (VS) are benign tumors of the vestibulocochlear nerve, most commonly driven by inherited or somatic mutations in the NF2 gene. Despite their benign histology, VS frequently cause debilitating symptoms, including progressive hearing loss and vestibular dysfunction. Like many solid tumors, VS exhibit regions of intra-tumoral hypoxia. Hypoxia triggers a transcriptional program mediated largely by hypoxia-inducible factor 1 α (HIF-1 α), which has been linked to tumor progression, treatment resistance, and poor outcomes across a variety of cancers. In VS, HIF-1 α expression has been detected, and its inhibition has been shown to suppress tumor growth, suggesting that hypoxia may play a critical role in tumor progression. However, while prior studies have implicated hypoxia in VS progression, the broader impact of hypoxia on the tumor microenvironment and transcriptomic profiles of VS has not been characterized. In this study we aim to investigate how hypoxia influences cellular heterogeneity and gene expression patterns in primary VS cells and identify pathways that may be related to tumor growth and survival.

Methods: Patient-derived VS tumor chunks were enzymatically dissociated and cultivated in proliferative media at room air (21% O₂) and hypoxia (1% O₂). Cells were imaged using light microscopy every week for ~1 month. Cell cultures were then dissociated into single-cell suspensions and subjected to single-cell RNA sequencing (scRNA-seq) using the 10x Genomics Chromium platform. Libraries were prepared using the Chromium Single Cell 3' reagent kit and sequenced on an Illumina platform. Raw data were processed using the Cell Ranger pipeline to generate gene-cell count matrices. Downstream analyses were performed in Seurat, including quality control, normalization, dimensionality reduction, clustering, and differential expression analyses. Immunocytochemistry (ICC) was performed for Schwann cell markers.

Results: Across both conditions, scRNA-seq captured transcriptional profiles from 14,770 high-quality single cells. We identified distinct cellular subpopulations, transcriptional profiles, and enriched pathways between 21% and 1% O₂. The expression of Schwann cell markers will be measured using ICC.

Conclusions: We performed single-cell transcriptomic characterization of primary VS cultivated in room air and in hypoxia. Results will demonstrate how hypoxia shapes cell heterogeneity and transcriptomic profiles in VS. Furthermore, findings in this study may identify candidate pathways for future therapeutic treatments for VS.

SU102. Auditory Temporal Responses of Mutant Mice and Diagnosis of Hearing Loss Pathology

Neil Ingham^{*1}, Christopher Plack², Karen P. Steel¹

¹*Wolfson SPaRC, King's College London*, ²*Manchester Centre for Audiology and Deafness, The University of Manchester*

Background: As the search for treatments for hearing impairment gathers pace, it is becoming increasingly important to develop reliable tools to diagnose the underlying pathology so that the appropriate treatment method may be delivered. We use mutant mice to aid the development of non-invasive physiological tests that may be transferrable into a clinical setting. These mice carry different single gene mutations and have known sites of lesion covering the three major

categories of sensorineural hearing impairment described by Schuknecht and Gacek (1993); Sensory (hair cell dysfunction), Metabolic (stria vascularis dysfunction), and Neural (auditory neuron defects).

Methods: Amplitude Modulation Following Responses (AMFR) were evoked by stimuli comprised of 12kHz (or 24 kHz) carrier tones presented at 80dB SPL (100ms duration, 5ms rise/fall time), which were 100% sinusoidally amplitude-modulated at rates (modulation frequency, fm) from 100-1750Hz, and by presentation of 1000 Hz fm across stimulus levels from 0 – 95 dB SPL. We calculated AMFR magnitude, phase, group delay and synchrony coefficient as a function of fm or stimulus level (eg Shaheen et al. 2015). Auditory Brainstem Responses (ABRs) and thresholds were recorded in the same mice.

Results: AMFR amplitude vs fm transfer functions recorded at 80dB SPL were typically multi-peaked in normal hearing littermate control mice, having peaks with a range close to modulation rates of 300 Hz, 600 Hz and 1000 Hz. *Klhl18* < lowf > (Inner Hair Cell dysfunction), *Mir96* < tm3.1Wtsi > (Inner and Outer Hair Cell dysfunction), *Slc26a5* < tm1-Cre > (Prestin, OHC dysfunction), and *Wbp2* < tm2a > (dysfunctional innervation) mutant mice all showed pronounced reductions in AMFR amplitudes and synchrony at these three fm ranges. *Sgms1* < tm1b > and *Slpr2* < stdf > mutant mice (both with a stria vascularis dysfunction resulting in a reduced endocochlear potential) showed reduced AMFR amplitudes and synchrony across a more limited span of fm in the 300 Hz and 600 Hz ranges, but in contrast to the other mutants examined, these AMFRs were almost indistinguishable from littermate controls at the higher modulation rates tested. AMFR amplitudes recorded at the lower and mid-range modulation rates across all mutant mice were correlated with the auditory brainstem response thresholds of these mice. However, at the higher modulation rates, amplitudes recorded from strial mutant mice were more comparable to controls. Typically, across all pathologies, mice with higher ABR threshold generated lower amplitude AMFR, and those with lower ABR thresholds generated higher amplitude AMFRs.

Conclusions: Reduced AMFR amplitudes in hearing-impaired mice may be a general feature across “neural” and “sensory” pathologies, in contrast to the normal AMFR amplitudes seen at higher modulation rates in “metabolic” impairment. These observations may help in the development of a non-invasive physiological diagnostic test battery to differentiate different sites of pathology underlying inner ear sensorineural hearing loss and help to inform better treatment strategies for individuals.

SU103. A Simplified Human Full-Head Model for Investigating Electric-Acoustic Interaction With Intra- and Extra-Cochlear Electric and Acoustic Stimulation

Yixuan Zhang^{*1}, Roman Stracke¹, Franklin Alvarez Cardinale¹, Waldo Nogueira²

¹*Medical University Hannover and Cluster of Excellence “Hearing4all”, Hanover, Germany,*

²*Medical University Hannover and Cluster of Excellence “Hearing4all”, Hanover, Germany, Institute of Neuroscience, Universitat Autònoma de Barcelona, Spain*

Background: Computational models of auditory nerve activity constitute indispensable tools for elucidating the neural mechanisms of sound perception. They enable systematic investigation of

the complex interactions between electric and acoustic stimulation (EAS) within the auditory system. A computational model has been substantially extended to represent more accurately the anatomical and electrical properties of the full human head. The extended model incorporates detailed 3D representations of the outer, middle, and inner ear, as well as the brain, forming a population-based full-head model. The model can be used to simulate intra- and extra-cochlear electric stimulation of the auditory system as well as the interactions between electric and acoustic stimulation. The goal of the computation model is to optimize the amount of current flow inside the cochlea by varying the location of the stimulating and reference electrode and assess interactions between electric and acoustic stimulation.

Methods: Finite element method (FEM) simulations were conducted under monopolar stimulation modes for both intra- and extra-cochlear electrodes. A novel computational framework was implemented to simulate both acoustically evoked compound action potentials (aCAPs), electrically evoked compound action potentials (eCAPs) and Electrocochleography (ECochG) in humans, with a specific focus on interactions arising from combined electric-acoustic stimulation (EAS) at the level of the auditory nerve. Key variables simulated include: transimpedance matrices (TIMs) of intracochlear electrodes, intra- and extra-cochlear voltages and currents, auditory nerve activity, and the resulting aCAPs, eCAPs and ECochG.

Results: The model reliably reproduced transimpedance matrices (TIMs) and response trends consistent with those reported in cochlear implant users with the same electrode array. Novel intra- and extra-cochlear current pathways through the scala tympani were identified, revealing distinct voltage and current density distributions between the two stimulation modes. The framework is capable of simulating electrocochleography (ECochG) responses resembling human recordings and providing a complementary means to assess electric-acoustic interactions. Preliminary simulations confirmed measurable interaction effects at hair cell and auditory nerve level. Simulated compound action potential (CAP) waveforms from intracochlear electrodes closely matched those observed in human recordings. A marked reduction in eCAP responses was observed under both intra- and extra-cochlear stimulation when an acoustic masker was applied. Mechanisms underlying EAS interactions in CAP responses were systematically investigated, with spike interactions in the apical cochlea and ectopic stimulation of the auditory nerve trunk emerging as the most plausible explanations.

Conclusions: This simplified full-head human model represents a promising tool for investigating electric-acoustic interactions and optimizing electric stimulation for both intra- and extra-cochlear electric stimulation in cochlear implant users. These results are relevant to create a diagnostic to diagnose hearing loss and a prosthetic device that augments acoustic hearing with extra-cochlear electric stimulation.

SU104. ADARB1 as a Nuclear Marker of Spiral Ganglion Neurons Across Species and Age

Garner Fincher¹, Punam Thapa¹, Steven Gressett¹, Bradley J. Walters¹

¹*University of Mississippi Medical Center*

Background: Spiral ganglion neurons (SGNs) are the primary neurons responsible for transmitting auditory signals from the inner ear to the brain. Degeneration of SGNs occurs in various conditions including auditory neuropathies, traumatic brain injury, and aging, thus

contributing to acquired hearing loss. Precise characterization and quantification of SGNs are critical for advancing the understanding of auditory pathology and evaluating potential therapeutic interventions. Here we show that immunolabeling for ADARB1, an RNA editing enzyme enriched in the nuclei of glutamate receptor-expressing neurons, is a reliable method for SGN identification and quantification in young adult mice. We compared manual SGN counts obtained via neurofilament heavy chain (NFH) immunolabeling to automated counts generated with ADARB1 immunofluorescence. We further characterized ADARB1 immunoreactivity in aged mice (24 months), as well as in human and macaque inner ear tissues. Co-labeling sections for ADARB1 and HuD, NFH, GATA3, or SOX2 was undertaken to confirm neuronal identity.

Methods: Mid-modiolar cochlear sections were obtained from 3-week-old CD1 mice, 24-month-old C57Bl/6 mice, and archived (> 5 years) temporal bone sections from macaques (4 years-old) and human cadavers of varying ages (all > 40 years of age). The human, macaque, and 24-month-old mouse samples were immunolabeled with antibodies against ADARB1 and neurofilament heavy chain (NFH), while the 3-week-old mouse samples were immunolabeled with antibodies against ADARB1, NFH or HuD, and either SOX2 or GATA3. Micrograph images were acquired using laser scanning confocal microscopy with a 40X objective. Image processing, including manual thresholding and noise reduction, was performed using ImageJ (Fiji).

Results: Within Rosenthal's canal, ADARB1 immunolabeling yielded specific and robust staining of spiral ganglion neurons (SGNs), allowing for reliable automated quantification using the analyze particles function in ImageJ. Comparison across over 30 sets of images yielded a Lin's concordance correlation coefficient > 0.95, indicating strong agreement between manual and automated counts. Strong ADARB1 expression was observed in surviving SGNs in 24-month-old mouse samples demonstrating utility in a context where hair cell and SGN loss were evident. ADARB1 labeling of SGN nuclei was also prominent in macaque and human sections, though some variability was noted in the cadaveric samples. Colocalization analyses demonstrated that ADARB1 labels both type I and type II SGNs, as evidenced by overlap with HuD, NFH, and GATA3-labeling. Conversely, a lack of colocalization between ADARB1 and SOX2 indicated minimal ADARB1 expression in glial cells.

Conclusions: These studies demonstrate the specificity and robust expression of ADARB1 in spiral ganglion neurons (SGNs) and validate the effectiveness of ADARB1 labeling for automated quantification of SGNs, indiscriminate of type, and across diverse mammalian species.

SU105. Reimbursement for Laryngology Procedures Performed in Facility-Based Versus Non-Facility-Based Settings: Trends and Implications for Practice

John Wilson^{*1}, G. Todd Schneider¹, Ellen L. Ferraro¹

¹*University of Rochester Medical Center*

Background: The Centers for Medicare and Medicaid Services (CMS) create a method of payment for enrolled healthcare providers called the Medicare Physician Fee Schedule (MPFS). Procedures have separate reimbursement rates for physician services provided in facility and non-facility-based settings. When procedures are performed in facility-based settings, CMS

reimburses a technical fee and allows devices to be billed for separately from the procedure (e.g., laser fibers and balloons.) Conversely, devices used in non-facility-based settings cannot be billed separately from the procedure CPT code; thus, when assessing profitability, the cost of these is subtracted from the total reimbursement. Hence, device cost can be prohibitive in performing these procedures in the non-facility-based setting, forcing procedures to be done in higher-cost locations such as the operating room (OR) or surgery center. There are limited studies examining reimbursement patterns in these two different practice settings. Thus, this study compares the reimbursement rates of commonly performed office-based Laryngology procedures, considering the cost of devices, fillers, and pharmaceuticals, for facility-based versus non-facility-based settings.

Methods: The MPFS Look-Up Tool was used to determine the reimbursement for 11 common office-based Laryngology clinic procedures for facility-based and non-facility-based locations. The technical fee for the facility-based setting was provided by a CMS billing consultant. The cost of pharmaceuticals, devices, or fillers was subtracted from the reimbursement for each procedure to determine the profit margin per procedure, which was calculated for all procedures.

Results: Procedures requiring balloon devices, injection augmentation materials, and laser fibers in the non-facility setting reimbursed significantly lower (76.5%, 62.6 – 95.9%, and 99.7% lower, respectively) compared to facility settings that receive both technical and professional fee reimbursements ($p < 0.05$). When accounting for procedural materials (e.g., injectable filler), profit margins were considerably lower in the non-facility setting (40.5%, 4.8 – 60.6%, and 2.3% relative profit margins, respectively.) All other procedures were profitable in both settings but more so in the facility setting (52.5 – 87.3% reductions in reimbursement in non-facility versus facility settings.)

Conclusions: Overall healthcare utilization cost of Laryngology procedures in a clinic setting is favorable to an OR setting, but clinicians who practice in non-facility-based clinics are at risk for a monetary loss due to lower reimbursements and expensive devices. Performing office-based procedures is an important component in providing equitable and timely treatment. If reimbursement rates continue to bias in favor of facility-based settings, there is a risk of non-facility-based clinics no longer performing procedures or of increasing overall healthcare costs by shifting them to the OR setting.

SU106. Effect of IL-8 Inhibition on Cancer Cell Proliferation and Migration in Oral Cavity Squamous Cell Carcinoma

Michelle Pei^{*1}, Tonya Aaron², Bryan Souza², Mikhail Marasigan³, Olena Bracho³, Zoukaa Sargi³, Donald Weed³, Erin Kaye³, Christine Dinh³

¹University of Southern California, ²University of Miami, ³Miller School of Medicine, University of Miami

Background: Oral cavity squamous cell carcinoma (OCSCC) is the most common SCC of the head and neck and the 6th most common cancer worldwide. A significant poor prognostic factor in OCSCC is perineural invasion (PNI), which occurs in an estimated 24-31% of cases and can lead to taste alterations. PNI is the spread of cancer into or around nearby nerves, and when present, is associated with higher locoregional recurrence and worse disease-free and overall survival. The mechanisms underlying PNI is still unresolved, however recent evidence suggest

that both Schwann cells and cancer secrete IL-8, which may have a role in promoting OCSCC cell migration and proliferation. We hypothesize inhibiting IL-8 signaling in OCSCC cells will reduce cancer cell proliferation and migration.

Methods: Human OCSCC (SCC9, UCSFOT1109) and Schwann cell lines (HS11, FHSC) were cultured in maintenance media. Cell-conditioned supernatants were collected at 48 hours, and antibody arrays were utilized to profile the secretion of 80 cytokines. A top secreting cytokine was determined to be interleukin-8 (IL-8). Subsequently, OCSCC cells were cultured in serum-reduced conditions and exposed to 0 or 1000 ng/ml anti-IL-8 neutralizing antibody for 12, 24, and 48 hours. Transwell and scratch assays were performed to measure the effect of anti-IL-8 on chemotaxis and cell migration. Viability assays were utilized to determine the impact of anti-IL-8 on cell proliferation.

Results: IL-8 was highly secreted by SCC9, UCSFOT1109, HS11, and FHSC. Anti-IL-8 antibody significantly reduced gap closure on scratch assay in both OCSCC cell lines at 4 hours; however, the effect did not persist at longer time points. Additionally, on transwell assay, anti-IL-8 antibodies also significantly reduced the number of migrated cells at all time points in SCC9 and early point of 12 hours in UCSFOT1109. Anti-IL-8 antibody did not significantly affect the proliferation of either OCSCC cell lines at any time point.

Conclusions: We found that OCSCC and Schwann cells secrete high levels of IL-8 into the tumor-nerve microenvironment. Inhibiting IL-8 signaling in vitro using anti-IL-8 neutralizing antibodies reduced migration, but did not affect proliferation, of OCSCC. Further investigation into the role of IL-8 in the tumor-nerve microenvironment may provide additional insights into cancer spread and perineural invasion and may reveal novel therapeutic targets for treatment of OCSCC.

SU107. Hypoxia-Induced BNIP3 and HIF-1 α Reveal Metabolic Vulnerabilities in Vestibular Schwannoma

Carly Misztal*¹, Bryan Souza², Olena Bracho², Mikhail Marasigan², Michael Ivan², Carolina Benjamin², Fred Telischi², Simon Angeli², Vivek Kanumuri², Pei-Ciao Tang², Cristina Fernandez-Valle³, Daniela Frasca², Christine Dinh²

¹University of Miami-Jackson Health System, ²Miller School of Medicine, University of Miami ³Burnett School Biomedical Sciences, College of Medicine, University of Central Florida

Background: Under hypoxic conditions, cancer cells can undergo metabolic reprogramming through the induction of hypoxia-inducible factors (HIF-1 α) and Bcl-2/adenovirus E1B 19 kDa interacting protein 3 (BNIP3), enabling them to generate energy and biosynthetic precursors needed for survival. Vestibular schwannomas (VS), benign tumors of the vestibulocochlear nerve, are known to express HIF-1 α , which promotes angiogenesis and tumor growth. However, the metabolic response of VS to hypoxia, and how it compares to wild-type Schwann cells (WT-SCs) and merlin-deficient Schwann cells (MD-SCs), remains poorly understood. This study aims to define how oxygen tension influences metabolism and hypoxia-related signaling across these cell types.

Methods: Primary VS cells were derived from patient tumors, while MD-SCs were generated by introducing NF2 mutations into WT-SCs derived from fetal tissue and human induced

pluripotent stem cells. VS, WT-SCs, and MD-SCs were cultured for 72 hours under normoxia (21% O₂), physioxia (5% O₂), or hypoxia (1% O₂). Metabolic activity was assessed using CellTiter-Glo assays, and immunocytochemistry (ICC) was performed for BNIP3 and HIF-1 α . Data were analyzed with descriptive statistics and one-way ANOVA.

Results: VS cells demonstrated the lowest ATP production at 1% O₂, consistent with reduced oxidative phosphorylation under hypoxia. A majority of VS cultures exhibited robust upregulation of HIF-1 α and BNIP3 at 1% O₂, with concordant expression patterns within samples. In contrast, WT-SCs and MD-SCs did not show significant hypoxia-induced upregulation of these markers.

Conclusions: Most primary VS cells upregulate BNIP3 and HIF-1 α under hypoxia, demonstrating their ability to undergo metabolic reprogramming and adapt to oxygen-limited conditions. In contrast, WT-SCs and MD-SCs did not exhibit this response, suggesting that NF2 loss alone is insufficient to drive these changes. These results highlight hypoxia-driven adaptations as a defining feature of VS biology and point to metabolic pathways as promising therapeutic targets for VS.

SU108. Global Mapping of Clinical Trials in Hearing Disorders (2019–2024): A Systematic Mapping Review

Alain Chedotal^{*1}, Isabelle Boutron², Lina Ghosn², Carolina Riveros², Marie-Josée Duran³

¹*Sorbonne Université, INSERM, CNRS, Institut de la Vision, Paris, France; Institut de Pathologie, Groupe Hospitalier Est, Bron, France; MeLiS, CNRS UMR5284, Inserm U1314, University Claude Bernard Lyon 1, Lyon, France.*, ²*Cochrane France, Paris, France; Centre d'Epidémiologie Clinique, AP-HP, Hôpital Hôtel Dieu, Paris, France; Université Paris Cité and Université Sorbonne Paris Nord, Inserm, INRAE, Center for Research in Epidemiology and StatisticS (CRESS), Paris, France,* ³*Fondation Pour l'Audition, Paris, France*

Background: Hearing disorders pose a significant public health burden, yet no comprehensive mapping of clinical research exists. This project systematically catalogues and analyzes clinical trials over the past five years to identify evidence gaps and redundancies in prevention and treatment strategies in the field.

Methods: We conducted a systematic search of four international trial registries, the US ClinicalTrials.gov registry, the Australian New Zealand Clinical Trials Registry (ANZCTR), the ISRCTN registry in the United Kingdom and the European EU clinical Trials Register and Clinical Trials information system (EUCTR/CTIS), identifying interventional studies first posted between January 1, 2019, to August 14, 2024. Eligible studies evaluated interventions for hearing disorders across all ages and severities. Data were extracted using a standardized PICO (Population, Intervention, Comparison, Outcome) framework, covering study design, populations, interventions, outcomes, sample size, funding, and geographical distribution. Additional study characteristics, including randomization, trial phase, recruitment status, and number of arms, were recorded, along with the results posting and associated publications of completed studies. Two epidemiologists independently screened records (30% duplicate screening for quality assurance). A hierarchical classification system was developed for interventions (pharmacological, devices, gene therapy, etc.) and hearing conditions by laterality,

onset, and severity following WHO criteria and the International Bureau for Audiophonology BIAP Recommendation 02/1).

Results: Of 1,679 identified records, 547 trials met inclusion criteria (67% excluded, primarily for non-interventional designs or off-topic focus). Most were randomized (58.9%), assessed therapeutic interventions (66%), and involved adults (81.6%). Common conditions included sensorineural hearing loss (19.9%), tinnitus (19.2%), and presbycusis (4.3%). Device-based interventions were the most prevalent (37.1%), followed by non-pharmacological therapies (17.1%) and pharmacological treatment (10.3%).

Data on hearing loss characteristics were variably reported. Regarding the type of hearing loss, 9.1% were unilateral, 19.2% bilateral, 11.6% included both types, and 1.6% had normal hearing; 58.5% were not reported.

Only 13.3% of completed trials (n=210) had results posted in registries; 31 were linked to PubMed publications. Geographically, the U.S. (34.7%), France (6.8%), and Australia (6.8%) led research output, with 85.7% of studies being nationally focused. Descriptive statistics and an interactive evidence map were generated.

Conclusions: This first systematic map of hearing disorders' trials reveals disparities in research focus, with underrepresentation of pediatric populations and low publication rates despite trial completion. The interactive dashboard highlights regional and thematic gaps. Such mapping is essential for identifying areas of research that have already been thoroughly explored, thereby limiting duplication, as well as highlighting persistent gaps in the scientific literature. This open-access platform will serve as a data-driven decision-making tool, facilitating the identification of research priorities and optimizing the impact of scientific work in the field of hearing health.

SU109. Incidence and Risk Factors of Postoperative Sensorineural Hearing Loss After Cholesteatoma Removal

Archer Schaeffer*¹, Kim Le², Rohan Vuppala³, Christian Jung², Keshav Shah², Daniel Talian², Tiffany Hwa²

¹Baylor College of Medicine, ²Perelman School of Medicine at the University of Pennsylvania,

³Medical College of Georgia

Background: While cholesteatoma and chronic ear disease are primarily associated with conductive hearing loss, all otologic surgical intervention carries a risk of sensorineural hearing loss (SNHL). This study aims to evaluate the incidence of SNHL following cholesteatoma surgery and identify potential risk factors contributing to its development.

Methods: A retrospective chart review was conducted of 345 patients who underwent surgery for cholesteatoma removal between January 2021 and June 2024. Data included patient demographics, prior ossicular reconstruction, prior surgery, extent of surgery, disease characteristics, and audiometric data. Multivariable logistic regression was utilized to assess associations between potential risk factors and the development of SNHL. SNHL was defined as a ≥ 20 dB drop in bone conduction threshold at any frequency from 250-4000Hz on postoperative audiograms ranging from 2-24 months.

Results: 345 patients [mean age 51.2 ± 17.3 years; 187 (54.2%) males] were analyzed. 301 had preoperative mixed or conductive hearing loss, mean air-bone gap (ABG) was 26.1 dB, and 182

(61.7%) demonstrated postoperative improvement in the ABG (mean 21.3 dB). 59 patients (17.1%) developed postoperative SNHL, with 56 patients (16.2%) demonstrating SNHL within the first year. 3 patients (0.9%) presented with SNHL at 12-24 months. Prior ossicular prostheses (OR 3.74 [1.08, 13.2]; $p=0.037$) was associated with increased risk of postoperative SNHL, whereas new prosthesis placement (OR 0.19 [0.055, 0.545]; $p=0.0041$) and a canal wall down approach (OR 0.268 [0.110, 0.614]; $p=0.0026$) was associated with a decreased likelihood when controlling for race and surgeon. Revision surgery, age, sex, and race did not reach significance. The 17.1% incidence of SNHL, primarily in the first year, constitutes a clinically meaningful risk profile that should inform prognostic counseling and follow-up planning.

Conclusions: These findings provide contemporary incidence and risk profiling relevant to otologic surgical planning, prognosis, and patient expectation setting. SNHL is a non-negligible complication after cholesteatoma surgery, with patients' risk profiles influenced by a prior and current prosthesis placement as well as the extent of surgical intervention. Key takeaways include: (a) postoperative SNHL > 20 dB at any frequency after cholesteatoma surgery is not rare (~1 in 6); (b) most cases appear within 12 months; (c) prior ossicular prosthesis is a salient risk marker; and (d) in this cohort, canal wall down approach and new prosthesis placement correlate with lower odds of developing postoperative SNHL. While canal wall down approach generally entails a more extensive surgery, this association may reflect technique-mediated protection (e.g., less ossicular manipulation) or be explained by greater rates of preoperative SNHL (i.e., confounding by indication). Future research with larger patient cohorts may help optimize risk stratification, identify causal pathways, and develop hearing preservation protocols to enhance patient counseling and surgical management.

SU110. The Role of Concomitant Medications in Improving SPI-1005 Study Outcomes in Meniere's Disease Patients in a Phase 3 Randomized Placebo-Controlled Trial (STOPMD-3)

Emily Harruff¹, Kalie Uberti¹, Jonathan Kil^{*1}

¹*Sound Pharmaceuticals, Inc.*

Background: Meniere's disease (MD) involves episodic vertigo or dizziness, fluctuating low frequency hearing loss, and intermittent or constant tinnitus. No FDA-approved drug therapies exist for MD or its auditory or vestibular symptoms. Medical management with diuretics, betahistidine, and corticosteroids have demonstrated low evidence of efficacy. SPI-1005, a novel anti-inflammatory drug, has shown safety and efficacy in three MD studies: Phase 1b (N=39), Phase 2b (N=126), Phase 3 (N=221) randomized clinical trials (RCTs) after 21 or 28-days of oral treatment. In the Phase 3 RCT, SPI-1005 treatment showed significant improvements in two pre-specified primary efficacy endpoints involving low-frequency hearing and speech discrimination over placebo. Here, we present post-hoc analyses of the Phase 3 RCT involving common concomitant medications (CM) used to manage MD.

Methods: Adults (18-75 years) were enrolled at 11 US sites (NCT04677972) and were randomized to either SPI-1005 400 mg or placebo BID, for 28 days. Participants were allowed to continue existing CM, excluding corticosteroids. Pure-tone audiometry (PTA), words-in-noise (WIN), tinnitus-functional-index (TFI) including VAS-loudness (TL), vertigo-symptoms-scale (VSS), dizziness-handicap-inventory (DHI), and VAS-aural fullness (AFS) were assessed at

baseline, 28, 56, and 84-days. Compliant participants entered OLE and received SPI-1005 400 mg BID, for up to 12-months, and were reassessed every 3-months. Improvements in low-frequency PTA (LFPTA) and WIN scores in either ear from baseline were applied: ≥ 10 dB at 250, 500, or 1000 Hz; and ≥ 4 -words in WIN at 84-days. CMs taken by $> 15\%$ of participants were identified and stratified.

Results: 191 Per-Protocol subjects (mean age 55.5; 103 males/88 females) were analyzed. CM use was 94 (49.2%) for hydrochlorothiazide, 74 (38.7%) for triamterene, 44 (23.0%) for hydrochlorothiazide/triamterene, 38 (19.9%) for diazepam, 35 (18.3%) for betahistine, and 34 (17.8%) for meclizine.

LFPTA improvements for SPI-1005 vs placebo with hydrochlorothiazide (27/48, 56.3%, vs 15/46, 32.6%, $p=0.0243$); triamterene (22/36, 61.1%, vs 12/38, 31.6%, $p=0.0190$); hydrochlorothiazide/triamterene (12/17, 70.6%, vs 8/27, 29.6%, $p=0.0128$); diazepam (12/16, 75.0%, vs 9/22, 40.9%, $p=0.0516$); betahistine (9/18, 50.0%, vs 7/17, 41.2%, $p=0.7380$); meclizine (11/18, 61.1%, vs 5/16, 31.3%, $p=0.1005$).

WIN improvements for SPI-1005 vs placebo with hydrochlorothiazide (21/48, 43.75%, vs 15/46, 32.6%, $p=0.2950$); triamterene (16/36, 44.4%, vs 13/38, 34.2%, $p=0.4757$); hydrochlorothiazide/triamterene (9/17, 52.9%, vs 10/27, 37.0%, $p=0.3588$); diazepam (4/16, 25.0%, vs 7/22, 31.8%, $p=0.7292$); betahistine (8/18, 44.4%, vs 3/17, 17.6%, $p=0.1464$); meclizine (9/18, 50.0%, vs 4/16, 25.0%, $p=0.1717$).

During OLE, subjects treated with SPI-1005 and CM continued to show LFPTA (27-65%) and WIN (18-50%) improvements at 3- to 12-months. No significant differences were found between SPI-1005+CM vs SPI-1005 alone.

Conclusions: Adjunctive therapy with SPI-1005 on to the existing medical management for MD involving diuretics (hydrochlorothiazide, triamterene, or hydrochlorothiazide/triamterene) demonstrated significant improvements in low-frequency hearing but not speech discrimination over placebo. Non-significant improvements were observed for diazepam, betahistine, and meclizine.

SU111. Systemic Ebselen Treatment Prevents Amikacin Induced Ototoxicity and Nephrotoxicity in Mice

Kushal Sharma¹, Sedona Ward¹, Sao-Mai Gahr¹, Rende Gu¹, Ryan Longenecker¹, Jonathan Kil*¹

¹*Sound Pharmaceuticals, Inc.*

Background: Aminoglycosides (AGs), such as tobramycin and amikacin, commonly used to treat recurrent pulmonary infections, are ototoxic and nephrotoxic. Our previous mouse studies showed that 14-days of amikacin (500 mg/kg/day) induced temporary threshold shifts (1-11 dB), tinnitus (24%), and hyperacusis (82%) which were attenuated by ebselen (20 mg/kg/day). The present study determined whether 28-days of amikacin increases the severity/duration of ototoxicity and if ebselen prevents amikacin-induced ototoxicity and nephrotoxicity.

Methods: Adult CBA/CaJ mice (N=32) 3-7 months old were divided into three groups: 1) Control (N=10); 2) Amikacin (N=10); and 3) Amikacin+Ebselen (N=12). Groups 2 and 3 received vehicle or ebselen (20 mg/kg/day x 28-days i.p.) followed by amikacin (500 mg/kg/day

x 28-days s.c.) 30-minutes later, respectively. Auditory brain-stem response (ABR) and acoustic startle response (ASR) were performed at baseline and at 4-, 8-, 12-, and 16- weeks from the start of treatment. ABR was also performed at 35-weeks. Clinically relevant change (CRC) using ABR threshold shift criteria (hearing loss), gap-induced-prepulse-inhibition of the acoustic startle changes (tinnitus), and startle magnitude shifts (hyperacusis) were analyzed. Cochlear histopathology was performed using Myosin-7a immunolabeling to identify outer hair cell (OHC) loss. Serum samples were collected at baseline and 4-weeks for blood urea nitrogen (BUN) and creatinine (Cr) levels (nephrotoxicity).

Results: Control mice showed permanent threshold shifts (PTS) of 1–12 dB at multiple frequencies and time-points. CRC rates were 25%, 20%, 15%, 35%, and 65% at 4-, 8-, 12-, 16-, and 35-weeks, respectively. Tinnitus incidence was 0%, 0%, 0%, and 10% at 4-, 8-, 12-, and 16-weeks, respectively with no observed hyperacusis.

28-day amikacin resulted in PTS of 14–25 dB at multiple low frequencies and time-points. CRC rates were 75%, 60%, 45%, 50%, and 94%, respectively. Tinnitus incidence was 22%, 22%, 33%, and 0%, respectively with no hyperacusis.

28-days ebselen significantly reduced amikacin-induced PTS to 4–20 dB at multiple low frequencies and time-points: 4-weeks ($p=0.0029$) and 8-weeks ($p=0.0032$). CRC rates were also reduced to 29% ($p=0.0056$), 8% ($p=0.0003$), 33%, 46%, and 79%, respectively. Tinnitus incidence was 13%, 25%, 0%, and 13%, respectively with no hypoacusis.

Ebselen prevented amikacin-induced changes in Cr levels at 4-weeks, -0.042 vs $+0.030$ mg/dL ($p=0.0216$). BUN levels did not significantly change from baseline levels in either group.

Conclusions: 28-days of amikacin increased the severity and duration of ototoxicity that was significantly reduced by ebselen. Amikacin-induced nephrotoxicity (increased Cr) was significantly reduced by ebselen. Interestingly, no hyperacusis was observed in any group and may be a consequence of greater PTS. These findings are consistent with recent clinical data from a Phase2-RCT involving adults receiving 14-days of IV-tobramycin. These results extend our earlier findings involving 14-days of amikacin using a dose schedule that mimics the clinical treatment of multi-drug resistant TB and NTM.

SU112. Furosemide Attenuates Noise-Induced Hearing Loss and Potentiates Preventive Effect of N-Acetylcysteine

Hongguo Su¹, Su-Hua Sha^{*1}

¹*Medical University of South Carolina*

Background: Noise-induced hearing loss (NIHL) is a major cause of sensory hair cell damage, primarily driven by dysregulation of reactive oxygen species (ROS) homeostasis. Antioxidants such as N-acetylcysteine (NAC) have demonstrated protective effects, underscoring the role of ROS in NIHL. However, no FDA-approved pharmaceutical treatment currently exists, partly due to the complexity of cochlear damage mechanisms and the restrictive nature of the blood-labyrinth barrier (BLB), which limits drug delivery to the inner ear. This study investigated the protective mechanisms of furosemide (FRS) against NIHL and its potential to enhance the efficacy of NAC.

Methods: FVB/NJ mice were pretreated with a single dose of FRS (200 mg/kg) prior to noise exposure. Auditory brainstem response (ABR) thresholds and endocochlear potential (EP) were measured to assess auditory function. The permeability of the stria vascularis (SV) to small molecules and protein-bound tracers was evaluated. The combined effect of FRS and NAC on outer hair cell (OHC) survival and hearing prevention was also examined.

Results: FRS pretreatment temporarily reduced EP without elevating ABR thresholds and significantly attenuated NIHL. The most effective protection was observed when FRS was administered immediately before noise exposure. FRS selectively increased SV permeability to small molecules, facilitating drug delivery without affecting larger protein-bound tracers. Combined FRS and NAC treatment enhanced antioxidant effects, resulting in additive protection against OHC loss and NIHL, with near-complete preservation of OHCs.

Conclusions: Furosemide effectively attenuates NIHL by transiently modulating cochlear physiology and enhancing drug permeability across the BLB. Its combination with NAC offers a promising strategy for preventing NIHL, highlighting a potential therapeutic approach for clinical application.

SU113. Insulin-Like Growth Factor 1 Protects Cochlear Outer Hair Cells Against Cisplatin by Reducing Oxidative Stress and Inhibiting Apoptosis

Kohei Yamahara^{*1}, Hiroe Ohnishi², Takayuki Nakagawa², Koichi Omori², Norio Yamamoto³

¹*School of Medicine, Fujita Health University*, ²*Graduate School of Medicine, Kyoto University, Kyoto, Japan*, ³*Kobe City Medical Center General Hospital*

Background: Cisplatin is a widely used and highly effective anti-neoplastic agent included in numerous oncology treatment protocols for both pediatric and adult patients. However, one of its most serious adverse effects is ototoxicity, which currently lacks any clinically approved preventive or therapeutic interventions. Histological studies have shown that cochlear lesions following cisplatin administration are particularly prominent in outer hair cells (OHCs) located in the organ of Corti, contributing significantly to irreversible sensorineural hearing loss and decreased quality of life. Our previous studies demonstrated that insulin-like growth factor 1 (IGF1) has a protective role in the cochlea, promoting the survival of auditory hair cells (HCs) after diverse forms of cochlear injury, including noise trauma, ischemia, surgical insult, and exposure to aminoglycoside antibiotics. These findings prompted us to explore whether IGF1 can protect cochlear sensory HCs against cisplatin-induced toxicity. In this study, we utilized a cochlear explant culture model derived from postnatal day 2 mice to evaluate the otoprotective efficacy of IGF1 against cisplatin exposure.

Methods: To determine the protective effects of IGF1 against cisplatin, the explants grown in the medium containing 10 μ M cisplatin were treated for 36 h with 1 or 5 μ g/ml recombinant human IGF1. To assess whether the protective effects were induced by IGF1 binding to its receptor (IGF1R), the receptor-competitive antagonist or the IGF1R tyrosine kinase inhibitor was used. Apoptosis in the cochlear epithelium was determined by treating the explants with 10 μ M cisplatin with or without 5 μ g/ml IGF1 and immunostaining with anti-cleaved caspase 3 antibodies. The effects on the cell cycle were examined by adding 3 μ g/ml 5-bromo-2'-deoxyuridine (BrdU) to the explants treated with 10 μ M cisplatin with or without 5 μ g/ml IGF1

for 36 h. To determine the antioxidant capacity of IGF1, the glutathione to glutathione disulfide (GSH/GSSG) ratios of the cochlear supernatant were measured using the GSH/GSSG-Glo assay.

Results: Administration of IGF1 to the explants grown in the medium containing cisplatin markedly protected outer HCs from cisplatin-induced damage. Pharmacological inhibition of IGF1R using an IGF1R antagonist or inhibitor markedly attenuated the protective activity of IGF1, indicating that IGF1R is specifically required for IGF1 effects in HCs against cisplatin. As a protective mechanism against cisplatin, we found that the administration of IGF1 reduces cisplatin-induced oxidative stress. IGF1 effects on the maintenance of HC numbers are achieved by inhibiting the apoptosis of HCs, not by inducing the proliferation of HCs or supporting cells (SCs).

Conclusions: These data suggest that IGF1 may serve as a promising and clinically applicable therapeutic strategy for preventing cisplatin-induced ototoxic damage in patients undergoing chemotherapy.

SU114. Predicting the Ototoxic Risk of Fda-Approved Drugs Through Machine Learning and in Vivo Approaches

Sneha Pradhan¹, Yehonatan Tamman¹, Timm Derrickson², John Harkness², Allison Coffin^{*1}

¹Creighton University, ²Rewire AI

Background: The ototoxic potential of drugs is rarely evaluated during pre-clinical development or clinical trials, resulting in hearing loss as an underrecognized adverse effect of many medications in use. Ototoxicity likely remains underreported for numerous FDA-approved drugs due to a lack of predictive tools or mandatory regulation. Our goal is to predict the ototoxic potential of FDA-approved drugs using a machine learning (ML) model and to validate the predictions experimentally in the zebrafish lateral line.

Methods: The ML model was trained on a curated dataset of 283 compounds with established ototoxic or non-ototoxic classifications derived from published literature. This model was based on an F1-optimal threshold, high-recall screening, and well-calibrated probabilities, with flexible risk-tolerance tuning for new compound libraries. We applied the model to a DrugBank database of 2423 FDA-approved drugs, then validated a subset of model predictions in larval Brn3c:mGFP transgenic fish, which express hair cell-specific GFP. The larvae were exposed to various concentrations of predicted ototoxins and compared to vehicle-treated controls, followed by hair cell quantification using fluorescence microscopy.

Results: Our model predicted that among the FDA-approved drugs, 692 compounds have ototoxic potential based on their physicochemical and pharmacological properties. Of the top 60 compounds, 18 were known ototoxins such as aminoglycosides and loop diuretics. From the predicted list, we selected 30 drugs with a model-assigned probability of ototoxicity between 67–100% for experimental validation. Known ototoxins were excluded to focus on compounds previously not associated with auditory toxicity. To date, we have experimentally tested eight compounds and confirmed that two drugs, Dantrolene and Nitrofurantoin, were ototoxic. A third, Fruquintinib, showed hair cell loss only at the highest dose, suggesting general cytotoxicity. Among the 32 evaluated drugs, the model correctly predicted 20 as ototoxic (18 known and 2 experimentally validated), corresponding to 62% alignment with expected outcomes.

Conclusions: Preliminary findings demonstrate that ML-based predictions for unrecognized ototoxic compounds need improvement, as 2 out of 8 tested drugs were confirmed as ototoxins in zebrafish. Further experiments will explore whether the confirmed ototoxic drugs from the predicted list enter via mechanotransduction (MET) channels, affect ribbon synapses, and ultimately impact hair cell function. Our future work will focus on refining the model to achieve > 90% prediction confidence and developing it into an accessible, robust screening tool for drug-induced ototoxicity.

SU115. Prevention of Hearing Loss in the Cochlea of Type 2 Diabetes Model Mice

Junko Tsuda^{*1}, Kazuma Sugahara², Makoto Hashimoto²

¹*Yamaguchi University*, ²*Yamaguchi University Graduate School of Medicine*

Background: The number of patients with diabetes mellitus is increasing worldwide due to changes in lifestyle and social environment. Diabetic patients are more likely to develop hearing loss (diabetes-related hearing loss), which often occurs from a relatively young age and significantly reduces quality of life (QOL). To clarify the mechanisms and effective preventive strategies of diabetic hearing loss, we investigated auditory function, cochlear histopathology, and preventive interventions using a type 2 diabetes mouse model.

Methods: TSOD mice, a type 2 diabetes model, and control mice were used. Auditory function was evaluated periodically by auditory brainstem response (ABR). After evaluation, cochleae were harvested from the temporal bone, and vascular structures were examined by vascular staining along with assessment of hair cells and spiral ganglion cells. Preventive interventions included caloric restriction, administration of traditional Japanese herbal medicines (Bofutsusho-san and Dai-saiko-to), metformin, and SGLT2 inhibitors.

Results: TSOD mice exhibited hyperglycemia, obesity, and earlier onset of hearing loss compared with controls. In the cochlea, reduced capillary area was observed in the stria vascularis. Preventive interventions showed that caloric restriction and herbal medicine administration were effective, whereas metformin and SGLT2 inhibitors did not demonstrate significant protective effects compared with controls.

Conclusions: The number of patients with diabetes mellitus is increasing worldwide due to changes in lifestyle and social environment. Diabetic patients are more likely to develop hearing loss (diabetes-related hearing loss), which often occurs from a relatively young age and significantly reduces quality of life (QOL). To clarify the mechanisms and effective preventive strategies of diabetic hearing loss, we investigated auditory function, cochlear histopathology, and preventive interventions using a type 2 diabetes mouse model.

SU116. Effects of Cholesterol Modulation on Cisplatin-Induced Hearing Loss

Marcello Peppi^{*1}, John Lee¹, Megan Guidry¹, Katharine Fernandez¹, Franz Gareza¹, Abu Chowdhury¹, Lizhen Wang¹, Lisa Cunningham¹

¹*NIH/NIDCD*

Background: Cisplatin is a widely used and effective anticancer drug. However, it causes permanent sensorineural hearing loss in over 50% of treated patients. There are no FDA-approved therapies to prevent cisplatin-induced hearing loss (CIHL) in adults, highlighting a critical unmet clinical need. Previous studies suggest that statins, commonly prescribed cholesterol-lowering drugs, are associated with reduced incidence and severity of cisplatin-induced hearing loss. The mechanisms underlying the protective effect of statins are unclear; however, the hallmark activity of statins is inhibition of HMG Co-A reductase, resulting in reduced serum cholesterol. Thus, to begin to address the mechanisms underlying statin-induced protection, we asked whether a genetic model with reduced serum cholesterol is also protective.

Methods: Here we examine whether reduced plasma cholesterol confers protection against CIHL independent of statin treatment. We utilized mice lacking serine protease proprotein convertase subtilisin/kexin type 9 (Pcsk9 knockout mice) as a genetic model of reduced plasma cholesterol.

Results: We find that Pcsk9 KO mice have reduced cholesterol compared to their WT littermates. Pcsk9 KO mice were significantly protected against cisplatin-induced hearing loss, as reflected by significantly lower ABR and DPOAE threshold shifts relative to WT. Histological analyses confirmed preservation of cochlear outer hair cells (OHCs) in Pcsk9 KO mice treated with cisplatin, whereas WT mice showed significant OHC loss in the high-frequency cochlear regions. Finally, hearing loss positively correlated with baseline plasma cholesterol levels.

Conclusions: Together our data demonstrate that systemic cholesterol reduction provides significant protection against CIHL, and they suggest that the protective effect of statins against CIHL is, in part, mediated by cholesterol reduction.

SU117. Connexin30-Deficient Mice Increase Susceptibility to Noise via Redox and Lactate Imbalances

Jifang Zhang^{*1}, Jun Yang¹, MaoLi Duan²

¹Shanghai Jiao Tong University School of Medicine, ²Karolinska University Hospital

Background: Noise significantly contributes to one-third of the global burden of hearing loss. The intricate interplay of genetic and environmental factors impacts various molecular and cellular processes that lead to noise-induced hearing loss (NIHL). Defective connexin 26 (Cx26) and connexin 30 (Cx30), encoded by Gjb2/Cx26 and Gjb6/Cx30, respectively, are prevalent causes of hereditary deafness. However, the role of Cx30 in the pathogenesis of NIHL remains unclear.

Methods: Cx30-deficient mouse models related to NIHL were established and subjected to audiological follow-up using auditory brainstem response (ABR) measurements. Cochlear morphology was analyzed via immunofluorescence, transmission electron microscopy, and toluidine blue staining. Changes in oxidative stress were observed and compared using dihydroethidium (DHE), 4-hydroxynonenal (4HNE), and western blot assays. Cochlear glucose transport and energy metabolism were assessed via 2-NBDG glucose uptake and ATP release assays. Metabolomic analysis was employed to investigate mechanisms underlying cochlear energy alterations.

Results: We observed that homozygous Cx30 knockout (Cx30 KO) mice exhibited poorer hearing recovery after noise exposure (97 dB mean sound pressure level for 2 h) and increased susceptibility to noise. In addition to the exacerbation of noise-induced damage to hair cells and synapses, Cx30 KO mice exposed to noise exhibited increased oxidative stress. The 2-NBDG assay showed a reduction in glucose levels associated with a decrease in gap junctions as well as a reduction in adenosine triphosphate release. Glucose metabolomics analysis further revealed that Cx30 KO mice had elevated lactate and NAD⁺ levels after noise exposure, thus worsening anaerobic oxidation from glycolysis.

Conclusions: Our study emphasizes that Cx30-deficient mice increase susceptibility to noise via redox and lactate imbalances in the cochlea.

SU118. The Cisplatin-Induced Hearing Loss Model in Rats: An In-Depth Characterization to Optimize Therapeutic Development

Sandra Joppé¹, Karine Toupet^{*1}, Clément Vanbergue¹, Dylan Fefeu¹, Stacy Alves¹, Marianne Aincy¹, Marion Souchal¹, Carolanne Coyat¹, Maïa De Wavrechin¹, Lélia Pochet¹, Maelys Sinet¹, Sylvie Pucheu¹, Gaëlle Naert¹

¹*Cilcare*

Background: Cisplatin is a platinum-based chemotherapeutic agent widely used in the treatment of many cancers. However, its use is often associated with severe side effects including permanent hearing loss and cochlear inflammation. Despite its extensive use in clinical treatments, few protective strategies and no effective regenerative therapies are currently available. The development and characterization of experimental animal models are essential for understanding the mechanisms of cisplatin's ototoxicity and for developing effective treatments. This study aimed to optimize a reliable preclinical rodent model of Cisplatin-Induced Hearing Loss (CIHL) and to characterize the associated hearing impairment at functional, cellular, immunological and protein levels to efficiently develop and evaluate therapeutic compounds.

Methods: CIHL model was induced by administering a single intraperitoneal (IP) injection of cisplatin to rats (T0). Different doses of cisplatin were tested (8, 10 and 13 mg/kg). The ototoxic effects of cisplatin were evaluated and characterized using several methods: (1) Distortion Product Oto Acoustic Emission (DPOAE) and Auditory Brainstem Response (ABR) measures were conducted before and after cisplatin administration (T+3DAYS) to assess auditory function; (2) histological analyses were performed on cochleae sampled at T+3DAYS to assess hair cell (HC) loss and analyse the immune response induced by cisplatin exposure; (3) protein analyses were carried out on cochleae sampled at T+4HOURS using specific arrays to determine the signaling pathways activated by cisplatin injection.

Results: At T+3DAYS, DPOAE and ABR measures showed a dose-dependent alteration of auditory function at 10 and 13 mg/kg of cisplatin, indicating a progressive hearing loss. In contrast, a single dose of 8 mg/kg of cisplatin did not produce significant alterations in auditory function compared to controls. Immunostaining to quantify Inner and Outer Hair Cells (IHCs and OHCs) showed that the auditive deficits observed at 10 and 13 mg/kg were accompanied by a reduction in OHC density in a dose dependent manner. Histological analyses of the immune response were conducted on cochleae prepared either as flat surface or cross-sections. Ongoing analysis allowed the identification and quantification of macrophages (Iba1), T lymphocytes

(CD3) and B lymphocytes (PAX5) in the cochleae of rats exposed to cisplatin. Finally, protein analysis of cochlear tissue, targeting over 200 molecules, led to the identification and quantification of several cytokines, chemokines, growth factors and soluble receptors, most of which were classified as inflammatory and trophic factors.

Conclusions: Preclinical testing is a critical phase in drug development, underscoring the need to refine and expand tools to support in-depth characterization of in vivo models to improve the advancement of protective or regenerative therapies. In this study, 10 mg/kg of cisplatin lead to a relevant CIHL model. Its characterization from the functional to the molecular levels, including inflammatory component, yielded valuable data for the development of new therapeutic compounds.

SU119. Immune Cells and Hearing Disorders: Development of a Short In Vivo Model for Evaluating the Anti-Inflammatory Potential of Therapeutic Compounds

Karine Toupet^{*1}, Dylan Fefe¹, Maïa De Wavrech¹, Marianne Aincy¹, Frédérique Défosse¹, Sandra Joppé¹, Gautier Tejedor¹, Marion Souchal¹, Stacy Alves¹, Clément Vanbergue¹, Sylvie Pucheu¹, Gaëlle Naert¹

¹*Cilcare*

Background: Following exposure to noise, ototoxic agents, or aging, immune cells, particularly macrophages, are recruited to the cochlea to contribute to tissue repair. However, their excessive activation can lead to chronic inflammation, resulting in cochlear damage and hearing loss. A better characterization of macrophage recruitment kinetics, localization and signaling pathways is essential for optimizing the therapeutic potential of anti-inflammatory compounds. This study aimed to establish a short and well characterized in vivo model of cochlear inflammation to efficiently evaluate anti-inflammatory compounds.

Methods: Cochlear inflammation was induced in mice by transtympanic (TT) injection of lipopolysaccharide (LPS) in both ears (T0). Different parameters were evaluated: the dose of LPS (5 and 10 µg/ ear) and the timepoint for histological analyses of the immune response (T+2DAYS, T+4DAYS, T+7DAYS). Auditory Brainstem Response (ABR) thresholds were measured at each timepoint to assess associated hearing impairments. Histological analyses were conducted on cochleae prepared either as flat surface or cross-sections, followed by immunolabelling to identify macrophages (Iba1), T lymphocytes (CD3) and B lymphocytes (PAX5). Immune cells quantification and qualitative assessment of their localization in the cochlea were performed to correlate with ABR outcomes.

Results: LPS injection induced a significant increase in the number of immune cells in the cochlea, as demonstrated in flat surface preparations and cross sections. Immunolabelling of macrophages, T and B lymphocytes revealed that the immune response was mainly formed of macrophages, detected in the spiral ligament and spiral ganglion neuron regions. Macrophage recruitment in the cochlea was transient and increased at T+2DAYS and T+4DAYS, but not at T+7DAYS, compared to controls. Interestingly, in mice injected with LPS, the number of macrophages correlated with both the dose of LPS and the increased ABR thresholds at T+2DAYS and T+4DAYS. At T+7DAYS both markers completely recovered.

Conclusions: In LPS cochlea, a huge recruitment of inflammatory cells was reported, thanks to histological tools, and correlated with transient hearing loss. These results validate the local use of LPS as a rapid and efficient method to induce cochlear inflammation, providing a relevant in vivo model to evaluate anti-inflammatory compounds in vivo and their effects on hearing. Immune response characterization is now being completed with protein analysis of cochleae and Complete Blood Count (CBC) tests to further characterize the inflammatory response in this model.

SU120. Can Oncomodulin Be Expressed in Macrophages Following Cochlear Damage?

Mi-Jung Kim*¹, Robert Fuentes¹, Yingjie Zhou¹, Prerita Pandya¹, Jing Zheng¹

¹*Northwestern University*

Background: Oncomodulin (OCM) is the most abundant calcium-binding protein in outer hair cells (OHCs). In mice, the absence of OCM leads to progressive hearing loss and degeneration of OHCs, indicating that OCM is essential for maintaining cochlear function. Research has shown that OCM is transiently expressed and secreted by macrophages and neutrophils in response to injuries in the eye and spinal cord. The released OCM promotes nerve regrowth and repair for retinal ganglion cells and dorsal root ganglia. However, it remains unclear whether OCM can also be expressed in macrophages and neutrophils following injuries in the cochlea, just as in damaged eye and spinal cord. In the current study, we aim to investigate OCM expression in macrophages after cochlear damage using a new *Ocm*-KO/*lacZ* reporter mouse model (*Ocm* *tm1b*), which replaces *Ocm* translation with the expression of β -galactosidase (β -gal).

Methods: We created an *Ocm*-KO mouse model (*Ocm* *tm1a*) based on the ‘KO-first, conditional-ready’ strategy. *Ocm* *tm1a* mice were then crossed with CMV-Cre mice, which can delete the neo cassette and exon 3 of the *Ocm* *tm1a* allele to generate a *lacZ*-tagged global KO allele (*Ocm* *tm1b*). To confirm the absence of OCM in *Ocm**tm1b*/*tm1b* mice, we collected cochleae from WT and *Ocm**tm1b*/*tm1b* mice for immunofluorescence (IF) and Western blot with an antibody for OCM. To validate β -gal protein expression in the OHCs of *Ocm**tm1b*/*tm1b* mice, we performed X-gal staining in the cochleae from WT and *Ocm**tm1b*/*tm1b* mice. Additionally, we performed IF with antibodies for β -gal and OHC marker Prestin. To investigate whether OCM is expressed in macrophages within damaged cochlea, we administered a single intravenous dose of 16 mg/kg cisplatin to *Ocm**tm1b*/*tm1b* mice. One and two days after injection, we collected cochleae to perform IF with antibodies for β -gal and macrophage marker IBA1.

Results: OCM protein expression was not detected in *Ocm**tm1b*/*tm1b* cochleae, but it was present in WT cochleae. Additionally, β -gal protein expression was observed in the OHCs of *Ocm**tm1b*/*tm1b* cochleae but not in those of WT cochleae. There was no detectable β -gal staining in macrophages labeled with anti-IBA1 in untreated *Ocm**tm1b*/*tm1b* cochleae. However, a few β -gal and IBA1 positive cells were found in the stria vascularis of the *Ocm**tm1b*/*tm1b* cochleae collected 1 day after cisplatin injection.

Conclusions: These results show that OCM can be transiently expressed in macrophages in damaged cochlea. Since cisplatin damages many tissues and cells, it remains unclear whether the β -gal and IBA1 positive cells originate from resident macrophages in the cochlea or circulating

monocytes from the blood due to cisplatin-induced damage in other tissues. To address this uncertainty, we will use noise exposure to induce tissue damage exclusively in the ear. (Work supported by the Knowles Leadership Fund and NIH R56DC020542 to JZ).

SU121. Spatial Organization of Cochlear and Vestibular Lymphatics in the Mouse Model

Muhammad Rahman^{*1}, Md Ibrahim Razu¹, Shakila Mahmuda Fatima¹, Bryce Hunger¹, Md Fahad Hossain¹, Brian Mostaert¹, Nashwaan Khan¹, Md Shuaib Akhter¹, Robert Gay², Ya Lang Enke², Young-Kwon Hong³, Alexander Claussen¹, Marlan R. Hansen¹

¹*The University of Iowa*, ²*Cochlear Limited*, ³*Beth Israel Deaconess Medical Center*

Background: The lymphatic system circulates interstitial fluid and immune cells to return to the bloodstream, playing a critical role in tissue fluid homeostasis and the immune surveillance system. The system consists of lymphatic vessels (lymphatics) and lymph nodes. For many years, the nervous system has been considered devoid of a lymphatic vascular system. Recent discoveries of the lymphatic vascular systems draining the brain and cerebrospinal fluid have brought a paradigm shift. Lymphatics of some sensory systems, like the visual systems, have also been described. However, the lymphatic vascular system for the sensory organs of hearing (cochlea) and balance (vestibular system) has never been described. The current study is aimed at exploring the possibility of lymphatic vessels in the cochlea and vestibular systems.

Methods: 8-12-week-old mice were used to identify the cochlear and vestibular lymphatic vessels. Thy1+/YFP and PECAM1-EGFP mice on C57B6 background were used to differentiate lymphatics from SGNs and blood vessels, respectively. The cochlea and vestibule, fixed with 4% PFA, were decalcified with 0.12M EDTA and cryopreserved with increasing concentration (10%-30%) of sucrose. 30-100µm thick cochlear and vestibular sections and cochlear whole mounts were labeled with antibodies against lymphatic markers (PDPN, Lyve1, VEGFR3), anti-GFP (to amplify Prox1-EGFP signal), and Anti-myosin VIIa (hair cell marker) antibodies and imaged using a confocal microscope. Whole cochlea and vestibule samples labeled with markers of lymphatics were cleared using the CUBIC tissue clearing protocol.

Results: A robust lymphatic vascular network, labeled with markers of lymphatics, was observed in the cochlea and vestibular systems. Within the cochlea, lymphatics are observed in the spiral ganglia, stria vascularis, spiral ligament, Reissner's membrane, along the margins of the scala tympani and scala vestibuli, modiolus, and underneath the hair cells. PDPN+ lymphatics could be distinguished from Thy1+ SGN fibers and PECAM1+ blood vessels. We have observed the lymphatic vessels in different parts of the vestibular system, including the saccule, utricle, vestibule, and semicircular canals. Expectedly, both cochlear and vestibular lymphatics are adjacent to the cochlear blood vessels and located in strategic locations suitable for draining major sensory structures, and interstitial (perilymph and endolymph) fluids.

Conclusions: Our results suggest the presence of a cochlear and vestibular lymphatic network in adult mice. Further investigations using different lymphatic markers are necessary for anatomical and molecular characterization of cochlear lymphatics.

SU122. Role of the Cochlear ‘Immune Surveillance System’ in the Foreign Body Response Following Cochlear Implantation

Muhammad Rahman*¹, Shakila Mahmuda Fatima¹, Md Ibrahim Razu¹, Bryce Hunger¹, Md Fahad Hossain¹, Brian Mostaert¹, Nashwaan Ali Khan¹, Md Shuaib Akhter¹, Robert Gay², Ya Lang Enke², Young-Kwon Hong³, Alexander Claussen¹, Marlan R. Hansen¹

¹The University of Iowa, ²Cochlear Limited, ³Beth Israel Deaconess Medical Center

Background: The inflammatory foreign body response (FBR) following cochlear implantation (CI) has the potential to negatively impact CI outcomes, including increased electrode impedances, accelerated loss of residual acoustic hearing, reduced battery life, and, rarely, implant extrusion. Immune cells contribute to the FBR post-CI. Immune cells are trafficked to the tissue via blood vessels and return to the bloodstream via the lymphatic vessels, forming the ‘immune surveillance system’. This study aims to investigate the role of immune cell trafficking via cochlear blood vessels and the recently discovered cochlear lymphatic network in the FBR post-CI.

Methods: To investigate the immune cell trafficking through cochlear blood vessels and lymphatics, we used five mouse strains: CX3CR1+/GFP (reporter for mononuclear phagocytes/MNPs), CCR2+/RFP CX3CR1+/GFP (reporter for blood-derived/ hematogenous/ infiltrated/extravasated MNPs), Prox1tdTomato-CD11cGFP (lymphatic-dendritic cells dual reporter), Prox1tdTomato-CX3CR1+/GFP (lymphatic-mononuclear phagocyte dual reporter), and Prox1tdTomato-PECAM1GFP (lymphatic-blood vessel dual reporter). The left ears of 10-12-week-old mouse models were implanted with a standard non-functional CI. Following the euthanasia of mice at 28 days post-operatively, harvested cochleae fixed with 4% PFA were processed and cryosectioned at 30µm parallel to the mid-modiolar plane. Sections labeled with antibodies against appropriate markers were used to identify different cell types: CD45, CD3e, MHCII, anti-GFP, Lyve1, VEGFR3, and PDPN. Using IMARIS image analysis software, the density of MNPs, infiltrating immune cells, CX3CR1+MHCII+ (APC), CX3CR1-CD45+ (non-MNP immune cells), CX3CR1-CD45+ CD3e+ (T lymphocytes), and CD11cGFP+ (dendritic cells) was calculated. The volume of blood vessels (PECAM1+) and lymphatic vessels (Prox1tdTomato+, PDPN+VEGFR3+Lyve1+) was measured within the scala tympani of the base of the cochlea, and the density of the blood vessels and lymphatic vessels in the scala tympani of the cochlea was quantified. Intralymphatic immune cell density was quantified, creating masks for lymphatic vessels and the immune cells.

Results: Following CI, blood vessels proliferate into the cochlea, trafficking blood-derived immune cells into the cochlea. Cochlear implantation also leads to lymphatic vessel proliferation into the cochlea, trafficking immune cells. Recruitment of MHCII+APCs, dendritic cells, and T lymphocytes suggests an activation of the adaptive immune system.

Conclusions: Our data indicate that following cochlear implantation, vascular proliferation is associated with a two-way traffic of immune cells to (via blood vessels) and away (via lymphatics) from the cochlea. This supports the involvement of the cochlear ‘immune surveillance system’ in FBR post-CI.

SU123. Diagnostic Yield of Whole-Genome Sequencing in Hearing Impairment: A Five-Year Study in a Large German Cohort

Georg Schweizer¹, Yingqiu Peng¹, Siard Kleiner¹, Thore Schade-Mann¹, Sabrina Taddeo¹, Tobias B. Haack², Ana Beatriz Hinojosa-Amaya², Joohyun Park², Petra Stöbe², Olaf Riess², Hubert Löwenheim^{*1}, Anke Tropitzsch¹

¹University of Tübingen Medical Center ²Institute of Medical Genetics and Applied Genomics, University of Tübingen Medical Center

Background: Hereditary hearing loss is a genetically and clinically heterogeneous condition with variable age of onset, severity, and progression. Genetic testing has shifted from targeted panels and exome sequencing toward whole-genome sequencing (WGS), which enables more comprehensive variant detection and deeper insights into the genetic spectrum of hearing loss. This study aimed to retrospectively evaluate five years of whole-genome sequencing for hereditary hearing loss at a tertiary care center in Southwest Germany by assessing diagnostic yield, the spectrum of causative genes, and factors influencing the likelihood of a molecular diagnosis.

Methods: 383 index probands with suspected hereditary hearing loss were identified, who underwent WGS between April 2020 and July 2025. Phenotypic characterization was performed by reviewing the electronic medical records and the institutional audiometric database, collecting information on family history, age of onset, degree and laterality of hearing loss. These phenotypic variables were additionally complemented by genetically derived estimates of ethnicity and consanguinity. Logistic regression was applied to estimate the effects of predictors on diagnostic outcome, with significance levels adjusted for multiple testing.

Results: The age at genetic testing ranged from 0.2 to 84.6 years (mean $\pm$ SD: 33.8 ± 23.1 years). A postlingual onset of hearing loss was present in 53.0% of probands, while 31.3% presented with congenital and 14.9% with early-onset (pre- or perilingual) hearing loss. A positive family history of hearing loss was reported in about half of the probands (53.0%). Of the 383 probands analyzed, a genetic diagnosis was obtained in 106 cases (27.7%). Among the solved cases, autosomal-recessive inheritance predominated (63.2%), followed by autosomal-dominant inheritance (30.2%). The underlying variants were distributed across 37 genes, with a marked predominance of GJB2, which accounted for 35% of all solved cases. Six additional genes contributed 24.5% of diagnoses, including MYO6 (5.7%) and COCH, MYO15A, MYO7A, PTPRQ, and TMPRSS3 (all 3.8%). The remaining 40.5% of genetically diagnosed probands were linked to variants in 30 other genes. In logistic regression analysis, age at onset of hearing loss, positive family history, and degree of hearing loss emerged as significant predictors of diagnostic outcome. Pairwise contrasts of estimated marginal means further indicated higher predicted diagnostic rates in probands with a positive family history compared to those without, and in congenital or early-onset hearing loss compared to postlingual onset.

Conclusions: In this large German cohort, genetic testing for hereditary hearing loss revealed a broad spectrum of causative genes and provided an overview of the genetic landscape in the population, highlighting its clinical relevance. Certain clinical factors emerged as predictors of diagnostic outcome, emphasizing the value of detailed phenotyping for genetic diagnostics in hearing loss.

SU124. Inner Ear Malformations in Patients With Hearing Loss — Exploring the Genetic Architecture

Monika Oldak*¹, Natalia Baldyga¹, Nina Gan¹, Dominika Ozieblo¹, Marcin L. Leja¹, Mariusz Furmanek¹, Henryk Skarzynski¹

¹*Institute of Physiology and Pathology of Hearing*

Background: Inner ear malformations (IEMs) can occur in isolation or as part of genetically determined syndromes. Enlarged vestibular aqueduct (EVA) is the most frequently observed IEM, often accompanied by incomplete partition type 2 of the cochlea and a dilated vestibule. SLC26A4 is the major gene associated with IEMs, with 50% of EVA/IP2 patients carrying either two pathogenic SLC26A4 variants or one SLC26A4 pathogenic variant together with the CEVA haplotype. The genetic background of other IEMs is more diverse and remains poorly understood.

Methods: DNA was isolated from blood samples of 40 hearing loss (HL) patients with bilateral IEMs. Sequencing was performed using a custom multigene panel (237 or 263 genes).

Results: Genetic testing identified the cause of IEMs in 67.5% (27/40) of individuals. Among EVA/IP2 patients, six carried two pathogenic variants in SLC26A4, while another six had one SLC26A4 pathogenic variant together with the CEVA haplotype. The genetic cause still remains unknown in six EVA/IP2 patients. In patients with other IEMs, pathogenic variants were identified in POU3F4 as well as genes associated with CHARGE (CHD7), BOR (EYA1, SIX1), Waardenburg (SOX10), and Kabuki (KMT2D) syndromes. Additionally, a novel pathogenic variant in HOXA2 was identified in a single patient.

Conclusions: Mutations in SLC26A4 and the CEVA haplotype account for more than half of EVA/IP2 cases. Patients with other IEMs are frequently diagnosed with syndromic forms of HL. Further research is needed to identify pathogenic variants in noncoding regions of known HL genes or in novel genes.

Grants: 2021/41/B/NZ5/04390, National Science Centre, Poland

SU125. Immune Modulation of Zfp719 Dependent Hearing Loss

Tingfang Chen*¹, Sixing Chen¹, Staci Rakowiecki¹, Sophie Shapiro¹, Said Ibrahim¹, Robert K. Hu¹, Pablo Gonzalez Camara¹, Kevin Ohlemiller², Mark Rutherford², Todd Macfarlan³, Douglas Epstein*¹

¹*University of Pennsylvania*, ²*Washington University*, ³*National Institutes of Health*

Background: Hearing loss affects ~20% of the population, with sensorineural forms predominating. Causes include genetics, environmental factors, trauma, and aging. Adult-onset hearing loss not only impacts individual well-being but also carries substantial socioeconomic implications. Our research seeks to elucidate unexplained genetic underpinnings of adult-onset hearing loss, focusing on rare coding variants within established and undiscovered hearing loss genes. Taking advantage of a genome first approach in the Penn Medicine BioBank and functional studies in mice we identified ZNF175, and its mouse orthologue Zfp719, as a novel adult onset hearing loss gene. ZNF175/Zfp719 is a member of a large family of Krüppel-

associated box zinc-finger proteins that bind DNA and silence target gene expression, including transposable elements and host genes, through the formation of heterochromatin.

Methods: Genomic and bioinformatic analysis of snRNA-seq datasets, quantitative spatial transcriptomics, a flexible genetic system in mice were used to identify the gene targets of Zfp719 mediated heterochromatin silencing and determine the pathogenic consequences of their misregulation on calcium ion homeostasis, ribbon synapse integrity, hair cell viability, and innate immunity.

Results: Zfp719 mutant mice exhibited progressive synaptopathy, hair cell degeneration and hearing loss, with severity increasing in both an age- and gene dosage- dependent manner. Tissue-resident macrophages infiltrated the cochlea before overt signs of cellular damage and persisted as pathology advanced along the cochlear duct from base to apex. Selective deletion of Zfp719 in hair cells, but not in spiral ganglion neurons, recapitulated these cochlear defects, including macrophage activation. Strikingly, pharmacological depletion or genetic disruption of macrophages accelerated cochlear pathology in Zfp719 mutants, revealing a protective role in delaying both the onset and severity of hearing loss. Single-nucleus transcriptional profiling identified Gm15083, a long non-coding RNA, as one of the most upregulated genes in Zfp719 mutants. Gm15083 overlaps with Atp2b2 on chromosome 6 and is transcribed in antisense orientation, raising the possibility that derepression of Gm15083 interferes with Atp2b2 transcription. Atp2b2 encodes plasma membrane calcium transporting ATPase 2 (PMCA2), a crucial efflux pump required to maintain calcium homeostasis in outer hair cells. Consistent with this model, Atp2b2 decreased and Gm15083 increased in Zfp719 mutants outer hair cells. Moreover, Atp2b2 haploinsufficiency closely phenocopied the Zfp719 mutant phenotype, implicating disrupted calcium homeostasis as a primary driver of hearing loss. Ongoing experiments are testing whether loss of Gm15083 transcription restores Atp2b2 expression and auditory function in Zfp719 mutants.

Conclusions: Zfp719 is required in cochlear hair cells for normal auditory function, and its loss triggers gene dosage-dependent degenerative defects. Cochlear macrophages act protectively in this context. The concordant changes in Gm15083 and Atp2b2 expression indicate that disrupted calcium homeostasis is a principal consequence of Zfp719 deficiency. Given the multifactorial etiology of adult-onset hearing loss, our findings may help inform a broader understanding of the condition.

SU126. USH2A Variants as a Significant Genetic Factor an Mild to Moderate Hearing Loss

Dominika Ozieblo*¹, Natalia Baldyga¹, Marcin L. Leja¹, Magdalena Pankowska¹, Henryk Skarzynski¹, Monika Oldak¹

¹*Institute of Physiology and Pathology of Hearing*

Background: The most common genetic cause of mild to moderate hearing loss (HL) is STRC copy number variants (CNVs). Many patients with mild to moderate HL require further genetic testing due to the lack of molecular diagnosis. Literature indicates that, besides STRC, USH2A, MPZL2, and OTOG may also be responsible for mild to moderate HL. This study aimed to identify the genetic basis of isolated mild to moderate HL in patients without STRC CNVs.

Methods: The study included 47 patients with isolated mild to moderate HL without detected STRC CNVs or with one identified heterozygous STRC CNV. Genomic DNA was isolated from peripheral blood and NGS with a custom panel of HL-related genes (n=237 or 263) was performed. Selected variants were confirmed by Sanger sequencing.

Results: NGS revealed the genetic cause of HL in 51% (24/47) of patients. Among these, 25% (6/24) of causative variants were found in USH2A, linked to Usher syndrome. In 17% (4/24) of variants, mutations in OTOG were considered as the cause of HL. The remaining causative variants were detected in: ADGRV1, GATA3, MPZL2, OTOA, POU3F4, PTPRQ, REST, STRC, TBC1D24, and WFS1.

Conclusions: NGS revealed that, in addition to STRC, a significant proportion of patients with mild to moderate HL have causative variants in USH2A. Patients with USH2A pathogenic variants are likely to develop Usher syndrome type 2A, which includes both HL and retinitis pigmentosa. Identifying the genetic cause is crucial for providing personalized care from an early age.

Additional information: National Science Centre, Poland, 2020/37/N/NZ5/02800

SU127. Identification of Pathogenic Synonymous SLC26A4 Variants

Joseph Chin^{*1}, Amanda Odell², Diana L. Kolbe², Kevin T. Booth³, Hela Azaiez³, Richard J. H. Smith²

¹*University of Iowa Carver College of Medicine*, ²*University of Iowa Hospitals and Clinics*³*Medical and Molecular Genetics, Indiana School of Medicine*

Background: Variants in SLC26A4 are a common cause of autosomal recessive hearing loss (HL) associated with an enlarged vestibular aqueduct (DFNB4/non-syndromic enlarged vestibular aqueduct (EVA)) and Pendred syndrome (HL and thyroid goiter). In ~15-30% of cases, biallelic variants SLC26A4 are not identified, suggesting the presence of an unidentified second pathogenic variant. We hypothesized that in some unresolved cases, the second variant is a splice-altering synonymous change.

Methods: A prospective study identified candidate variants in persons tested using the latest version of our comprehensive genetic testing platform (OtoSCOPE®). Variants were filtered and prioritized based on minor allele frequency, in silico predictions, family history, and clinical correlation.

We also performed a retrospective analysis of 199 persons with a single SLC26A4 pathogenic/likely pathogenic variant, a phenotype potentially consistent with SLC26A4-related HL, and no genetic diagnosis using the current version of the bioinformatics workflow, which assesses synonymous variants to identify synonymous variants of interest that were being previously filtered out.

The functional impact of candidate variants was assessed using minigene splicing assays. Patient DNA containing the relevant SLC26A4 exon and a portion of the flanking intronic regions was

subcloned into a pre-constructed pET01 Exontrap vector encoding 5' and 3' exons separated by a multiple cloning site. Vectors were transfected into COS-7 cells. RNA harvest was performed 36-48 hours post-transfection. Changes in splicing were assessed using gel electrophoresis and Sanger sequencing.

Results: From the prospective analysis of patients, we identified a 2-year-old male with congenital, moderate-to-severe bilateral sensorineural HL and bilateral EVA. He carries the novel synonymous variant, NM_000441.2:c.600G > A, p.(Gln200=) together with a previously reported pathogenic variant, NM_000441.2:c.1151A > G, p.(Glu384Gly). The minigene splicing assay indicated that the c.600G > A variant results in skipping of exon 5, generating a frameshift.

From the retrospective analysis, we identified a 7-year-old female with sensorineural HL diagnosed at the age of 5, EVA, and a brother with HL. She carries the rare synonymous variant, NM_000441.2:c.1206G > A, p.(Val402=) variant together with the pathogenic variant, NM_000441.2:c.2284G > T, p.(Glu762*). The minigene splicing assay indicated that the c.1206G > A creates a cryptic splice acceptor 58 bases into exon 10 and a resulting frameshift.

Conclusions: This work highlights the importance of evaluating persons for splice-altering synonymous variants to identify pathogenic variants in autosomal recessive conditions. However, there are still many undiagnosed cases of presumed SLC26A4-related HL, highlighting the need for other methods of detection to resolve the challenge of missing heritability.

SU128. Identification of a Novel Founder EYA4 Structural Variant in North America

Miles Klimara^{*1}, Jacquelyn DeVries¹, Amanda Odell¹, Diana Kolbe¹, Nicole Meyer¹, Paige Harlan¹, Hela Azaiez², Richard JH Smith¹

¹*Molecular Otolaryngology and Renal Research Labs, University of Iowa Carver College of Medicine*²*Medical and Molecular Genetics, Indiana School of Medicine, Indianapolis*

Background: Autosomal dominant nonsyndromic hearing loss (NSHL) is a genetically heterogeneous disorder. Copy-number and structural variants (SVs) in EYA4 are a rare cause of hearing loss at the DFNA10 locus. We aimed to determine the genetic etiology of hearing loss in a series of families with autosomal dominant NSHL.

Methods: Retrospective review of patients referred for targeted genomic enrichment and massively parallel sequencing using the OtoSCOPE® panel, which covers all exons and flanking intronic sequences of known genes associated with NSHL. Genetic results and available phenotypic data were reviewed by a multidisciplinary team to assess variant pathogenicity. Haplotypes were reconstructed using short tandem repeat analysis (STRP) and variants in EYA4 and surrounding regions.

Results: A novel pathogenic SV in EYA4 was detected in five North American probands of European descent with family history suggestive of autosomal dominant NSHL, which involves a 5.8kb deletion of the C-terminal exons 19 and 20, and insertion of a 76-bp inverted downstream sequence. Segregation analysis revealed co-segregation with the hearing loss phenotype in 2 affected relatives. This SV is the most frequently detected pathogenic variant in

EYA4 in the OtoSCOPE® cohort, accounting for 5 of 25 (20%) of DFNA10 diagnoses to date and 5 of 15 (33%) diagnoses in probands of European ancestry. STRP haplotype analysis demonstrated an 857 kB region surrounding EYA4 in linkage disequilibrium, shared among all probands and affected family members.

Conclusions: This finding expands the mutational spectrum of EYA4-associated deafness, with identification of a novel SV as the most common pathogenic DFNA10 variant in a large hearing loss cohort. The complexity of this SV, coupled with haplotype reconstruction, strongly suggests a founder effect rather than a recurrent event. These data highlight the importance of critical analysis of high-quality next-generation sequencing in the assessment of complex SVs.

SU129. Genetic Insights Into Sensorineural Hearing Loss: Identifying Variants in Hispanic Children

Helen Gomez^{*1}, Kiera Willford², Shantha Nallapothula³, Brie Mallot¹, Talitha Karisse L. Yarza⁴, Landen Mayher¹, Julian Grandvallet Contreras¹, Tzu Phang¹, Maria Rina T. Reyes-Quintos⁵, Marcos V. Goycoolea⁶, Patricia J. Yoon⁷, Charlotte M. Chiong⁵, Maria José Herrera J⁸, Seema R. Lalani³, Regie Lyn Santos-Cortez¹

¹University of Colorado Anschutz Medical Campus, ²University of Colorado Anschutz Medical Campus, Pathways in Genomics Research for Undergraduate Experiences, ³Baylor College of Medicine, Houston, ⁴Philippine National Ear Institute and Newborn Hearing Screening Reference Center, University of the Philippines Manila - National Institutes of Health, Manila, Philippines, ⁵Philippine National Ear Institute and Newborn Hearing Screening Reference Center, University of the Philippines Manila - National Institutes of Health and Department of Otolaryngology – Head and Neck Surgery and University of the Philippines College of Medicine – Philippine General Hospital, Manila, Philippines, ⁶Children's Hospital Colorado, ⁷University of Colorado Anschutz Medical Campus and Department of Pediatric Otolaryngology, Children's Hospital Colorado, ⁸Clínica Universidad de los Andes

Background: Sensorineural hearing loss (SNHL) affects approximately 1 to 3 per 1,000 live births, with over half of congenital cases attributed to genetic causes. While major strides have been made in understanding the genetic basis of SNHL particularly in European and Asian populations, Hispanic/Latino populations remain vastly underrepresented in genetic studies and testing, limiting equitable access to diagnostics and potential interventions.

Methods: To address this disparity, we enrolled Hispanic-admixed pediatric patients with confirmed SNHL and their family members through collaborations across four sites in three countries. Saliva samples were collected using Oragene DNA kits, and comprehensive clinical information — including family history, audiologic evaluations, surgical reports, and imaging — was reviewed. Genomic DNA was isolated from saliva and submitted to either exome sequencing (n=26) at the University of Washington Northwest Genomics Core or whole-genome sequencing (WGS; n=25) at the University of Colorado Genomics Core. The generated sequence data were analyzed using a custom pipeline incorporating ANNOVAR and gnomAD minor allele frequency (MAF) filters. Prioritized variants were further assessed using functional prediction tools for single nucleotide variants and indels. Copy number or structural variants were called

using multiple tools including Manta, Strelka, CNVkit and FreeBayes. Identified pathogenic and putatively functional variants were Sanger-sequenced in the proband and other family members.

Results: Preliminary analyses based on exome sequence data identified several pathogenic or likely pathogenic variants in known hearing loss genes, including population-specific alleles such as GJB2 c.19C > T (p.Gln7*) that was previously identified in Ecuador and GJB2 c.131G > A (p.Trp44*) in Guatemala. Early findings suggest that allelic spectra defined by genes, variants, and MAF differ across recruitment sites and in comparison, to non-Hispanic populations reported in the literature. Furthermore, to date our cohort shows a higher proportion of syndromic relative to nonsyndromic HL, a trend supported by the few existing reports on Hispanic populations.

Conclusions: These results underscore both the shared and unique genetic architecture of SNHL in Hispanic groups. Importantly, the diagnostic yield from this study supports the inclusion of genetic testing in hearing care protocols for Hispanic children, with implications for early intervention and eligibility for emerging gene therapies. Future directions include analyzing additional WGS datasets, expanding recruitment across diverse Hispanic regions, optimizing variant interpretation, and disseminating findings to guide equitable implementation of precision medicine in otolaryngology.

SU130. Dysregulation of Extracellular Matrix and Inner Ear Components Underlying the Hypoplastic Endotype of Ménière's Disease: Role of ADAMTS18

Paula Robles-Bolivar^{*1}, David Bächinger², Alberto M. Parra-Perez³, Sebastian Zwicky⁴, Agnieszka Szczepek⁵, Jose A. Lopez-Escamez⁶, Andreas H. Eckhard¹

¹Mass Eye and Ear, Harvard Medical School, ²University Hospital Zurich, ³Universidad de Granada, ⁴University of Zurich, ⁵Charite Universitätsmedizin, ⁶The Kolling Institute, University of Sydney

Background: Meniere Disease (MD) is a chronic inner ear disorder characterized by fluctuating sensorineural hearing loss (SNHL), tinnitus, and episodic vertigo, with variable severity and progression. Its etiology remains unclear, with autoimmune, viral, allergic, vascular, developmental, and genetic factors under investigation. Previous studies of human temporal bone consistently identified abnormalities of the endolymphatic sac in MD, correlating with distinct clinical pictures. In ~30% of MD cases, the sac remains developmentally arrested or hypoplastic (MD-hp) with patients showing early-onset disease, male predominance, bilateral symptoms, temporal bone malformations, and familial clustering of MD or SNHL. These features point to a genetic cause for this endotype, and our aim was to define its underlying basis.

Methods: MD patients were recruited following diagnostic guidelines, and the MD-hp endotype was identified using a surrogate radiodiagnostic marker in CT. Whole-exome sequencing was performed from saliva-derived DNA. Enrichment of rare SNPs and InDels (AF < 0.05) with predicted high/moderate impact were analyzed through gene burden analysis against general population databases. Structural variants were also called and prioritized by high constraint or pathogenic prediction. Functional analysis was performed with candidate genes revealing

implicated biological pathways. Candidate gene expression was further evaluated by immunohistochemistry in human and mouse temporal bone across different development stages.

Results: Our final cohort consisted of 42 MD-hp individuals. Candidate genes included 94 genes enriched in potentially causal variants. Functional enrichment analysis revealed biological pathways related to extracellular matrix formation and maintenance, including bone matrix development and non-syndromic hearing impairment. Among these, ADAMTS18 emerged as the strongest candidate with 35.7% of MD-hp patients carrying 15 distinct variants in this gene. Immunolabeling confirmed ADAMTS18 expression in human and mouse temporal bone during embryonic and early postnatal stages, both surrounding sensory epithelia and within the maturing cartilage destined to form the otic capsule.

Conclusions: Our findings support a strong genetic contribution to the MD-hp endotype, with an accumulation of variants in genes involved in inner ear structures and in the ossification of the surrounding temporal bone. In particular, ADAMTS18 harbors variants predominantly in MD-hp patients, and its disruption may underlie abnormal development of these structures during embryonic and early postnatal stages. Genetic delineation of this endotype provides new insight into disease mechanisms, supports stratification of MD patients into biologically meaningful subgroups, and may ultimately guide precision approaches for diagnosis and therapy.

SU131. Uncovering the Genetic Relationship Between Dementia and Age-Related Hearing Loss

Andrew Van Domelen¹, Samah Ahmed¹, Kenneth Vaden², Judy Dubno², Britt Drogemoller¹

¹*University of Manitoba*, ²*Medical University of South Carolina*

Background: Hearing loss is an important modifiable midlife risk factor for dementia. Recent studies have investigated the genetic relationship between dementia and age-related hearing loss (ARHL) with conflicting results. These analyses have conveniently treated ARHL and dementia as monolithic conditions, when in reality both encompass distinct pathophysiological processes. We have previously shown that genes linked to frontotemporal dementia may play a role in the metabolic subtype of ARHL (MHL), but not other ARHL subtypes. Other emerging evidence also suggests that genetic risk for hearing loss associates with specific brain structural changes, though these findings are typically based on broad hearing phenotypes. Therefore, we sought to employ a comprehensive phenotyping strategy using audiological measures and brain magnetic resonance imaging (MRI) data to examine whether genetic variants that we have found to be associated with MHL also affect brain structure, potentially providing mechanistic insight into the genetic relationship between ARHL and dementia.

Methods: Through the Canadian Longitudinal Study on Aging (CLSA), we have access to high-quality genotype and audiological data for 17,531 older adults. Estimates of MHL were calculated from audiograms of European-descent participants and subjected to genome-wide association study (GWAS) analyses to identify genetic variants associated with the MHL subtype. MRI GWAS data were previously generated by the UK Biobank (n=33,000) and accessed online. A phenome-wide association study (PheWAS) was performed to identify brain MRI traits that shared risk loci with MHL. Genetic colocalization was then performed to confirm that the same causal genetic variants were underlying these shared signals.

Results: PheWAS identified 7 MRI phenotypes with the strongest evidence of association ($P < 2 \times 10^{-5}$) with MHL risk variants. Colocalization analysis of these prioritized MRI-MHL-variant triplets identified strong evidence (92.8% posterior probability) for a shared genetic variant (rs4413512) in ARHGEF28 underlying both MHL and white matter microstructure in the retrolenticular segment of the internal capsule, a white matter pathway transmitting sensory information. This finding suggests that genetic variants associated with MHL may also affect brain white matter integrity, though the functional significance requires further investigation.

Conclusions: This exploratory study suggests (1) the utility of highly specific, objective phenotyping in genetic analyses of complex traits, and (2) preliminary evidence for shared genetic architecture between ARHL and brain white matter. The colocalization of an intronic variant in ARHGEF28 with white matter microstructure measures in the internal capsule may reflect the gene's dual role in regulating both cytoskeletal organization and RNA metabolism, two processes essential for maintaining axonal integrity and myelination. Looking ahead, future research expanding to additional dementia endophenotypes and ARHL subtypes will help clarify the role of hearing loss as a modifiable midlife risk factor for dementia, guiding both clinical decision-making and research on the hearing-dementia association.

SU132. Optimizing Genetic Testing Referrals for Pediatric Hearing Loss

Julia Morris¹, Jennifer Coto², Valerie Yunis², Mustafa Tekin², Ivette Cejas², Xue-Zhong Liu²

¹University of Miami, ²University of Miami Miller School of Medicine

Background: Although the benefits of genetic testing in pediatric hearing loss are well established, referral rates for genetic testing remain low within otology and audiology practices. This study examined referral rates, referral pathways, and appointment completion for genetic evaluation in an ethnically diverse pediatric cohort before and after implementation of a quality improvement (QI) protocol.

Methods: In phase 1 (Jan-Aug 2023), chart reviews were conducted for 86 patients with hearing loss to determine if referrals to genetics were made. Data collected included demographics, referral modality (progress note documentation, routed note to genetics, or direct referral order) and genetics appointment status. In Phase 2 (Sep-Dec 2023), a standardized referral protocol was implemented requiring all newly diagnosed patients to be referred through one of three pathways (visit summary note, routed note, direct referral order). Providers received a brief training and reminder cards. Chart reviews were then conducted on 29 additional patients.

Results: In phase 1, 27.9% had a referral documented. Referrals were made by otologists (15.1%), audiologists (7%), or both (5.8%). A routed note occurred in 4.7% of cases, and a direct referral order in 15.1%. Among referred patients, 54.2% did not schedule an appointment, 20.8% had pending appointments, and 25% completed an appointment.

In phase 2, referral documentation increased to 55.2% of patients. Referrals were made by audiologists (31%), otologists (6.9%), or both (17.2%). A referral order was placed in 41.4% of patients, and 31% had a routed note. Appointment completion improved to 62.5% compared to 25% in Phase 1.

Conclusions: Genetic testing referrals remain underutilized but improved after implementing a standardized protocol. These findings emphasize the need to identify barriers in referral

pathways and provide ongoing provider training. Quality improvement projects offer a promising approach to optimize genetic evaluations and enhance precision care for pediatric hearing loss patients.

SU133. Estradiol Regulation of Cochlear Gene Expression in Female Mice

Mengxiao Ye¹, Celia Zhang², Brandon Marzullo³, Yue Li¹, Bohua Hu*¹

¹*University of Texas at Dallas*, ²*University of the Pacific*, ³*University at Buffalo*

Background: Sex is a biological factor that influences auditory function and disease susceptibility. Our recent study showed that sex affects cochlear gene expression, but the mechanisms regulating this sex-dependent expression remain unclear. Estrogen, a major female hormone, is known to modulate gene expression in many non-cochlear organs and tissues. This study aimed to investigate the effects of estradiol treatment on cochlear gene expression and to assess the functional implications of estrogen-responsive genes in the cochlea.

Methods: Young, healthy female CBA/CaJ mice were used. To eliminate gonadal hormone production, the mice underwent ovariectomy (OVX). OVX mice were then injected daily with 17 β -estradiol at a dose of 3 μ g dissolved in sesame oil for three consecutive days, while control OVX mice received equivalent volumes of sesame oil alone. At the end of treatment, mice were sacrificed and their cochleae were collected. Bulk RNA-sequencing was performed to compare cochlear transcriptomes between estradiol-treated and control mice. Differentially expressed genes (DEGs) were identified, and their functional associations were analyzed using multiple bioinformatics tools.

Results: Using the criteria of adjusted p-value < 0.05 and log2 fold change (FC) > 0.2, we identified 366 DEGs (165 upregulated and 201 downregulated). Of these, 98.4% were protein-coding genes, while the remainder were non-coding RNAs and pseudogenes. Most DEGs exhibited only mild expression changes with the log2 FC < 1. The five most upregulated genes with log2 FC > 1 were *Prl*, *Mgl2*, *Lars2*, *Siglec1*, and *Clec10a*. The three most downregulated genes were *Hspa1a*, *Kcnj11*, and *Hspa1b*. While these genes have diverse functions, many are involved in immune and stress responses. Gene Set Enrichment Analysis (GSEA) revealed distinct functional signatures for up- and downregulated genes. Among the upregulated genes, oxidative phosphorylation and fatty acid metabolism showed the highest normalized enrichment scores with adjusted p-value < 0.05. In contrast, downregulated genes were enriched for TGF- β (transforming growth factor β) signaling. This pathway regulates multiple processes, including development, immune function, and tissue repair. Additional biological processes and cell signaling identified through the Database for Annotation, Visualization, and Integrated Discovery (DAVID) included Wnt signaling, stress responses, transcriptional regulation, and biological rhythms.

Conclusions: Our study demonstrates that estrogen modulates the expression of cochlear genes with diverse functions, particularly those involved in energy metabolism and stress regulation. These findings enhance our understanding of sex-related differences in cochlear homeostasis and susceptibility to auditory disease and dysfunction.

SU134. Cellular and Transcriptional Heterogeneity Due to NF2 Deficiency: Insights From Human iPSCS

Dongjun Han^{*1}, Minjin Jeong¹, Sally Temple², Konstantina Stankovic¹

¹Stanford University School of ²Neural Stem Cell Institute

Background: Loss-of-function mutations in NF2 give rise to NF2-related schwannomatosis (NF2-SWN), a rare autosomal dominant disorder characterized by the development of benign tumors of the nervous system, most notably bilateral vestibular schwannomas. Clinically, NF2-associated vestibular schwannomas (VS) present with a spectrum of symptoms including sensorineural hearing loss (SNHL), tinnitus, vertigo, and balance dysfunction.

Methods: Herein, we employed sex- and age-matched human iPSC lines, including CRISPR/Cas9-mediated isogenic NF2^{-/-} iPSC derived from healthy controls, as well as iPSC obtained from a patient with NF2 VS. To further delineate the effects of NF2 loss, we implemented a Tet-On NF2 inducible system in NF2-deficient cells to establish transcriptomic and phenotypic contrast between NF2 loss- and gain-of-function state. Through comprehensive transcriptome analysis, we traced molecular footprints and phenotypic features altered by NF2 deficiency in SCP state.

Results: Multimodal comprehensive transcriptome analysis revealed genes that are perturbed and directly involved in cellular heterogeneity due to biallelic loss of NF2. In addition, we consistently observed elevated expression of collagen-containing ECM genes and hyperactivation of PI3K/AKT pathways that are critically involved in cell survival, proliferation, and apoptosis. Thus, we investigated the cytotoxicity and evaluated the synergistic potential of the PI3K/AKT pathway inhibitors HCQ and QC in NF2-deficient SCP lines.

Conclusions: Our findings offer new insights into tumorigenesis and cellular heterogeneity in NF2-associated VS and highlight the value of patient-derived iPSCs and their derivatives as robust in vitro platforms for drug screening and therapeutic development. Ultimately, by repurposing FDA-approved drugs, HCQ and QC, we propose a more expeditious and safer approach to developing therapeutic strategies for NF2-associated VS.

SU135. The Role of a Conserved Extracellular Loop in TMC1 Gating

Nurunisa Akyuz¹, Trey Scott², Corena Loeb^{*1}, Bifeng Pan¹, Charles Phillips¹, Yaqiao Li¹, David Corey¹

¹Harvard Medical School, ²Harvard University

Background: The transmembrane channel-like (TMC) family is an ancient group of proteins conserved across eukaryotes. During evolution, the mechanosensory channels TMC1 and TMC2 first appeared in the vertebrate lineage; they are expressed perhaps exclusively in vertebrate hair cells and seem to be highly specialized to mediate hearing and balance. In mammals, TMC1 appears to have undergone further specialization to function in its primary role in adult auditory transduction. Yet the molecular mechanism by which force opens TMC1 channels is not well understood. Here, we investigate the role of a conserved extracellular loop between transmembrane helices 1 and 2 (the 1-2 loop) that may contribute to channel gating.

Methods: We first used evolutionary analysis to find residues in TMC1 that were positively selected for and may underly its functional adaptations. We then used structural modeling to predict how these regions may affect overall structure and transduction complex binding partners. To assess functional consequences, we then selectively mutated individual amino acids in TMC1, constructed AAV vectors carrying the mutant sequence, injected AAVs into the cochleas of

Tmc1/2 null mice at P1, and recorded transduction currents from cochlear hair cells in vitro at P8-15.

Results: Evolutionary analyses revealed residues in the TMC1 1-2 loop that were positively selected in mammals. Structural modeling suggested that this loop arches over the extracellular side of the pore, approaching both the auxiliary subunit TM1E and the pore-lining helices TM4 and TM6. Mutating two conserved aromatic residues shifted channel activation towards the closed state without affecting slope, suggesting that these residues participate in biasing the channel to be open part of the time at rest.

Conclusions: A combination of evolutionary probing, structure analysis, and electrophysiology suggest the 1-2 loop has a specialized role in mammalian hearing. Targeted mutagenesis influences channel activation and in following, this loop contains several residues linked to hereditary deafness. Integration of evolutionary, structural and physiological studies provides a holistic platform for investigating residues of functional importance in sensory transduction channels.

SU136. Estradiol Increases the Vulnerability to Hidden Hearing Loss in Female Mice Lacking GluA3 Ampar Subunits

INDRA PAL¹, Bilal Mir², Max Aizenstein², Maria Eulalia Rubio-Valero*²

¹*University of Pittsburgh*, ²*University of Pittsburgh School of Medicine*

Background: The GluA3 AMPAR subunit is essential for cochlear ribbon synapse integrity. We previously showed that female GluA3-knockout (GluA3KO) mice develop an early-onset hidden hearing loss (synaptopathy) when raised in ambient sound levels, showing reduced ABR wave-1 amplitude, significant synapse loss and afferent terminals swelling by 5-weeks of age (Pal et al., 2025). This phenotype was absent in age-matched male GluA3KO mice (Rutherford et al., 2023). However, both female and male GluA3KO mice had higher GluA4:GluA2 ratio suggesting an increased in Ca⁺⁺-permeable AMPARs (cp-AMPA) at cochlear-ribbon synapses. This sex specific vulnerability suggests a hormone mediated mechanism. Among gonad-sex hormones, estradiol is thought to be otoprotective. However, it can also potentiate high-conductance synaptic cp-AMPA in the female brain (Jain and Woolley, 2023). We therefore hypothesized that in the absence of GluA3, estradiol could increase the hearing vulnerability to ambient sound, particularly affecting females.

Methods: To test the role of gonad sex hormones in hearing vulnerability, we performed bilateral gonadectomies (ovariectomy in females and orchidectomy in males) or sham surgery in female and male GluA3KO mice at postnatal day 22 (P22). Naïve wild-type (WT) female and male mice served as additional controls. We conducted a longitudinal assessment of cochlear function by measuring ABR clicks and pure-tones thresholds, and wave-1 amplitude and latency

in all groups at P20, P35, P65, and P90. Blood collection was performed at P90 to measure sex hormones levels. The structure of cochlear-ribbon synapses will be analyzed ultrastructurally.

Results: Only sham-operated female GluA3KO mice showed reduced wave-1 amplitude at P35 compared to WT controls, confirming early-onset of hidden hearing loss. Interestingly, ovariectomized female GluA3KO mice showed wave-1 amplitudes comparable to WT mice at P35. This protection persisted through P90, though wave-1 amplitude in ovariectomized GluA3KO females remained intermediate between WT and sham KO groups. In contrast, P35 male GluA3KO mice showed no hearing deficits, and orchidectomy had no effect.

Conclusions: Our results show a potential effect of estradiol on AMPARs at inner hair cell-ribbon synapses only in females. In addition, we show that estradiol increases the vulnerability of the female GluA3KO mice to hidden hearing loss.

SU137. Novel Stella Platform Reveals Single-Molecule Dynamics of MYO7A-Driven Active Cargo Transport in Live Hair Cell Stereocilia

Takushi Miyoshi¹, Harshad Vishwasrao², Inna Belyantseva³, Junko Miyoshi¹, Mrudhula Sajeevadathan¹, Yasuko Ishibashi³, Samuel Adadey³, Narinobu Harada⁴, Hari Shroff⁵, Thomas Friedman³

¹*Southern Illinois University School of Medicine*, ²*NIBIB/NIH*, ³*NIDCD/NIH*, ⁴*Harada Ear Institute*, ⁵*Janelia Research Campus*

Background: Unconventional myosins are motor proteins that function on the actin cytoskeleton. Genetic variants of four unconventional myosin genes, MYO3A, MYO6, MYO7A, and MYO15A, have been associated with human hereditary hearing loss. In particular, MYO7A is presumed to transport components of the mechanoelectrical transduction (MET) machinery as their “cargo” and anchor them to the actin core of stereocilia. However, the molecular mechanisms underlying myosin-driven active cargo transport in stereocilia are only partially understood. For example, it remains unclear whether MYO7A and other myosins function as a monomer like class-I myosins, a dimer like class-V myosins, or a higher-order oligomer like non-muscle class-II myosins. To fill this knowledge gap, we established a novel single-molecule imaging platform, STELLA (Single-Molecule Tracking and Enhanced Localization in Live Aural specimens), and investigated how MYO7A molecules traffic within stereocilia of live murine hair cells (Miyoshi et al., *Nature Communications*, 2025).

Methods: STELLA is currently built on a diSPIM light-sheet microscope (STELLA-diSPIM). Utricles and saccules were harvested from C57BL/6J mouse neonates at postnatal day 2–5 and cultured on a collagen matrix. MYO7A fragments fused with an N-terminal HaloTag were expressed in hair cells via Helios® gene gun transfection. HaloTag was fluorescently labeled with JFX554-ligands, which are brighter and more stable than fluorescent proteins, and visualized with a 561-nm laser light sheet. MYO7A motor activity was activated by several approaches, including chemical dimerization using the FKBP-AP20187 system, missense mutations destabilizing its autoinhibitory conformation, and tethering to the plasma membrane or actin filaments via the FKBP-FRB-Rapalog system.

Results: Under STELLA-diSPIM, MYO7A exhibited processive movement toward stereocilia tips when (1) chemically dimerized and (2) constitutively activated by missense mutations

disrupting its tail-mediated autoinhibitory mechanism. Velocity was 101 ± 53 nm/s ($n = 42$, mean $\pm$ SD) for dimers and 73 ± 47 nm/s ($n = 18$) for activated mutants, which were similar by Student's t-test. Wild-type MYO7A did not show directional motility at a detectable frequency. These results suggest that MYO7A traffics as a dimer within stereocilia when released from the autoinhibitory conformation. Cargo proteins of MYO7A, particularly SANS and harmonin (USH1C), may mediate this activation. MYO7A appears to exhibit stepwise motility when its tail is tethered to actin filaments via harmonin b fragments, which may represent how tip links adjust position and tension in mature stereocilia.

Conclusions: Through STELLA microscopy, we established real-time dynamics analysis of protein molecules within live hair cells. Such methods will remain essential tools in hearing research, as the intracellular environment of inner ear hair cells is not easily reconstituted. STELLA can also be used to functionally evaluate and reclassify genetic variants of uncertain significance (VUS), particularly to identify those with hidden pathogenicity that may mislead clinical decision-making.

SU138. FOXO3 Protects Hearing in Mice by Maintaining Outer Hair Cell Mitochondrial Function

Patricia White*¹, Daxiang Na¹, Jennifer Becker², Holly Beaulac¹, Dorota Piekan-Przybylska¹

¹*University of Rochester Medical Center*, ²*University of Rochester Medical Center, Genomics Resource Center*

Background: Noise induced hearing loss (NIHL) affects around 40 million adults in the United States, but little is known about genetic susceptibility to NIHL. FOXO3 is a conserved transcription factor with some genetic variants that are strongly linked to human longevity. We have previously found that homozygous Foxo3 knockout mice (Foxo3-KO) are more susceptible to noise damage than their wild-type littermates. Among other issues, outer hair cells (OHCs) in Foxo3-KO mice appear primed to die in response to a mild noise exposure. Here we compare the transcriptome of undamaged OHCs from wild-type and Foxo3-KO adult mice, in order to identify some of the mechanisms for this damage susceptibility.

Methods: A mouse line was created that harbored both the inducible CRE recombinase under control of the Slc26a5 (Prestin) promoter and the HA-tagged RPL22 (Ribotag) protein, which is incorporated into translating polyribosomes. These mice were bred to the Foxo3-KO line to obtain mice with one allele of Slc26a5-iCRE, one or two alleles of RPL22(HA), and either two wild-type or two knockout alleles of Foxo3. Mice were injected with tamoxifen to enable expression of RPL22(HA) in outer hair cells, which was validated by immunostaining. Immunoprecipitation was used to enrich for HA+ ribosomes from both wild-type and Foxo3-KO tissues. RNA samples were reverse-transcribed into cDNA and sequenced. Sequencing validation was performed with qPCR. Gene ontology terms were identified using R Studio. Adult OHC mitochondria were assessed using immunofluorescence, confocal microscopy, and blinded analysis in Imaris. OHCs in live preparations of organ of Corti from both genotypes were visualized with MitoTracker Green. Mitochondrial membrane potential was assessed with tetramethylrhodamine, calcium levels with rhodamine-2 AM, and superoxide levels with MitoSox.

Results: OHC expression of HA-tagged RPL22 was validated in in tamoxifen-injected littermates. Selected differentially expressed genes (DEGs) were validated by qPCR. Gene ontology analysis suggested that many terms associated with energy production differed between the genotypes. In particular, wild-type mice expressed higher levels of genes associated with mitochondrial maintenance, including the FOXO3 target Pink1. Morphologically, individual adult Foxo3-KO OHCs displayed equal volumes of mitochondria overall compared to OHCs in wild-types. However, individual mitochondria within Foxo3-KO OHCs were significantly larger, suggesting changes in mitochondrial dynamics. The live OHC mitochondrial analyses are ongoing, and results will be presented.

Conclusions: Mitochondrial dysfunction has previously been associated with hearing loss from noise, with some reports indicating that it may also play a role in NIHL. These findings suggest that FOXO3 promotes OHC survival after noise exposure in part through maintaining mitochondrial integrity and/or function. Understanding how mitochondria are involved in OHC resilience could lead to future interventions that help protect hearing from noise damage.

SU139. The Role of O-GlcNAcylation in the Inner Ear

André Deutschmann¹, Teresa Bartling¹, Ellen Reisinger*¹

¹*University of Tuebingen Medical Center*

Background: Post-translational modifications are essential for fine-tuning protein function by altering their activity, localization, and interactions with other molecules. O-GlcNAcylation (O-GlcNAc) is a posttranslational modification present across various tissues. This modification is dynamically regulated by only two key enzymes: O-GlcNAc transferase (OGT), which adds the N-acetylglucosamine moiety, and O-GlcNAcase (OGA), which removes it, making it an attractive target for pharmacological manipulation. However, its role in inner ear physiology remains largely unexplored.

Methods: Here we investigated the role of O-GlcNAcylation in the inner ear, using electrophysiological patch-clamp measurements and immunohistochemical stainings in inner hair cells and spiral ganglion neurons in acutely isolated cochlear tissue from mice.

Results: In this study, we demonstrate for the first time the presence of O-GlcNAcylation in multiple inner ear cell types, including auditory sensory epithelial cells. Pharmacological modulation of OGT and OGA activity alters O-GlcNAcylation levels in these cells, indicating that this modification is active and regulated in the inner ear. Moreover, patch-clamp recording after the inhibition of OGT and OGA reveals alterations in voltage-gated K⁺, and Ca²⁺ channels, in inner hair cells and spiral ganglion neurons.

Conclusions: These findings suggest a potential regulatory role for O-GlcNAcylation in inner ear function and open new avenues for investigating its contribution to auditory physiology and pathology.

SU140. Further Characterization (Structural, Quantitative and Multi-Omic) of Inner Ear Mitochondria

Anna Lysakowski*¹, Team Mito¹, Steven D. Price¹, Guy Perkins²

¹*Univ. of Illinois at Chicago*, ²*University of California at San Diego*

Background: In this study, we quantified multiple aspects of mitochondrial structure in the vestibular inner ear. Our main hypothesis in this research is that mitochondria are structurally heterogeneous, depending on which hair cell (HC) type is under consideration and the specific locations of mitochondria in relation to other hair cell organelles. One such structural relationship that we have reported on previously is the polarization of mitochondrial crista junctions (CJs), openings of the internal mitochondrial membrane into the intermembrane space that is likely responsible for transport of molecules from the mitochondrial matrix out to the cytoplasm.

Methods: Inner ear vestibular tissue obtained from Long-Evans rats under an approved UIC IACUC procedure was used for electron microscope tomography. Data were processed with the IMOD (v.3.13.6) software package (Kremer et al., 1996) and serial tomograms were joined using the etomo subroutine (IMOD). Manual segmentation was done with the 3dmod subroutine (IMOD) to obtain final models. Reconstructions were visualized using 3dmod (IMOD), including its SLICER option, to track relevant features in 3 dimensions. Several IMOD drawing tools (Sculpt, Join, Warp, Interpolator) and a proximity analysis tool (Mtk) with a randomization feature, were also used. Proteomic and genomic analyses are also being performed on the 3 different size classes.

Results: Quantitative analyses were performed to test our hypothesis, including total mitochondrial counts in both types of vestibular HCs (compared to cochlear HCs), efferent boutons, and afferent calyces, counts of CJs on either side of a mitochondrion relative to other cellular organelles, analyzing polarization ratios vs distances, bioenergetic calculations of ATP production, and an Mtk proximity analysis test, using CJ randomization as a control. Results support our hypothesis of structural heterogeneity of mitochondria, as CJs are polarized toward specific organelles within the cell and appear to be non-randomly distributed. Finally, vestibular HCs have < half the number of mitochondria compared to cochlear HCs, although some are larger than cochlear mitochondria.

Conclusions: These results have functional implications for the various structural differences. CJ polarization toward organelles that use energy can transport ATP more efficiently. For example, the cuticular plate is an organelle that functions to return stereocilia rootlets back to their original position. Our results show a non-random orientation of mitochondrial crista junctions toward the cuticular plate. These structural differences may provide key information to better understand their function and to address mitochondrial deafness and dizziness disorders.

SU141. MYO3A and MYO3B Regulate Stereocilia Tip Widening via Their Kinase and Motor Domains

Xiayi Liao¹, Chun-Yu Tung¹, Benjamin Perrin*¹

¹*Indiana University - Indianapolis*

Background: The formation of stereocilia depends on tightly regulated actin dynamics and the targeted delivery of actin modulating proteins by non muscle myosins. Class III myosins, MYO3A and MYO3B, localize the actin binding proteins ESPN1 and ESPNL to stereocilia tips and contribute to stereocilia widening. Although mutations in Myo3a cause several hereditary hearing disorders, including DFNB30, the underlying pathogenic mechanisms remain poorly

understood. Both MYO3A and MYO3B possess an N terminal kinase domain that phosphorylates the motor region, thereby attenuating motor activity. In this study we dissect the distinct and overlapping contributions of MYO3A and MYO3B to hair bundle development.

Methods: We generated a series of mouse models: a Myo3a knockout, a Myo3a / Espn1 double knockout (to test whether MYO3B requires ESPN1 for tip localization), and a Myo3a knockout combined with a Myo3b allele bearing a four amino acid deletion in the N terminal kinase domain. Protein localization and hair bundle architecture were examined using high resolution Airyscan microscopy and expansion microscopy.

Results: Loss of MYO3A produced markedly elongated stereocilia throughout the cochlea, establishing its role in limiting stereociliary elongation. Although MYO3B tip localization increased in the absence of MYO3A, it offered only modest compensation; MYO3B failed to control short actin filament levels at stereocilia tips or to transport ESPN1 effectively. Strikingly, simultaneous deletion of MYO3A and ESPN1 yielded a distinct phenotype characterized by the loss of MYO3B from stereocilia tips and a sharp tapering of the tip region, indicating that MYO3 complexes specifically modulate actin incorporation along the upper shaft. Moreover, in the absence of MYO3A, the kinase deficient MYO3B mutant increased stereocilia length and altered distribution of MYO7A and EPS8L2, revealing an unexpected role for the kinase domain in regulating tip localized actin dynamics.

Conclusions: Our findings establish MYO3A as the dominant class III myosin in inner hair cells, essential for preserving normal stereociliary dimensions. The data illuminate how MYO3A mediated actin regulation shapes hair bundles and suggest mechanistic pathways by which MYO3A dysfunction contributes to DFNB30 associated deafness.

SU142. Functions of CCDC181 in Kinocilium Formation and Auditory Perception

Chang Liu*¹, Jinan Li¹, Bo Zhao¹

¹*Indiana University School of Medicine*

Background: Auditory hair cells exhibit a highly specialized ciliary architecture, consisting of a bundle of stereocilia that is responsible for the mechanotransduction and a single kinocilium that governs hair bundle polarity during development. In murine cochlear hair cells, the kinocilium appears during embryonic development alongside the formation of stereocilia bundles, and it degenerates by around postnatal day 12 as the stereocilia mature. Despite this well-defined developmental timeline, the molecular mechanisms governing kinocilium formation and subsequent degeneration remain largely unknown.

Methods: immunohistochemical staining, ABR, SEM, knockout mouse

Results: Through immunohistochemical staining, we found that CCDC181, a microtubule-binding protein, is abundantly expressed in the postnatal cochlear hair cells and specifically localized to the kinocilium. To investigate its function in kinocilium development, we generated a Ccdc181 knockout mouse. Hair cell morphology was characterized by using immunostaining and electron microscopy, and auditory function was then evaluated by measuring auditory brainstem responses.

Conclusions: Our preliminary data suggest that ablation of CCDC181 has minimal effects on kinocilium formation, hair cell polarity, or auditory function in mice.

SU143. Characterizing the Mechanosensitive Recruitment and Protein Partners of Hair Cell Repair Protein XIRP2

Alyssa Luz-Ricca*¹, Elizabeth Wagner¹, Cara Barnett², Stefano Sala², Patrick Oakes², Jung-Bum Shin¹

¹*University of Virginia School of Medicine*, ²*Loyola University Chicago*

Background: Hearing depends on the precise function of auditory hair cells, whose actin-based stereocilia deflect in response to sound to activate mechanotransduction channels. Hair cell death and damage to hair cell structures, such as stereocilia, can contribute to hearing loss. Therefore, understanding endogenous repair mechanisms is crucial for developing therapeutic targets for progressive hearing loss. Our lab previously found that noise exposure induces F-actin damage in stereocilia that is subsequently repaired, suggesting an endogenous repair process. A critical question remains: how do hair cells sense and repair F-actin damage, and how does this process prevent hearing loss? XIRP2, an actin-associated protein enriched in stereocilia, accumulates at damage sites, and Xirp2 knockout mice show impaired hair cell repair and progressive hearing loss. I hypothesize that XIRP2 is a key player in the hair cell actin repair process, working in concert with other stereocilia proteins that we aim to identify using proteomic approaches.

Methods: To investigate XIRP2's role in actin repair, we used two complementary approaches. First, we employed an in vitro model of actin damage to identify which domain of XIRP2 mediates its recruitment to F-actin lesions. We used laser photoablation to induce localized strain sites in stress fibers of fibroblast cells transfected with full-length or truncated XIRP2 constructs. Recruitment indices of each construct were compared to assess mechanosensitivity.

Second, to identify other proteins involved in hair cell repair, we developed a proximity labeling strategy in vivo. We generated a TurboID-XIRP2 knock-in mouse model, enabling biotinylation of proteins near XIRP2 in the context of F-actin damage. These proteins were then isolated and analyzed by mass spectrometry to define potential XIRP2 interactors.

Results: Our in vitro experiments indicate that XIRP2 is recruited to damaged actin in a force-dependent manner, and we have mapped the minimal mechanosensitive domain responsible for this recruitment. We also verified normal expression and localization of XIRP2 in the TurboID knock-in model. Mass spectrometry analyses identified candidate interactors that may participate in actin repair.

Conclusions: XIRP2's recruitment to actin damage requires its minimal mechanosensitive domain. Using our TurboID-XIRP2 knock-in strategy, we created and validated a new proximity labeling approach in auditory hair cells. This platform not only revealed candidate proteins involved in stereocilia repair but also establishes a broadly applicable method for studying protein interactions in the inner ear. By expanding the toolkit for proteomics in hair cells, this work provides new opportunities to uncover pathways that could be involved in progressive hearing loss.

SU144. Mechanoelectrical Transduction in Cnidarians Nematocytes and the Evolutionary Origin of Vertebrate Hair Cells

Zeeshan Banday¹, Zhen Tong¹, Emily Watto¹, Jamie Havrilak², Michael Layden², Jocelyn Malamy¹, Eduardo Perozo*¹

¹*University of Chicago*, ²*Lehigh University*

Background: The conversion of mechanical stimuli to electrical signals is of fundamental importance in many physiological responses, including auditory and vestibular functions in vertebrates, and a host of sensory functions in invertebrates. Vertebrate inner ear hair cells contain a mechanoelectrical transduction (MET) complex located at the tips of stereocilia. Transmembrane Channel-like 1 and 2 (TMC-1/2) proteins in complex with have been suggested as the key mechanosensitive channel in this complex. Biochemical and structural characterization of the MET complex in vertebrate hair cells has been, and continues to be a major challenge.

Methods: We pursued morphological pharmacological, functional, bioinformatic and reverse genetic approaches to evaluate the evolutionary relationship between the cnidarian nematocyte and vertebrate hair cells.

Results: Here, we present new evidence pointing to a relationship between the vertebrate hair cell and the Cnidarian stereocilia-containing hair cells, which include nematocytes and other sensory ectodermal cells. Single cell differential transcriptomics together with targeted knock down of candidate mechanosensitive molecules, directly point to members of the TMC family of ion channels/scramblases as key participants in the generation of mechanically-evoked receptor potentials and the eversion of cnidocysts. Furthermore, dependence on extracellular Ca²⁺, pharmacological susceptibility to ototoxic aminoglycoside antibiotics and the spontaneous accumulation of the water-soluble styrene fluorophore FM1-43 also support an evolutionary relation between a putative MET complex in nematocytes and its equivalent in vertebrate hair cells.

Conclusions: Our computational, biochemical, and genetic studies corroborate a direct link to vertebrate hair cells and point to evolutionarily conserved mechanotransduction mechanisms.

SU145. The Role of PCDH15-CD3 in Stability of Tip Links in Mammalian Auditory Hair Cells

Emma Bondy*¹, Abigail Dragich¹, Dooreen Mockel¹, Zubair Ahmed², Gregory Frolenkov¹

¹*University of Kentucky*, ²*University of Maryland School of Medicine*

Background: Sound detection is initiated by deflection of stereocilia, mechanosensitive projections at the apex of auditory hair cells. Stereocilia are arranged in rows of increasing heights and interconnected by extracellular tip links that convey forces to the mechano-electrical transduction (MET) channels. Tip links are formed by cadherin-23 (CDH23) and protocadherin-15 (PCDH15), at the upper and lower ends of a tip link, respectively. Mutations in genes encoding these proteins result in deafness. Hair cells express only one isoform of CDH23 but multiple isoforms of PCDH15, grouped into three classes (CD1, CD2, and CD3). Though both PCDH15-CD3 and PCDH15-CD2 are localized at the tips of stereocilia, only PCDH15-CD3 is

localized exclusively at the tips of transducing 2nd and 3rd row stereocilia within a hair bundle, suggesting the PCDH15-CD3 is the isoform class forming tips links. Yet, *Pcdh15-CD3*^{-/-} mice have normal hearing thresholds and overexpress PCDH15-CD2, indicating potential compensation by CD2. Further, disruption of tip links with Ca²⁺-free extracellular media results in the disappearance of PCDH15-CD3 immunolabeling, while PCDH15-CD2 immunolabeling is still present. We hypothesize that tip links of *Pcdh15-CD3*^{-/-} mice may have different stability and recovery after disruption.

Methods: We generated a novel mouse strain lacking only CD3 isoform of *Pcdh15* (*Pcdh15-CD3*^{-/-}). To study the role of CD3 isoform in tip link breakage and regeneration, we incubated organ of Corti explants (from *Pcdh15-CD3*^{-/-}, *Pcdh15-CD3*^{+/-}, and *Pcdh15-CD3*^{+/+} mice) in Ca²⁺-free medium (supplemented with 5 mM of BAPTA) for one minute to break the tip links and then followed tip link recovery in regular Ca²⁺-containing media at 0, 3, 6, 9, and 12 hours after breakage using high-resolution scanning electron microscopy (SEM). Control samples were incubated in regular Ca²⁺-containing HBSS (1.26 mM of Ca²⁺) and the tip links were visualized by SEM and counted at the same time points after incubation.

Results: 1) Shorter incubation in Ca²⁺-free medium supplemented with BAPTA (one minute instead of 15 minutes used previously) results in effective disruption of at least 80% of the tip links in wildtype inner hair cells but followed by a faster tip link recovery. 2) Tip links in *Pcdh15-CD3*^{-/-} hair cells recover more slowly after disruption. 3) Most strikingly, more tip links (up to 40%) are present in *Pcdh15-CD3*^{-/-} inner hair cells immediately after disruption with BAPTA and many of them appear to be shorter than normal.

Conclusions: So far, our data argues that the CD3 isoform is compensated by PCDH15-CD2 in *Pcdh15-CD3*^{-/-} hair cells, and these tip links are more resilient to disruption. The shorter length of these tip links also indicates that temporary homomeric PCDH15-PCDH15 links could be present due to overexpression of PCDH15-CD2.

SU146. Persistent Remodeling of Hair Cell Mitochondrial Networks in Response to Low Dose Cisplatin Exposure

Elayna Malak*¹, Josef Trapani², Lavinia Sheets¹

¹*Washington University Medical School*, ²*Amherst College*

Background: Cisplatin is a widely used chemotherapeutic agent with broad efficacy. However, its clinical utility is limited by dose-dependent toxicities, including ototoxicity that can lead to permanent hearing loss.

While high-dose cisplatin-induced hair cell apoptosis has been well characterized, the cellular effects of clinically relevant, sub-lethal doses remain poorly understood. Notably, some patients experience delayed-onset, progressive hearing loss after treatment, suggesting that surviving hair cells may undergo lasting subcellular stress. Mitochondria have been identified as early and critical targets of cisplatin-induced death in hair cells (Lee, 2024), yet how mitochondrial structure and function respond to low dose, non-lethal exposure has not been fully explored.

In this study, we used a zebrafish model to investigate the effects of low dose cisplatin exposure on hair cell mitochondria. We assessed mitochondrial morphology, calcium dynamics, and membrane potential as indicators of early dysfunction, to better understand low dose cisplatin-induced hair cell injury and identify potential mechanisms of vulnerability and repair.

Methods: Transgenic zebrafish larvae expressing a mitochondrial calcium indicator in hair cells (Tg(myo6b:mitoGCaMP)) were exposed to (30 μ M, 100 μ M, 300 μ M, 1 mM) cisplatin for 2 hours, followed by (0, 6, 24, 48, 72) hour recovery. Larvae were then fixed in paraformaldehyde and imaged using super-resolution confocal microscopy. Mitochondrial morphology was quantified using 3D image analysis. Ongoing studies include live imaging of mitochondrial membrane potential with TMRE and time-lapse super-resolution microscopy to assess dynamic mitochondrial remodeling. Functional consequences are being evaluated using a microflume-based rheotaxis assay to detect subtle deficits in hair cell-mediated behavior.

Results: Low dose cisplatin exposure induced significant changes in mitochondrial morphology in neuromast hair cells, even in the absence of overt hair cell loss. Our data revealed time and dose dependent changes in morphology features (count, branch length, branch junctions, sphericity) associated with mitochondrial network complexity. Notably, we observed the formation of toroidal (“donut”) mitochondria, which increased in frequency with higher cisplatin doses and persisted through the recovery period. Our data also suggests mitochondrial calcium dysregulation and loss of mitochondrial membrane potential. These changes were dose-dependent and evolved throughout the recovery period, with distinct morphological and functional trajectories observed at different concentrations.

Conclusions: Our findings show even clinically relevant, low dose, cisplatin causes persistent disruption of hair cell mitochondrial morphology and functionality. The persistence of mitochondrial morphological abnormalities supports a model in which hair cells experience chronic subcellular stress, potentially priming them for later vulnerability to additional insults, such as noise or aging. These insights lay the groundwork for developing targeted strategies to preserve hearing in patients undergoing cisplatin chemotherapy.

SU147. Live Imaging of Presynaptic Ribbons in the Aging Mouse Cochlea

Peu Santra¹, Ian R. Matthews¹, Sanyukta Oak¹, Dylan Chan¹, SANYUKTA OAK*¹

¹*University of California, San Francisco*

Background: Ribbon synapses in inner hair cells (IHCs) mediate rapid and precise neurotransmission to spiral ganglion neurons (SGNs), enabling accurate auditory signaling. With advancing age, both humans and mice experience synaptic alterations that contribute to hearing impairment. However, the cellular mechanisms underlying age-related synaptic decline remain poorly defined. Direct observation of presynaptic ribbon behavior across the lifespan may clarify how synaptic architecture changes with aging.

Methods: We used RIBEYE-tagRFP mice to visualize presynaptic ribbons in cochlear explants at three age groups: 3–4 months, 6 months, and 17–18 months. Whole-mount preparations were imaged with a Nikon A1R confocal microscope equipped with a 60 $\times$ water immersion objective. Confocal z-stacks spanning the IHC region were acquired, and RIBEYE puncta were analyzed using Imaris for number, size, and motility parameters. Group comparisons were made across age cohorts to identify trends in ribbon morphology and dynamics.

Results: Age was associated with progressive changes in presynaptic ribbon architecture. The total number of RIBEYE puncta decreased from young adult (3–4 months) to middle-aged (6 months) and further into aged (17–18 months) cochleae. In parallel, the average puncta size increased with age, suggesting enlargement or aggregation of remaining ribbons. Despite these morphological changes, ribbon motility, as assessed by speed of movement, remained similar across all three age groups. These findings indicate that while the structural landscape of synapses is altered during aging, the intrinsic dynamic properties of ribbon mobility are preserved.

Conclusions: This study demonstrates an age-dependent decline in ribbon number accompanied by enlargement of surviving puncta, consistent with synaptic remodeling in the aging cochlea. The preserved motility of ribbons across ages suggests that dynamic capacity for movement is maintained, even as synapse density diminishes. These data support a model in which aging preferentially affects ribbon abundance and morphology, rather than mobility. Ongoing work incorporating auditory brainstem response (ABR) measurements will link these synaptic changes to hearing function. Together, these findings highlight presynaptic ribbon remodeling as a potential contributor to age-related auditory decline and establish live imaging of RIBEYE-tagRFP cochleae as a powerful tool for studying mechanisms of synaptic aging.

SU148. Rapid Peri/Post-Mortem Technique for Harvesting and Dissecting Human Temporal Bones That Circumvents Extended Decalcification

Yassine Bahli¹, Zahra Sayyid¹, Hakim Hiel¹, Mohamed Lehar¹, George Liu¹, Julie Winston¹, Bryan Ward¹, Adam Kaufman², Amanda Lauer*¹

¹*Johns Hopkins University*, ²*University of Maryland Baltimore*

Background: The otic capsule, the densest bone in the body, encases the inner ear structures the cochlea, vestibule, and semicircular canals. Postmortem temporal bone processing typically requires slow fixation and prolonged decalcification taking weeks to months, which can compromise molecular integrity. Here, we present a novel method for rapid fixation and whole-mount dissection of the human cochlea and vestibular end-organs harvested peri/postmortem from human organ donors. This approach minimizes decalcification time, preserves the tissue's structural integrity, facilitates rapid histological analysis, and enables future proteomic and multi-omic studies.

Methods: We have developed an efficient workflow, in collaboration with the federally designated organ recovery organization for Maryland, Virginia, and Washington, DC to harvest temporal bones from organ donors within a very short peri/post-mortem interval of 1 to 2 hours. Using an extracranial approach with a bone plug autopsy saw, specimens were collected and fixed in 10% formalin after disarticulating the stapes footplate. The preparation was subsequently trimmed using a surgical drill in two stages: first, the bone plug was reduced to the otic capsule; second, the various neurosensory tissues were collected, beginning with the vestibular organs (the three cristae, utricle, and saccule) and concluding with delicate drilling around the cochlear capsule, followed by dislocation of the cochlear sensory epithelium from the modiolus. A brief 24-hour decalcification in 14% EDTA was then performed to decalcify the spiral laminae and otoconia.

Results: Whole-mount cochlea with minimal mechanical damage was obtained, as well as round window membrane, ossicles, and spiral ganglion neurons from the Rosenthal canal. In addition, all five vestibular organs—the lateral, anterior, and posterior cristae, the utricle, and the saccule—were harvested. These structures were imaged under light microscopy generating a unique image library of human inner ear structures and nerve fibers. The resulting tissue is suitable for histology, immunostaining, and multi-omics analysis.

Conclusions: This method enables successful harvest of intact cochlear and vestibular organs within hours of death, eliminating the need for extended decalcification, and preserving tissues for histology and multi-omic analyses. This represents a significant advance for human inner ear research.

SU149. Anatomical Integrity of the Human Organ of Corti Visualized Using Paired Optical Coherence Tomography and Histology

Paul Secchia^{*1}, Ephraim Oyetunji¹, Aleksandrs Zosuls¹, Yew Song Cheng², Anbuselvan Dharmarajan¹, Jennifer O'Malley¹, MengYu Zhu¹, Sunil Puria¹, Andreas Eckhard¹, Hideko Heidi Nakajima¹

¹Harvard Medical School, Massachusetts Eye and Ear, ²UCSF

Background: Human cochlear microstructures are delicate and hard to access, making it difficult to noninvasively image intracochlear anatomy and pathology. Towards this need, optical coherence tomography (OCT) has been proposed to visualize OoC structures in situ in fresh human cochleae through the intact round window membrane (RWM). However, granular OCT images cannot reliably identify the distinct cell types that make up the OoC. To more confidently interpret OCT images, we analyzed histology obtained from the same donor for direct comparison between OCT features and histologic structure.

Methods: Pairs of fresh temporal bones (4-24 hours postmortem) were obtained with IRB approval from the Mass General Hospital from donors without a history of unilateral ear disease. One ear was prepared for OCT imaging and the contralateral ear was immediately fixed. After the middle ear cavity was surgically opened to access the cochlea, OCT images were collected from unfixed cochleae through the intact RWM using a 900-nm center wavelength OCT system (Gan6201C1, Thorlabs, Germany). Time of imaging was 10-28 hours postmortem. Following imaging, both ears were histologically processed using a rapid, non-decalcifying histological processing workflow developed in our lab: whole bony specimens were fluorescently labeled and embedded in resin (Technovit 9100NEW®). Embedded blocks were oriented to align the histological sectioning plane with the OCT imaging plane using a customized disc sander. Thin (~100 µm) sections were produced with precision diamond wire saws, followed by confocal and super-resolution microscopy to visualize cochlear microstructures. OCT–histology registration was performed at matched cochlear locations, with 3D reconstructions used to confirm correspondence.

Results: OCT images and histological sections from the same cochlear location across paired human temporal bones were obtained. There was high contralateral symmetry in cochlear morphology within individuals. Direct registration enabled confident interpretation of granular OCT features; e.g., differentiating intact versus collapsed OoC architecture and recognizing

regions indicative of cell loss, all based on histologic ground truth. These comparisons establish OCT signatures for the human OoC that correspond to graded microanatomical pathology.

Conclusions: Paired OCT images and histology registered from the same donor showed similar OoC anatomy and verified our ability to accurately interpret OCT images. OoC anatomy across individuals varied, and pathological states could be differentiated. These results demonstrate the capability of OCT to non-traumatically visualize cochlear integrity through the RWM, highlighting its potential as a diagnostic tool. The ability to determine the presence of hair cells and supporting cells in live patients would enable more precise individualized assessment with potential to guide emerging therapies (e.g., gene- and regenerative approaches). In vivo OCT could assist in targeted therapies, determining anatomic barriers to local delivery such as false round-window membrane, and prevent trauma such as fractures of the osseous spiral lamina.

SU150. The Inner Ear in NF2-Related Schwannomatosis: Histological and Molecular Perspectives

Eleanor Brown^{*1}, Liyam Laraba², David B. Parkinson², Daniel J. Jagger¹

¹*University College London*, ²*University of Plymouth*

Background: NF2-SWN is a rare autosomal dominant genetic disorder characterised by bilateral vestibular schwannomas and progressive hearing loss. It results from pathogenic variants in the NF2 gene, located on chromosome 22q, which lead to loss or dysfunction of the tumour suppressor protein Merlin. Although vestibular schwannomas commonly occur as sporadic, unilateral tumours, NF2-SWN is distinguished by its inherited nature and earlier onset. While tumour compression of neural structures is well recognised, mechanisms of sensory loss beyond tumour burden remain unclear. We are currently studying archival human temporal bones (Brown et al., Hearing Research, 2025) and a mouse model to investigate inner ear pathologies in NF2-SWN.

Methods: Human temporal bone sections stained with haematoxylin and eosin were assessed for cochlear and vestibular degeneration using light microscopy (subject ages 14-65; samples held under UK Human Tissue Authority licence #12161). A conditional knockout mouse model (Postn-Cre; Nf2flox/flox; Gelhausen et al., J Neurosci, 2015) was used to examine inner ear pathology via immunofluorescence. Antibodies targeting endogenous total merlin (DS3SW, Cell Signaling Technology), Aldh1a1 (tumour marker), and Iba1 (macrophage marker) were used to identify molecular and cellular changes. Cre-negative littermates served as controls.

Results: Human samples with bilateral vestibular schwannomas showed widespread degeneration of cochlear and vestibular structures, including loss of spiral ganglion neurons and nerve fibres, disorganisation of the organ of Corti, and Schwann cell proliferation with subsequent nerve compression. Some tumours had a complex composition, with evidence of mixed schwannomas and meningiomas. In 3-month-old Postn-Cre; Nf2flox/flox mice, increased localised expression of Aldh1a1 (but without evidence of tumour growth) and increased numbers of Iba1-labelled macrophages within neural tissues possibly indicated early inflammatory and metabolic stress responses. These changes were absent in Cre-negative controls.

Conclusions: These findings suggest that hearing loss in NF2-SWN may begin with subtle, tumour-independent changes within the cochlea and auditory nerve, linking NF2 gene loss to early sensory dysfunction. Elevated Aldh1a1 expression and increased macrophage indicate that inflammatory and structural mechanisms are active prior to tumour progression. Together, these processes likely contribute to hearing loss and other symptoms. A multi-layered therapeutic approach – targeting both early, non-tumour related changes and later tumour-driven effects – may more effectively preserve hearing and improve outcomes in NF2-SWN.

SU151. Loss of Orexin 2 Receptor Signaling Exacerbates Noise-Induced Hearing Loss

John Roberson*¹, Douglas Vetter¹, Kathleen Yee¹

¹*University of Mississippi Medical Center School of Medicine*

Background: Orexins, also known as hypocretins, are neuropeptides produced by hypothalamic neurons involved in the sleep-wake cycle, food intake, and autonomic output. We discovered that orexin ligands and receptors are also expressed in the cochlea. Mutation of orexin 2 receptor (Ox2R) leads to early onset narcolepsy. Dual orexin receptor antagonist (DORA) medications are used to treat insomnia with new drugs targeting orexin signaling being tested. Given the previously unrecognized expression of orexin signaling molecules within the cochlea, constitutive loss or knock down of orexin through prolonged DORA medications could alter mechanisms underlying normal hearing sensitivity and/or resilience against damage. We begin to address this by examining hearing in constitutive Ox2R mouse mutants subjected to noise.

Methods: Ox2R wild-type (WT) and knockout (KO) mice were used to investigate the role of Ox2R in moderate noise-induced hearing loss. We used Auditory Brainstem Response (ABR) testing and anatomical assessments to analyze effects of noise on physiological and morphological integrity of the cochleae of Ox2R WT and KO mice. Half of the mice (WT and KO groups) were noise exposed (97dB SPL, 8-16kHz, 2h). ABRs were performed before noise exposure to measure baseline hearing thresholds and post-noise periodically through 21 days to track hearing threshold recovery on all mice. A second cohort of WT and KO mice, under identical conditions as the first, underwent transcardial perfusion (4% paraformaldehyde) 5 days post-noise exposure. The temporal bones of WT and KO mice were isolated, processed, cryostat-sectioned, and hematoxylin and eosin (H and E) stained. Immunohistochemistry was performed on alternate sections using primary antibodies (Ox1R, Aqp1, F4/80) and appropriate secondary antibodies. Photomicroscopy was performed (Leitz DSM and Zeiss LSM880 Confocal).

Results: Hearing thresholds of Ox2R WT noise-exposed mice recovered after 5 days post-noise while threshold shifts in Ox2R KO noise-exposed mice remained elevated and began to decline at 7 days post-noise. Ox2R WT thresholds returned close to baseline while Ox2R KO thresholds did not decline to similar levels by day 21 post noise, indicating that a noise-induced temporary threshold shift in WTs became a permanent shift in KOs. In noise-exposed KO mice, there were morphological changes (H and E) in the stria vascularis, decreased protein localization of i) Ox1R in supporting cells and ii) aquaporin 1 in the spiral ligament, and increased F4/80 localization in the spiral ligament.

Conclusions: The functional and anatomical hearing-related changes observed in our mouse model of constitutive Ox2R loss-of-function may reflect constitutive gene loss in human

narcolepsy and could mirror effects following potential long-term use of DORA medications. The effects on hearing may be predictive of patients who are using drugs long-term which alter the orexin signaling system, potentially putting them at risk for augmented hearing loss.

SU152. The Auditory-Nerve Initial-Peak (ANIP) Response to High-Level Clicks is From a Unidirectional Stereocilia Deflection Away From the Nearest Saturation of OHC Mechano-Electric Transduction

John Guinan*¹, Hui Nam²

¹*Mass. Eye and Ear*, ²*Harvard-MIT HST, Speech and Hearing Bioscience and Technology Program*

Background: The auditory-nerve initial peak (ANIP) response is a mysterious response that doesn't fit with most conceptions of how the cochlea works. It is the earliest response from moderate-to-high-level rarefaction clicks in cat auditory-nerve (AN), type-1 fibers with characteristic frequencies (CFs) < 3 kHz. It was first shown to be unusual by its strong inhibition by stimulation of medial-olivocochlear (MOC) efferents, which contrasted with the lack of MOC inhibition of the first peak of basilar membrane click responses. The MOC inhibition of ANIP indicates that the ANIP response is affected, or generated, by outer-hair-cell (OHC) motility. Consistent with this, the ANIP response was shown to be suppressed when high-level, low-frequency "bias" tones quasi-statically pushed the OHC mechano-electric transduction (MET) function into low-slope, saturating edge regions. Contrary to prior theory, our preliminary results showed that the bias-tone phase that produced the most suppression (the major-suppression phase) was opposite for ANIP responses compared to low-level click or tone responses.

Methods: In anesthetized cats, we recorded single-fiber AN responses, in response to low-level clicks, low-level tones, and ANIP-producing, higher-level clicks, with/without 50 Hz bias tones. We used new methods to exclude the AN-fiber excitation from high-level bias-tones, so that this excitation doesn't obscure bias-tone suppression of AN responses.

Results: The major suppression phases for ANIP responses were nearly opposite (~180 degrees different), compared to those of low-level clicks and tones.

Conclusions: An "ANIP-MET-asymmetry hypothesis" is consistent with the results: Low-level responses take several cycles to build up and depend on the local slope in both directions of the MET function; their major suppression phase is when the bias tone quasi-statically deflects the MET operating point to its nearest low-slope, saturation edge. In contrast, while ANIP responses oscillate for many cycles like low-level responses, ANIP is only the first half cycle and requires an OHC stereocilia deflection only in one direction. When a bias tone puts the OHC-MET operating point at its nearest saturating edge, low-level, multi-cycle responses are suppressed, but a rarefaction-click's unidirectional initial stereocilia deflection is away from this saturation, enabling a large traverse of the MET function and a large depolarizing OHC current. The ANIP major suppression arises from bias-tone deflections to the MET-function opposite saturation. Our presentation will point out that the ANIP-MET-asymmetry hypothesis fits well with the new theory that cochlear amplification of low-level responses is due to OHC motility changing the local OoC cross-sectional area at a phase that adds energy to the traveling wave in the scala media-tympani fluid. The ANIP-MET-asymmetry hypothesis also fits with low-level responses

being carried primarily by the traveling wave while ANIP is carried by a cortilymph wave, with both waves accumulating gain as they travel to the CF region.

SU153. Investigation on Organ of Corti Micro-Mechanics and Inner Hair Cell Stereocilia Stimulation Mechanisms Through 3D Finite Element Models of the Mouse Organ of Corti

Yanli Wang¹, Hamid Motallebzadeh², Sunil Puria¹

¹*Harvard Medical School, Mass. Eye and Ear*, ²*California State University*

Background: The intricate cytoarchitecture of the organ of Corti (OoC) stimulates inner hair cell (IHC) stereocilia, triggering mechano-electrical transduction (MET) channels. Recent advancements in Optical Coherent Tomography (OCT) technology allow detailed motion measurement of the tectorial membrane (TM) and reticular lamina (RL) relative to the motion of basilar membrane (BM) in both transverse and radial directions. High speed camera imaging also revealed stereocilia motion relative to RL radial direction motion. These experimental data enable modeling effort to capture and explain OoC micro-mechanics, but most modeling effort still lack such details. A slice modeling technique using a 3D Finite Element Model (FEM) for a cochlea with Floquet boundary conditions meets the required details with reasonable computational cost (Wang and Puria, 2025, HR).

Methods: A 3D Finite Element Model (FEM) of a slice of the mouse OoC of the apex was built. The cellular structure of the OoC is reconstructed based on 2-photon measurements on fresh tissue (Soons et al. 2015), as well as Scanning Electron Microscopy and histology slices on fixed tissues (Davies and Forge 1987, Taylor et al. 2012). The model captures the realistic representation of the Deiter cells, Outer Hair Cells (OHCs), IHCs, inner and outer pillar cells, Hensen cells, as well as the fluid space of the inner sulcus, tectorial membrane, and the cortilymph consisting of the inner tunnel of Corti, the space of Nuel, and the outer tunnel. It includes the longitudinal inclination of the outer hair cells, Deiter cells, phalangeal processes and the outer pillar cells resulting in the mosaic pattern of the reticular lamina. The material properties were determined using Machine Learning algorithm to fit experiment data on mouse apex (Lee et al. 2016).

Results: The slice model was able to fit the experimental data of the passive postmortem measurements with reasonable tolerance. The TM and RL motion relative to BM motion were observed. Besides being able to fit the data, we are also able to identify the contribution of the stiffness of each structure, such as TM and RL, on the micro-mechanical motion of the OoC. For example, the stiffness of the OHCs and pillar cells have more significant effect on the motion of the RL than RL stiffness itself. The relationship of the stereocilia motion and its surrounding fluid motion are observed. The two key hypotheses that the model tests are: 1) whether the IHC stereocilia are stimulated by inner sulcus fluid, and 2) the effect of stimulation mode on frequency.

Conclusions: FEM slice cochlear model is a powerful tool to study cochlear OoC micro-mechanics and test IHC stereocilia stimulation mechanism hypotheses. Work supported by R01 DC007910 and R21 DC022922 from the NIDCD of NIH.

SU154. Outer Tunnel Vibration Within the Cochlear Partition of the Basal Turn in Sensitive Gerbil Cochleae

Wenxuan He¹, Tianying Ren^{*1}

¹*Oregon Health Science University*

Background: The outer tunnel is the largest fluid-filled space within the auditory sensory organ, the organ of Corti, in the basal turn of the gerbil cochlea. It consists of motile outer hair cells, the soma and the phalangeal processes of the Deiters' cells. The phalangeal processes connect the somatic cupula of the Deiters' cells to the cuticular plate of the outer hair cells, forming part of the reticular lamina. Despite its structural prominence, the functional role of the outer tunnel in cochlear mechanics remains poorly understood.

Methods: Young Mongolian gerbils of either sex with normal hearing were used in this experiment. The bulla on the left side was opened through a ventrolateral surgical approach. After the stapedial artery was removed from the bony surface of the cochlea, an opening was made in the lateral wall of the scala tympani of the basal turn. When the cochlear partition was positioned approximately in the horizontal plane, the magnitude and phase patterns of the vibrations were measured at the best frequency and frequencies more than one octave below the best frequency from the cross-sections of the outer tunnel and the cochlear partition using a scanning heterodyne low-coherence interferometer.

Results: At the best frequency, all structures of the outer tunnel and the cochlear partition moved coherently in the same direction, with the greatest displacement observed at the top of the outer hair cells. As the sound pressure level increased, the vibration peak extended to other structures, particularly the basilar membrane.

At low frequencies, however, the reticular lamina at the apical end of the outer hair cells and the somatic region of the Deiters' cells moved in approximately opposite directions. Additionally, the top and bottom of the outer tunnel exhibited antiphase motions.

Conclusions: These results suggest that the organ of Corti's response at low frequencies reflects localized, outer hair cell-driven motion, while the response at the best frequency is dominated by amplified traveling waves that mask local cellular activity. When sound-induced length change in outer hair cell alters the outer tunnel's circumference of the outer tunnel, they generate fluid pressure oscillations within the tunnel. Due to the incompressibility of cochlear fluid and the forward-propagating traveling wave, these pressure oscillations in the outer tunnel and other fluid spaces produce longitudinal fluid motion within the cochlear partition. This fluid motion, in turn, enhances the traveling wave, thereby increasing cochlear sensitivity.

SU155. Cochlear Fluid Flow Driven by Active Outer Hair Cells

Choongheon Lee¹, Mohammad Shokrian¹, Kenneth Henry¹, Laurel H. Carney¹, J. Chris Holt¹, Jong-Hoon Nam^{*1}

¹*University of Rochester*

Background: Fluids in the inner ear are considered stationary because the inner ear fluid system is nearly isolated from other body fluid systems, such as the cerebrospinal fluid and the blood.

Two lymphatic fluids fill three tube-like cavities in the cochlea. The fourth fluid-filled cavity along the tunnel of Corti is unique to mammals (non-mammalian sensory epithelia do not have such an ample extracellular fluid space). Recent studies have shown that the organ of Corti is 3-dimensionally deformed by active outer hair cells, resulting in a change in the cross-sectional area of its fluid-filled space. We hypothesized that active outer hair cells can induce cochlear fluid circulation.

Methods: Experiment) An excitotoxic drug (10 mM kainic acid) that affects afferent synaptic terminals was delivered to the intact round window of young gerbils. A multi-channel electrode placed at the anteroventral cochlear nucleus measured neural signals while the drug diffused along the cochlea. During the drug delivery, sounds at different levels and frequencies were played. Model simulations) The computational model incorporates structural mechanics, hair cell physiology, and fluid dynamics. Three layers of fluid mechanics were essential to this study: interaction between the scala fluid and the cochlear partition, interaction between the Corti fluid, the organ of Corti and active outer hair cells, and advection-diffusion in the scala and Corti fluids.

Results: Sounds affected cochlear drug delivery. At 50 dB SPL, playing sounds had a minimal effect on the drug's effect time. Between 60 and 80 dB SPL, as the sound level increased, the effect time got shorter. Lower frequency was more effective in facilitating drug delivery. At locations apical to the CF location of sounds, often the delivery took equal or longer time when played loud sounds (< 75 dB SPL). Computer model simulations could explain experimental observations such as the accelerating region (located basal to the CF location of sounds) and the transport barrier (near the CF location).

Conclusions: Our measurements and model simulations show that: 1) Active outer hair cells can drive fluid circulation in the cochlea; 2) Two routes construct the fluid circulation: flux toward the apex along the tunnel of Corti and flux toward the base along the scala tympani; 3) A pure tone stimulus generates an accelerated transport region and a transport barrier.

Supported by NIH NIDCD R01 DC020150.

SU156. Electrically Evoked Displacements of Outer Hair Cells in the Fresh Cadaveric Human Cochlea

Aleksandrs Zosuls^{*1}, Paul Secchia², Sunil Puria², Hideko Heidi Nakajima²

¹*Mass Eye and Ear, Boston University*, ²*Harvard Medical School, Mass. Eye and Ear Infirmary*

Background: Prestin, a protein crucial for cochlear hair cell electromotility, has been detected using immunohistochemistry in the lateral cell membrane of outer hair cells (OHCs) in human cadaver cochlear tissue, suggesting its structural preservation even postmortem (Rask-Andersen et al., 2010). Little is known about the human organ of Corti (OoC) displacement generated by the electromotile forces from the OHCs.

Methods: Optical coherence tomography (OCT) was used to image and measure vibrations of the cochlear partition (CP) in the apical region of fresh (< 28 hours postmortem) cadaveric human cochleae in response to acoustic stimulation and electrical stimulation. In all cases, the scala vestibuli was fenestrated for OCT and electrode access. The cochlea was immersed and maintained in chilled artificial perilymph media during preparation and measurements.

Acoustical stimulation was performed with an ear canal probe tube speaker. In one case, the incudostapedial joint was disarticulated and a piezoelectric stack was used to drive the stapes. Electrical stimulation was performed by inserting a glass pipette with a 70 μ m diameter tip into the scala media. The return electrode was placed in the dish. Discrete sinusoidal signals over a range of 100 Hz to 20 kHz were used as a stimulus and the OCT measured displacement response of structures within the CP.

Results: Acoustical stimulation OCT vibrometry results indicated CP tuning of approximately 250 Hz in two preparations that were also subject to electrical stimulation. The electrical stimulation frequency response was more broadly tuned, showing a higher frequency cutoff than the acoustic. With acoustic stimulation, the CP structures moved in phase. With electrical stimulation, out of phase displacement between the basilar membrane and reticular lamina was seen only along the axis of the outer hair cells and Deiters' cells. This suggests that the outer hair cell force effect was activated and localized to the OHCs and Deiters' cells axis. These results are consistent with previously reported measurements in animals (Strimbu et al., 2022, Puria et al., 2025).

Conclusions: Prestin's normal electromotile function requires membrane potential, which is absent postmortem. To overcome this limitation, we introduced a scala media electrical probe, which generated an extracellular potential that partially restores OHC motility in our human cadaver preparation and measured with high resolution OCT.

SU157. Immediate Post-Noise and Short-Time Systemic Elevation of Progesterone Promotes Recovery of Cochlear Synapses From Noise-Induced Synaptopathy in Mice

Ning Hu^{*1}, Steven Green¹

¹*University of Iowa*

Background: Female mice are generally less susceptible than males to noise-induced cochlear synaptopathy (NICS). Remarkably, susceptibility to NICS in females varies through the estrous cycle. Females exposed to noise in the luteal phase (metestrus and diestrus) exhibit reduced synapse loss, while females exposed to noise in the follicular phase (proestrus and estrus) exhibit synapse loss like that in noise-exposed males (Hu et al, ARO-Meeting-2017). Reduced susceptibility to NICS correlates with elevated systemic progesterone (P4) levels, the dominant hormone in the luteal phase, but not with estrogen (E2), the dominant hormone in the follicular phase. To test the hypothesis that P4 could protect against NICS or facilitate recovery from NICSs, P4 was chronically administered via an implanted pellet or acutely administered via subcutaneous injections at various times, pre-noise or post-noise, in CBA/CaJ mice.

Methods: 12-14-week-old males or ovariectomized (OvX) females were exposed to 100 dB SPL, 8-16 kHz octave band noise for 2 hours. Auditory brainstem response (ABR) and DPOAEs were measured at 8, 16, and 32 kHz at three times: pre-noise, post-noise day 1 (PND1), and PND14 to assess baseline thresholds, temporary threshold shifts, and recoveries in a within-subject design. For chronic administration, a P4-pellet (P4P) was implanted subcutaneously, with ABRs measured pre- and post-implantation/pre-noise. For acute administration, water-soluble P4 (P4W) or P4 in sesame oil (P4O) was injected 2-hr pre-noise and/or immediately pre-noise (PrN2, PrN0), and/or immediately or 2-hr post-noise (PN0, PN2). Changes in ABR wave-I

amplitudes at PND14 were quantified as amplitude decline relative to pre-noise. To quantify synapses/inner hair cell, postsynaptic densities, presynaptic ribbons, and hair cells were visualized using anti-PSD95, anti-Ribeye/CTBP2 and anti-myosin antibodies, respectively, in organ of Corti wholemounts at 8, 16, and 32 kHz locations in mice euthanized at PND14.

Results: In P4P OvX females, pre-noise ABR wave-I amplitudes were slightly reduced. Recovery of amplitude on PND14 was not significantly better than nonimplanted controls; synapse counts remained lower than in non-noise exposed controls although slightly higher than nonimplanted controls. In acute P4W or P4O groups, post-noise recovery of ABR amplitudes and synapse numbers were better than the saline control, with no difference between males and OvX females. In both males and OvX females, P4O administered at PN0-only showed similar results to P4O at pre- plus post-noise and better recovery than PrN-only in amplitude recoveries and synapse counts. We did observe increased risk of PTS associated with P4 administration.

Conclusions: P4 ameliorates NICS assessed by ABR amplitude and synapse counts. This appears to be due primarily to facilitating post-noise recovery rather than protection during noise. Chronic P4 delivered from an implanted pellet provides relatively little recovery from NICS relative to acutely-delivered P4 administered by injection following noise exposure. (Supported by NIDCD R01 DC015790)

SU158. Transient Transfection of Fibroblasts to Produce Bdnf on the Surface of Cochlear Implants

Lukas Lübbersmeyer¹, Kirsten Wissel¹, Thomas Eickner², Andrea Hoffmann¹, Thomas Lenarz¹, Gerrit Paasche*¹

¹Hannover Medical School, ²IBMT Rostock University

Background: After cochlear implantation, connective tissue is formed around the implanted electrode array. Despite many different efforts to reduce connective tissue formation, some cells will always remain on the electrode surface. Furthermore, the function of a cochlear implant (CI) is relying on the presence of intact spiral ganglion neurons (SGN). Survival of SGN can be supported by the application of neurotrophic factors such as brain-derived neurotrophic factor (BDNF). The aim of our approach is to modify existing fibroblasts on the surface of a CI electrode array to produce and deliver BDNF. This production on the electrode surface could also provide a directional cue in case new neurites are formed by SGN.

Methods: Two recombinant vectors coding for td-Tomato and BDNF (5.6 and 8.8 kbp) were used to transfect NIH/3T3 cells. The plasmids were complexed using different amounts of branched 25 kDa polyethyleneimine (PEI). Complex formation (size and surface charge) was investigated using a zetasizer for different ratios of PEI and DNA. The substances alone as well as the complexes were tested regarding cytocompatibility using cell viability tests. For transfection, the cells were incubated with the complexes for 3 hours before further cultivation. Transfection efficiency was determined 24 hours after starting the incubation by comparing cells exhibiting red fluorescence to the total number of cells.

Results: Complexes between DNA and PEI were successfully formed. Up to an amount of PEI of 1000 ng per well, the complexes appeared to be cytocompatible. Transfection efficacy at 24 hours after start of the incubation was below 1% for the large vector and close to 10% with the

smaller vector with the highest values for equal amounts of DNA and PEI in the solution. The complexes could be incorporated into polymeric coating that can be used for cochlear implant electrode arrays.

Conclusions: With the smaller vector, a system to transfect fibroblasts to produce and deliver BDNF is available that can potentially be combined with CI electrodes. This system can now be used to investigate further questions such as release from the coating, duration of transfection etc.

SU159. Clustering Analysis Reveals Distinct Macrophage Phenotypes Following Excitotoxic Injury in the Zebrafish Lateral Line

Prithwijit Roychowdhury¹, Mark Warchol¹, Lavinia Sheets¹

¹*Washington University School of Medicine*

Background: Macrophages exhibit diverse morphological and motile features that reflect distinct responses to cochlear injury and subsequent synaptic repair. Recent studies in mice demonstrate that macrophages are recruited to the cochlea after moderate-intensity noise exposure, but the dynamic transitions between macrophage states during excitotoxic injury remain poorly understood. Real-time visualization of macrophage-synapse interactions in the intact mammalian inner ear is challenging, but the zebrafish lateral line provides a powerful model to enable fluorescent labeling and time-lapse imaging of macrophage behavior in vivo. Here, we employed live imaging and unsupervised clustering of macrophage tracks and features to identify and characterize discrete macrophage phenotypes following excitotoxic injury.

Methods: 6-7 day old transgenic zebrafish expressing a red fluorophore in macrophages (tg(mpeg1:tdtom)) and either GFP in afferent neurons (tg(neurod:GFP)) or a cytosolic targeted Ca²⁺ indicator (tg(hsp70:GCaMP6s:sill1)) were imaged with a spinning disc confocal microscope. Fish were paralyzed with α -bungarotoxin and mounted in an imaging chamber before visualizing the neuromast hair cells and afferent neurons. After obtaining baseline images, fish were exposed to 100-300 μ M AMPA for 15-30 minutes to simulate excitotoxic injury and were then rinsed with embryo media. Time-lapse imaging followed for 2-3 hours, and results were compared to control fish without AMPA exposure. Automated tracking (FIJI-Trackmate) and unsupervised clustering analysis (CellRomeR) were utilized to compare morphologic (area, circularity) and motility (speed, directional change rate) features to identify phenotypic clusters unique to each condition.

Results: Cluster analysis revealed distinct macrophage phenotypes with different prevalence in the control and AMPA-exposed conditions. The control condition was composed primarily of macrophages that were larger and slower without significant directional changes, which was consistent with a “surveillance” phenotype. In the AMPA-exposed group, there were multiple distinct phenotypes with a portion of macrophages adopting the “patrolling” phenotype but a larger proportion that were smaller and faster with a high directional change. Such behavior is consistent with an “activated” phenotype. These experiments are ongoing.

Conclusions: Our findings demonstrate that excitotoxic injury results in shifts between distinct macrophage phenotypes in the zebrafish lateral line. The results highlight the utility of clustering analysis in identifying discrete macrophage subtypes in vivo and for linking dynamic morphologic and motility features to injury. Further work will involve implementing a similar

cluster analysis paradigm for the lateral line imaged with light sheet microscopy after excitotoxic injury.

SU160. Investigating the Role of Neogenin in Cochlear Synaptopathy

Nicholas Barad^{*1}, Tiffany Huang², Noriomi Suzuki², Albert Edge¹

¹*Harvard Medical School*, ²*Mass Eye and Ear*

Background: Synapses between cochlear hair cells and Type 1 auditory nerve fibers are the most vulnerable to acoustic trauma, leading to permanent synaptopathy despite recovery of temporary threshold shifts. Previous therapeutic interventions in mouse models have demonstrated a limited window for synaptic recovery. Treatments, such as neurotrophins, administered before or immediately after noise trauma have shown a protective rather than a regenerative effect. However, an antibody targeting Repulsive Guidance Molecule A (RGMa) restored synapses for up to 1 week after noise exposure, suggesting a regenerative effect on the synapse. RGMa is involved in axonal guidance through interactions with neogenin1 (Neo1), a cell surface receptor expressed on auditory nerve fibers. Epigenetic barriers can restrict synaptogenesis in the adult sensory nervous system, limiting the restoration of the cochlear afferent synapse in the noise-exposed inner ear. Here, we hypothesize that RGMa-Neo1 interactions inhibits synaptic repair by facilitating the nuclear translocation of the Neo1 intracellular domain (Neo-ICD), which mediates epigenomic changes after acoustic trauma.

Methods: We developed clonal Neo-HA Neuro-2a cell lines and generated Neo1 and Neo-ICD EGFP tagged constructs to evaluate regulated intramembrane proteolysis and subcellular localization of fragments using immunoblotting and immunofluorescence under different pharmacological conditions. Nuclear activity and chromatin binding of Neo-ICD was assessed in-vitro using Cut and Run assays. To evaluate functional recovery of synapses, we inhibited Neo-ICD cleavage in an ex-vivo kainic acid (KA) excitotoxicity model of cochlear synaptopathy and quantified synaptic counts.

Results: Neo1 undergoes endogenous stepwise proteolysis to release the Neo-ICD in-vitro. We observed that intramembrane proteolysis is mediated by γ -secretase and Neo-ICD undergoes rapid degradation by the proteasome. Nuclear translocation is tightly regulated where nuclear export, but not nuclear import, determines steady state localization. Cut and Run assays revealed that Neo-ICD binds to chromatin with co-localization to histone markers. Preventing intramembrane cleavage of Neo-ICD in ex-vivo KA models showed a dose-dependent effect to regenerate cochlear synapse counts.

Conclusions: Our findings identify neogenin1 as a potential epigenetic regulator of chromatin accessibility and may provide a novel therapeutic strategy to extend the therapeutic window for synaptogenesis in the cochlea.

SU161. Using Simulations and Non-Stationary Fluctuation Analysis of Synaptic Currents to Uncover the Properties of Cochlear AMPA-Type Glutamate Receptors: Ca²⁺ Permeable and Impermeable

Mona Jawad^{*1}, Mark Rutherford¹, Juan Goutman², James Huettner¹, Walen Gribaud³

¹Washington University St. Louis, ²INGEBI (CONICET), ³Instituto de Investigaciones en Ingeniería Genética y Biología Molecular

Background: AMPA receptor/channels are concentrated in specific regions of synapses called postsynaptic densities (PSDs) where they mediate fast neurotransmission. PSDs vary in size among synapse type, differing in number, spatial density, and composition of subunits. For spiral ganglion neurons (SGNs) contacting inner hair cells, PSD composition heterogeneity may in part determine sound response properties. However, the number of AMPARs within single PSDs, their spatial organization, and their molecular heterogeneity are currently unknown.

Nonstationary fluctuation analysis (NSFA) has been used to quantify the number of receptors (N) and their unitary currents (i) in synapses of the CNS. By recording and analyzing excitatory postsynaptic currents (EPSCs), NSFA can characterize AMPAR properties. Yet while NSFA outputs a single estimate for i, unitary currents depend on AMPAR subunit composition. Depending on the absence or presence of the GluA2 subunit, AMPARs are calcium permeable (CP-AMPARs) or calcium impermeable (CI-AMPARs), respectively.

To extract distinct i estimates for CP-AMPARs and CI-AMPARs and their relative abundance, here we report on a method of analysis taking advantage of IEM-1925, a selective CP-AMPAR blocker. We will also share the parameters of a simulation matching the kinetics of physiological EPSCs. Finally, we will compare NSFA results on simulated EPSCs (sEPSCs) to NSFA on vesicular EPSCs (vEPSCs), EPSCs evoked by glutamate uncaging (uEPSCs), and vEPSCs of cells treated with IEM-1925.

Methods: Explants of the organ of Corti from P15-P17 C57BL/6 mice were used for patch-clamp recordings. uEPSC recordings were generated via rapid homogeneous uncaging of glutamate on the entire PSD. vEPSCs were recorded before and after treatment with IEM-1925. EPSC simulations and NSFA tools were scripted in Python.

Results: To reproduce the ranges and distributions of amplitudes and kinetics observed in vEPSCs, the simulations required that each EPSC be generated from variable N and [glutamate], defined by normal distributions, fit to an ensemble of physiological data: $\mu=2200$, range=50–3422; and $\mu=2.5\text{mM}$, range=1–5.8mM, respectively.

It is unclear how robustly NSFA can extract N and i in recordings from synapses with such heterogeneous EPSCs. For sEPSCs, some permutations of NSFA produced accurate estimates of i. However, information on N and Popen remain obscure.

For sEPSCs and uEPSCs, where each channel sees glutamate simultaneously, the pattern of EPSC amplitudes and kinetics are similar, but both differ from patterns observed for vEPSCs. Inclusion of a simple model of glutamate diffusion may in part explain these differences.

NSFA revealed significantly lower N and i for IEM-1925 versus control. By comparing mean i between EPSCs recorded under control vs. a saturating concentration of IEM-1925, we extracted i for CP-AMPARs and CI-AMPARs and their relative proportions.

Conclusions: Simulations of EPSCs recorded from SGNs can validate NSFA on physiological data to extract essential channel properties in support of pre-clinical translational research.

SU162. Single-Cell and Spatial Transcriptomic Analysis of Noise-Induced Cochlear Synaptopathy

Abel David^{*1}, Brooke Wang², Sina Schwinn³, Janice Chung⁴, Yohan Song⁵, Srinivas Saladi⁶, Taha Jan⁷, David Jung⁵

¹*Feinberg School of Medicine, Northwestern University*, ²*Tufts University School of Medicine*, ³*Universitätsklinikum Hamburg-Eppendorf*, ⁴*University of California Los Angeles*, ⁵*Massachusetts Eye and Ear, Harvard Medical School*, ⁶*University of Toledo College of Medicine and Life Sciences*, ⁷*Vanderbilt University Medical Center*

Background: Noise-induced hearing loss (NIHL) may arise in part from cochlear synaptopathy, the loss of ribbon synapses between inner hair cells and spiral ganglion neurons (SGNs). This process, thought to be driven by glutamate excitotoxicity, occurs even in the absence of hair cell loss and disrupts the fidelity of auditory signaling. Synaptopathy has been studied as a cause of auditory dysfunction, and has demonstrated tonotopic differences in synapse loss after noise exposure. However, the cellular heterogeneity of SGN responses and the molecular mechanisms that mediate synaptic degeneration and repair remain incompletely defined.

Recent evidence has identified the molecular subtypes of SGNs, which correlate with their electrophysiological properties and susceptibility to excitotoxic injury (Shrestha et al. 2018). There are three Type 1 SGN subtypes (1A-C), with Type 1C being the most susceptible to noise-induced synaptic loss. We aim to determine the underlying molecular responses in noise-induced hearing loss and cochlear synaptopathy using single-cell and complementary RNA in situ hybridization for spatial relationships. We hypothesize that there are SGN-specific and tonotopic-regional differences in synapse related genes after noise exposure.

Methods: A two-tiered approach was used to investigate transcriptional changes after glutamate excitotoxicity and noise-induced cochlear synaptopathy. First, an in vitro 3D cochlear explant model of neonatal mice (P2-3) were exposed to a glutamate agonist or glutamate agonist and neurotrophins to induce synapse regeneration. Following treatment, explants underwent single cell RNA sequencing and computational analysis.

To validate transcriptomic findings in vivo, an established mouse model for noise induced synaptopathy was used. The synaptopathy phenotype was confirmed using ABR/DPOAE measurements and synapse quantification on immunohistochemistry using anti-CtBP2 and anti-GluR2 antibodies. Cochleae were harvested 24 hours post noise-exposure and tonotopically microdissected. Spatial expression of candidate genes was examined using RNA in situ hybridization (RNA-ISH) in a whole mount preparation in the 11.33 kHz and 32 kHz regions. Machine learning-assisted three-dimensional imaging analysis was used for quantification.

Results: Single-cell RNA sequencing of cochlear explants following glutamate excitotoxic injury and neurotrophin exposure yielded high-quality cells across conditions. Clustering identified populations of hair cells and spiral ganglion neurons identified using their canonical markers. After glutamate agonist exposure, there was an increase in the expression of glutamate receptor subunit mRNA and an even greater increase after NT3 exposure. In vivo validation using RNA-ISH in noise-exposed mice confirmed spatially distinct increases in glutamate receptor subunit mRNA by SGN subtype and by tonotopic region.

Conclusions: These data suggest that subtypes of spiral ganglion neurons susceptible to synaptic loss due to noise trauma, respond in turn by generating more synapses. These findings provide a greater insight into the mechanisms that underlie synaptic loss and recovery which could garner targeted treatments for noise-induced hearing loss.

SU163. Glu2Py as a Novel Neurotrophic Agent for Inducing Neuritogenesis in Spiral Ganglion Cultures

Neeraj Thakur^{*1}, Xiangping Huang², Xiaoping Du², Venkateswararao Eeda¹, Vibhudutta Awasthi¹, Matthew West²

¹University of Oklahoma Health Sciences Center, ²Hough Ear Institute

Background: Cochlear synaptopathy, involving the loss of afferent ribbon synapses between cochlear hair cells and spiral ganglion neurons (SGNs), is a leading cause of sensorineural hearing loss and continues to present a major clinical challenge due to the lack of effective therapeutic options. The development of neurotrophic compounds that can promote spiral ganglion (SG) neurite outgrowth and enhance neuronal survival is critical for advancing hearing restoration strategies. Glucosyl-2-pyrrolopyrimidinone (Glu2Py), a novel pharmacologic inhibitor of Misshapen Kinases, has shown potential neurotrophic activity in preliminary studies. However, its specific effects on auditory neurons and nerve fibers remain to be systematically characterized.

Methods: We evaluated the neurotrophic effects of Glu2Py (1, 5, and 10 μ M) using multiple experimental models, including SH-SY5Y human neuroblastoma cells, cochlear spiral ganglion explants, and dissociated SGN cells from postnatal day 3.5 CD1 mouse pups. SH-SY5Y cells were treated with Glu2Py for either 24 or 48 h followed by 48-h recovery periods, while SG tissues were exposed to Glu2Py for 24-48 h depending on the experimental design. Cell morphology measurements and neurite length analysis were performed using fluorescence microscopy and ImageJ software with NeuronJ plugin. Statistical analysis employed appropriate parametric and non-parametric tests based on data distribution.

Results: Glu2Py demonstrated significant dose-dependent and time-dependent neurotrophic effects across all models. In SH-SY5Y cells, 24-h treatment showed concentration thresholds with increased neurite-to-cell outgrowth at 1 (1.00 ± 0.42), 5 (1.23 ± 0.10), and 10 μ M (1.52 ± 0.05) versus untreated cells (0.56 ± 0.14). Neurite outgrowth directly affected mean cell area, confirming treatment effects. Treatments at 1, 5, and 10 μ M significantly increased cell areas (547.95 ± 246 , 599.51 ± 326.21 , and 572.61 ± 296.61 μ m², respectively, $p < 0.0001$) compared to controls (341.49 ± 170.16 μ m²). In 48-h treatment groups, mean area increased at 5 μ M (601.43 ± 308.64 μ m², $p < 0.01$) and 10 μ M (1183.48 ± 442.81 μ m², $p < 0.0001$) versus controls (423.67 ± 111.31 μ m²), while 1 μ M showed no significant effect. Spiral ganglion explants demonstrated robust concentration-dependent neurite outgrowth, with highly significant increases at 5 μ M (94.21 ± 31.39 μ m) and 10 μ M (102.63 ± 33.04 μ m) compared to controls (65.44 ± 14.55 μ m, $p < 0.0001$), while 1 μ M showed no significant effect (59.51 ± 21.91 μ m). Remarkably, separated spiral ganglion cells exhibited enhanced sensitivity, showing significant neurite extension at all concentrations: 1 μ M (81.19 ± 17.62 μ m), 5 μ M (77.55 ± 33.62 μ m), and 10 μ M (99.90 ± 20.01 μ m) compared to controls (53.54 ± 17.92 μ m, $p < 0.0001$). Differential

responses between explant and separated cultures suggest tissue architecture and cellular microenvironment significantly influence compound efficacy and cellular responsiveness.

Conclusions: Glu2Py exhibits potent neurotrophic activity with particular efficacy in promoting SGN outgrowth. The compound shows time-dependent effects in a human neuronal model and potency in primary tissue explants and dissociated SGNs. These findings establish Glu2Py as a promising therapeutic candidate for cochlear neuropathy and synaptopathy, warranting further investigation in ototoxicity protection and regenerative sensorineural hearing loss treatment applications.

SU164. Daily Dynamics of the Electrode-Tissue Interface in Cochlear Implants With and Without Steroid-Eluting Electrodes

Seba Ausili^{*1}, Federico Di Lella²

¹*University of Miami*, ²*Hospital Italiano de Buenos Aires*

Background: Cochlear implant electrode impedance provides insight into inner ear tissue responses. After implantation, impedance typically rises due to protein adsorption and inflammatory tissue changes, then several changes occur after the onset of electrical stimulation. Excessive impedance growth is linked to fibrotic encapsulation of the electrode and can negatively impact device performance. Steroid interventions (e.g. topical or eluting dexamethasone) have been explored to mitigate these foreign body responses and impedance increases. However, the day-to-day impedance dynamics in the immediate remain poorly characterized. This study aimed to monitor daily impedance changes and their resistive vs. polarization subcomponents in cochlear implant recipients with and without sustained steroid delivery, and to relate these changes to device usage patterns.

Methods: A prospective observational design was used to analyze daily impedance telemetry (morning and night) in cochlear implant recipients. Four groups were studied based on implant type and steroid administration: (1) CI612 electrodes with no dexamethasone application, (2) CI612 electrodes with a single intraoperative topical dexamethasone application, (3) CI632 electrodes with the same topical dexamethasone treatment, and (4) CI632 electrodes incorporating a self-eluting dexamethasone polymer for sustained release. Impedance was measured daily from the day of surgery through the post-activation period using standard clinical telemetry. To dissect impedance components, we calculated the resistive and polarization subcomponents. Patients' device data-logging records (hours of use per day) were also collected in a subgroup to examine the influence of daily cochlear implant use on impedance fluctuations.

Results: Daily impedance monitoring revealed consistent temporal patterns across patients. As expected, impedance increased during the early postoperative period and stabilized over time. Significant differences were observed across electrode types and dexamethasone delivery methods. After activation, clear diurnal fluctuations emerged, primarily driven by changes in the polarization component, while the resistive component remained stable. The self-eluting dexamethasone electrode exhibited the most stable profile, significantly reducing day-to-night changes and flattening the polarization impedance curve. Differences in the resistive subcomponent were minimal across groups. Notably, patients with greater daily CI use showed larger diurnal impedance shifts, suggesting that electrical stimulation modulates the electrode-tissue interface.

Conclusions: Our findings demonstrate that the polarization component of electrode impedance is highly sensitive to changes in cochlear implant (CI) stimulation and is significantly modulated by anti-inflammatory interventions. Dexamethasone, particularly when delivered via a self-eluting electrode array, not only attenuates the post-surgical rise in impedance but also reduces day-to-day variability, leading to a more stable electrode–tissue interface. In contrast, the resistive component remains largely unaffected by both steroid intervention and electrode type. From a clinical perspective, daily impedance monitoring offers a high-resolution window into cochlear healing and tissue response. When combined with targeted steroid delivery, this strategy may enable earlier detection of abnormal biological responses and support more personalized postoperative management.

SU165. Feasibility of Endoscopic Microneedle-Guided Round Window Membrane Perforation and Perilymph Sampling in Human Cadaveric Temporal Bones

Aykut Aksit^{*1}, Sharon Feng², Stephen Leong², Daniella Hammer³, Jeffrey Kysar³, Anil Lalwani², Justin Golub²

¹Haystack Medical, ²College of Physicians and Surgeons, Columbia University, ³Columbia University

Background: Diagnostic and therapeutic interventions for inner ear disorders remain limited by the lack of safe, controlled access to the perilymphatic space. Haystack Medical has developed a microneedle-endoscope system designed for minimally invasive round window membrane (RWM) perforation and fluid aspiration under direct visualization.

Methods: Hollow microneedles (outer diameter 100 μm , lumen diameter 35 μm) were fabricated by two-photon lithography and mounted onto polyimide tubing. A refined deployment tube (23 Ga) enabled endoscopic visualization and precise positioning adjacent to the RWM. Cadaveric human temporal bones (n=7) were used to evaluate procedural feasibility. Following endoscopic RWM perforation, perilymph aspiration was performed using a syringe pump at $\sim 1 \mu\text{L}/\text{min}$. Aspirated volumes were quantified microscopically via droplet measurement.

Results: Controlled, reproducible RWM perforation was achieved in all specimens (100% success, n=7) without tearing or enlargement of the membrane. Aspiration was successful in all cases, with mean volume 0.89 μL (SD 0.20 μL), slightly below DI water controls (1.0 μL). Needle integrity was preserved after each use, and no uncontrolled RWM damage was observed. Some aspirates contained visible blood contamination, likely attributable to cadaveric conditions.

Conclusions: Haystack Microneedles enabled consistent, visually guided perforation and reliable perilymph aspiration in human cadaveric models. Achieved aspiration volumes are sufficient for biomarker analyses, demonstrating feasibility of minimally invasive diagnostic sampling. These Phase I outcomes establish a strong foundation for clinical translation and regulatory preparation.

SU166. Development of a Drug-Induced Ototoxicity Model Using Inner Ear Organoids and Investigation of Protective Mechanisms

Beom Gi Kim*¹, SEULGI LEE¹, So-Young Chang², Ji-Eun Choi³, Jae Yun Jung³, Min Young Lee³

¹*Dankook University*, ²*Beckman Laser Institute Korea, Dankook University*, ³*Dankook University Hospital*

Background: Ototoxic drugs such as aminoglycoside antibiotics and cisplatin are widely used in clinical practice

but are a major cause of irreversible hearing loss, primarily through damage to cochlear hair cells.

Current ototoxicity studies primarily rely on animal models or two-dimensional cultures, which fail

to adequately reproduce the structural and functional complexity of the human inner ear. Human pluripotent stem cell–derived inner ear organoids represent a physiologically relevant platform with the potential to model both auditory development and drug-induced damage. The aim of this study is to establish an inner ear organoid–based ototoxicity model and to explore protective mechanisms through the modulation of key signaling pathways, including Wnt, PI3K/PTEN, and

YAP

Methods: Human embryonic stem cells and induced pluripotent stem cells were differentiated into inner ear

organoids using protocols established in our laboratory. This process involved the induction of otic placode formation, vesicle development, and sensory epithelium differentiation. Organoids are

characterized by immunostaining and molecular assays for lineage-specific markers, including ATOH1, POU4F3, and MYO7A (hair cells), as well as SOX2 and PROX1 (supporting cells). To model

ototoxic injury, organoids will be treated with aminoglycoside antibiotics and cisplatin, followed by

evaluation of cell survival, ROS generation, and morphological changes using immunostaining and

LDH assays. Protective strategies will be tested by applying small molecules, including the Wnt activator CHIR99021, the PTEN inhibitor VO-OHpic, and the ROS scavenger N-acetylcysteine.

Transcriptomic profiling via RNA-seq will be performed to identify molecular pathways involved in

damage and recovery.

Results: Preliminary experiments have focused on directing human pluripotent stem cells toward inner ear

organoid differentiation. Organoid formation efficiency is currently being systematically evaluated

across multiple cell lines, and immunostaining is being used to quantify the proportion of organoids expressing otic lineage markers. Ototoxic drug treatment has not yet been initiated; protocols for exposure to aminoglycoside antibiotics and cisplatin are under development. Comprehensive quantitative analyses will be conducted in the next phase, and results will be presented at the meeting.

Conclusions: This study highlights the potential of human pluripotent stem cell–derived inner ear organoids as

a physiologically relevant model for investigating drug-induced ototoxicity. Modulation of Wnt, PI3K/PTEN, and YAP signaling pathways is expected to provide novel insights into protective mechanisms for auditory hair cells. Such an approach may contribute to the establishment of a precise preclinical drug-screening platform and facilitate the development of innovative therapeutic strategies aimed at preventing or reducing hearing loss induced by ototoxic agents.

SU167. A Novel Device for Atraumatic Perilymph Sampling

Till Buschhorn^{*1}, Caroline Sesztak¹, Anselm Joseph Gadenstaetter¹, Erdem Yildiz¹, Matthias Gerlitz¹, Hinrich Staecker², Clemens Honeder¹, Christoph Arnoldner¹

¹*Vienna General Hospital, Medical University of Vienna*, ²*Auditory and Vestibular Neuroscience (AVN) laboratory*

Background: A promising approach to investigating cochlear physiology is the analysis of perilymph, a sodium-rich extracellular fluid present in the cochlea and vestibular system with interaction with key auditory structures. Because of its anatomically challenging location and the immediate risk of irreversible hearing loss following cochlear injury, perilymph sampling in humans is currently only feasible during surgical procedures that are already expected to result in hearing loss, such as cochlear implantation or removal of vestibular schwannoma. In contrast, animal models allow the evaluation of innovative approaches for perilymph collection. Several techniques are available for obtaining perilymph from animal models, varying in their degree of invasiveness and potential to cause irreversible damage. The choice of methodology should be guided by the specific scientific objective, with the aim of collecting perilymph as atraumatically and uncontaminated as possible to ensure its validity as a diagnostic tool.

Methods: In three pigs (*Sus scrofa domestica*), surgical access to the inner ear was established, and the round window membrane was exposed. A novel sampling device was advanced through the round window membrane to collect perilymph. In two animals, auditory brainstem responses (ABRs) were recorded both preoperatively and one week postoperatively to assess potential changes in auditory function resulting from the procedure. Following functional assessment, the inner ears were harvested and subjected to high-resolution micro-computed tomography (micro-CT) analysis. To confirm that the collected fluid was indeed perilymph, the presence of cochlin was verified using an enzyme-linked immunosorbent assay (ELISA).

Results: After surgical exposure of the round window, perilymph was successfully collected using the novel device. In three samples, a volume of 3–5 µL was obtained, in which the presence of cochlin was clearly confirmed via ELISA. The structural integrity of the cochlea

remained largely preserved, as shown in the micro-CT data. In the two animals monitored for one week postoperatively, minor shifts in hearing thresholds were observed in some instances, with an average change of 5 dB across all frequencies.

Conclusions: Atraumatic collection of perilymph using the novel device was successfully demonstrated in a large animal model. The procedure required minimal training for surgeons and allowed the collection of sufficient volumes for diagnostic and analytical purposes. Although slight shifts in hearing thresholds were observed, these were minimal and cannot be conclusively attributed to the device itself, as the surgical procedure inherently carries a risk of minor threshold changes. Micro-CT imaging revealed only limited structural alterations at the round window membrane, suggesting favorable conditions for subsequent healing. To further assess recovery and long-term outcomes, studies with extended follow-up periods are warranted.

SU168. Perilymph-Sampling: A Translational Journey

Till Buschhorn^{*1}, Anselm Gadenstaetter¹, Matthias Gerlitz¹, Erdem Yildiz¹, Caroline Sesztak¹, Hinrich Staecker², Clemens Honeder¹, Christoph Arnoldner¹

¹*Vienna General Hospital, Medical University of Vienna*, ²*School of Medicine, University of Kansas*

Background: Translational cochlear implantation, gene therapy and pharmacological distribution strategies require robust animal models to effectively mimic human cochlear anatomy and physiological responses, as well as a similar genetic profile. The pig has emerged as an ideal large animal model due to its anatomical and physiological similarities to the human inner ear. Here, we summarize recent advancements and outcomes from out pig-based cochlear implantation, gene and drug delivery studies providing crucial translational insights.

Methods: We established and continually refined a cochlear implantation surgical protocol in pigs designed to replicate human cochlear anatomical dimensions. This approach facilitates the examination of trauma induced by electrode insertion and optimizes implantation techniques for clinical translation. Drug delivery studies, conducted using various infusion methods with and without CE-certified catheters, provided critical insights into fluid dynamics within the large cochlea.

Results: Utilizing robotic-assisted cochlear implantation, we observed significant reductions in electrode impedance and improved hearing preservation compared to conventional manual insertions, highlighting the potential of robotic assistance to enhance implantation outcomes and reduces intracochlear trauma. We developed and implemented comprehensive perilymph sampling protocols in the pig, including traumatic and atraumatic round window membrane sampling, stapedotomy and stapes fenestration, semicircular canal opening and apical sampling. These methods enabled detailed proteomic and transcriptomic characterization of perilymph before and after cochlear implantation. Notably, our data represents the first description of porcine cochlear expression profiles, providing unique opportunities for comparative analysis with human perilymph expression data. Additionally, we assessed cochlear distribution and off-target effects of various viral vectors, particularly adeno-associated viruses (AAV). Our results from gene delivery studies demonstrated successful cochlear transduction without requiring fenestration, suggesting that intracochlear administration of AAVs is feasible and effective

across the entire cochlear length. However, distribution patterns varied considerably between the chosen vector and the methodology of injection.

Conclusions: Data generated from porcine studies offer a high degree of translationality to clinical application. Differences in transduction from gene delivery studies correlate indirectly with functional outcomes in ongoing otoferlin gene therapy studies, emphasizing the importance of vector selection and delivery precision.

Collectively, these findings underscore the pig's model utility in translational auditory research, providing pivotal insights that advance multiple fields from cochlear implantation to gene therapy strategies for hearing loss treatment.

SU169. Histamine Receptors in the Auditory Midbrain and Thalamus of the Mouse

John Kara^{*1}, Tashonda Vaughn², Charles Lee²

¹*Louisiana State University Health Science Center*, ²*Louisiana State University*

Background: The central histaminergic nervous system, originating from the tuberomammillary nucleus (TMN) of the hypothalamus, widely innervates almost the whole brain including the midbrain and thalamus. Brain histamine regulates diverse physiological functions, including wake and arousal states, forming part of the ascending reticular activating system. While the modulatory role of histamine in the brain, particularly in the cerebral cortex, is widely explored, very little is known about its function in the auditory system; in particular, histamine's role in the auditory midbrain (inferior colliculus: IC) and auditory thalamus (medial geniculate body: MGB) has been largely unexplored

Methods: Therefore, to assess histaminergic innervation of these auditory structures, we neuroanatomically and physiologically assessed IC and MGB neurons for functional histamine receptors. We immunohistochemically stained for histamine receptor subtypes (H1R, H2R, H3R) in both the IC and MGB. In addition, we employed in vitro whole-cell patch-clamp to record from IC and MGB neurons in response to bath application of histaminergic agonists.

Results: From our studies, we find a unique distribution of histamine receptors in the IC and MGB of the mouse that correlates with the responsiveness of neurons to histaminergic agonists, which in general act to depolarize auditory neurons

Conclusions: Overall, our data suggests that histamine can selectively heighten the responsiveness of auditory thalamic and midbrain structures to acoustic signals and highlights the overlooked role of histamine in these structures of central auditory processing

SU170. Acetylcholine Release in the Inferior Colliculus During a Stimulus-Specific Adaptation Paradigm

Courtney Myers^{*1}, Mariam Safirta¹, Michael Roberts¹

¹*University of Michigan*

Background: Stimulus-specific adaptation (SSA) is a neural process that supports novelty detection by selectively diminishing responses to repeated sensory stimuli. Detection of novel

sounds is important for survival and communication, but the neural mechanisms underlying novelty detection in the central auditory system remain largely unclear. The inferior colliculus (IC) serves as a major hub for auditory information integration and is the first auditory subregion to exhibit SSA in the ascending auditory pathway. Additionally, exogenous application of acetylcholine (ACh) reduces SSA in the IC by enhancing responses to repeated sound stimuli (Ayala and Malmierca, 2015). Previous anatomical studies indicate the IC receives dense cholinergic innervation from the pedunculopontine tegmental nucleus (PPN), a key component of the reticular activating system that influences arousal, attention, and sensory processing. Several studies have indicated that PPN neurons respond to sounds and rapidly adapt to repeated sounds, but how cholinergic signaling from the PPN shapes responses in the auditory system remains largely unknown. We hypothesize that cholinergic signaling from PPN projections to the IC modulates SSA in the IC. As the first step in testing this hypothesis, here we examine how novel and repeated sounds shape ACh release in the IC.

Methods: We are currently investigating ACh release in the IC using in vivo fiber photometry in mice. Adult P60-P90 B6.CAST-Cdh23Ahl⁺ mice, balanced for sex, are injected in the IC with an adeno-associated virus encoding the fluorescent ACh sensor, GRAB-ACh3.0 (GPCR-Activation-Based-ACh), and implanted with an optical fiber in the IC. Several weeks later, mice are head-fixed in a sound-isolation booth and exposed to a pure-tone oddball stimulation paradigm, consisting of standard tones at 70 dB SPL for 200 ms for 90% of trials pseudorandomly intermixed with deviant tones at 70 dB SPL for 10% of trials. Interstimulus intervals vary by 2-5s for a 30-minute recording period. Fluorescent GRAB-ACh3.0 signals are analyzed to determine the amount of ACh release evoked by the standard and deviant tones.

Results: Thus far, we have successfully expressed AAV9-hSyn-GRAB_ACh3.0 in the IC and confirmed that GRAB-ACh3.0 fluorescent signals change in response to novel acoustic stimuli. Experiments to assess how ACh release in the IC changes during SSA stimulus paradigms are currently underway.

Conclusions: This project aims to elucidate how acoustic stimuli influence the release of ACh in the IC and the role of cholinergic signaling in the IC in SSA. We expect our results will show that novel sound stimuli elicit more ACh release in the IC than repeated sound stimuli. We will next use optogenetic tools to manipulate cholinergic PPN projections to the IC to test how inhibiting and enhancing these projections alters IC neuron responses to novel and repeated stimuli.

SU171. Decoding Single and Multi-Neuron Activity in Inferior Colliculus for Speech Digits in Natural Environmental Noise

Ruotong Li¹, James Dion¹, Jenna Blain¹, Ian Stevenson¹, Monty Escabi¹

¹*University of Connecticut*

Background: Inferior colliculus (IC) is one of the brain's crucial auditory processing and integration centers. Previous results suggest that IC may play a key role in the representation of spectral and temporal modulation statistics (Zhai et al., 2020), and computational models of IC have recently been shown to predict how different background sounds impact speech recognition accuracy (Clonan et al. 2025). Although previous work in IC has examined on how simple sounds, such as tones, are segregated from background noise, how IC contributes to the encoding

and segregation of speech in the presence of natural background sounds is not yet well understood.

Methods: This project aims to characterize how spectrum and modulation cues in natural background sounds influence the representation of speech in IC activity of un-anesthetized rabbits. Using an stimulus paradigm based on a previous study in human listeners (Clonan et al 2025), we delivered speech digits (0 to 9) embedded in 11 original (OR) natural background sounds and perturbed variants where we either preserved the spectrum (spectrum matched, SM) or modulation (modulation matched, MM) statistics of each sound at 0 dB signal-to-noise ratios (SNR). We then use a decoding approach to classify digits based on single neuron recordings from IC was obtained while animals listen to these speech-in-noise stimuli. Using Spike Distance Metric classifiers that analyze spike trains from individual or multiple single neurons at different time-scales we evaluated how IC responses contribute to speech identification.

Results: As expected, classification accuracy improved with increasing number of neurons. While the single- and multi-neuron digit classification accuracy for clean speech was often very high (~99%), accuracy for speech-in-noise varied widely depending on the background. Accuracy varied substantially from background to background and was generally highest for SM backgrounds and lowest for MM. We observe that the discriminability of spike trains peaks at frequency bands with center frequency of ~4 Hz and ~100 Hz, corresponding to word rates and periodicity pitch frequencies of the speech vocalizations.

Conclusions: The general classification accuracy trends for OR, SM and MM backgrounds are correlated with those observed in human behavior (Clonan et al 2025) suggesting that spectrum and modulation statistics of each background influence decoding accuracy. Furthermore, the results indicate that rhythm (~4 Hz) and periodicity pitch (~100 Hz) bands may play a critical role in the subcortical representation of speech. Funded by NIH (R01DC020097).

SU172. Characterization of Subcortical Presynaptic Inputs to Inferior Colliculus Subdivisions

Hailey Acosta^{*1}, Michellee Garcia¹, Michael Kasten¹, Paul Manis¹, Hiroyuki Kato¹

¹*University of North Carolina at Chapel Hill*

Background: The inferior colliculus (IC) is a mandatory relay station in ascending auditory pathways and plays an important role in sensory integration. Classically, the IC is divided into core (lemniscal) and shell (non-lemniscal) regions, which differ in sound response properties and connectivity. While projections to the core, or central nucleus (CIC), are well established across species, inputs to the shell, or dorsal (DCIC) and external (ECIC) cortices, remain understudied. Furthermore, our recent work showed that rostral and caudal ECIC subregions relay ascending inputs to distinct thalamic targets with different latencies, raising the possibility that they may convey specialized information from distinct sources.

Methods: In this study, we quantified ascending inputs to the IC subdivisions by performing monosynaptic retrograde tracing from CIC, DCIC, rostral ECIC, and caudal ECIC using fluorophore-conjugated wheat germ agglutinin in mice. Coronal brain sections were aligned to a brain atlas for systematic quantification of input cell distributions.

Results: Preliminary results show distinct subcortical input patterns across subregions. Inputs to CIC were largely consistent with previous literature, with dense projections from the ventral cochlear nucleus, intermediate and ventral nuclei of the lateral lemniscus, and the lateral superior olive. In contrast, shell regions received broader inputs, including strong projections from the paralemniscal nucleus, dorsal and intermediate nuclei of the lateral lemniscus, and additional contributions from motor-related areas in the medulla, pons, and superior colliculus. Notably, rostral ECIC received a higher fraction of input from the ventral cochlear nucleus than caudal ECIC or DCIC, potentially supporting its short-latency sound responses.

Conclusions: Ongoing experiments will further compare input patterns across these IC subdivisions. These detailed connectivity data will provide new insights into the information transmitted through these IC subdivisions and guide future research to understand the functional roles of these pathways.

SU173. Effects of Fluid Volume, Viscosity, Head Orientation, and Negative Pressure on Wideband Acoustic Immittance in Middle-Ear Effusion and Residual Fluid

Hamid Motallebzadeh¹, W. Robert J. Funnell², Navid Shahnaz³

¹California State University, Sacramento, ²McGill University, ³University of British Columbia

Background: Otitis media with effusion (OME) is among the most prevalent conditions in the pediatric population and represents the leading cause of conductive hearing loss in children. In neonates, residual amniotic or other postnatal fluid in the middle ear can also complicate newborn hearing screening, contributing to false-positive referrals. While fluid volume and head orientation have been recognized as important factors, the combined influence of negative middle-ear pressure and the wide range of effusion viscosities (spanning $\sim 1\text{--}10,000\times$ that of water, from serous to thick mucoid) on acoustic responses remains poorly characterized.

Methods: We extended a previously validated finite-element (FE) model of middle-ear wideband acoustic immittance (WAI), tuned using simulation-based inference. Parametric sweeps examined the effects of effusion volume, head orientation, negative pressure loading, and viscosity. Baseline simulations with an air-filled cavity provided reference immittance and absorbance spectra. Comparative analyses were performed against both our own and published clinical data.

Results: Simulations showed that fluid volume and head orientation strongly altered WAI through changes in effective air space and variations of fluid–TM contact area, producing spectral shifts consistent with clinical observations. Negative pressure further accentuated impedance changes, particularly at low frequencies. Increasing viscosity reshaped the absorbance profile, introducing sharper peaks shifted above 1 kHz.

Conclusions: This study demonstrates how a fluid–structure interaction framework can explain the combined influences of testing conditions (e.g., head orientation) and pathological changes (e.g., fluid presence, volume, viscosity, and negative pressure) on WAI. By capturing these diverse conditions, the model provides mechanistic insight into how OME alters middle-ear transmission and how variability in measurement settings can shape observed WAI responses. Because WAI reflects the acoustic transmission properties of the ear, these findings also help to

interpret how middle-ear status influences otoacoustic emissions (OAEs, forward and backward transmission) and auditory brainstem responses (ABRs, forward transmission). The effect of head orientation is particularly relevant for newborns, who are typically tested in convenient, non-standardized resting positions that may increase variability, reduce test–retest reliability, and contribute to false-positive referrals. Finally, the framework establishes a foundation for applying machine-learning approaches trained on diverse fluid and orientation scenarios to improve diagnostic accuracy in pediatric OME evaluation.

SU174. Sensitivity-Guided Inference: A Structured Approach to Reduce Simulation Burden in Neural Network–Based Diagnosis

Hamid Motallebzadeh*¹, Xiyang Guan²

¹*California State University, Sacramento*, ²*Wayne State University*

Background: Neural networks and deep learning are increasingly used for diagnostic modeling, but their growing complexity often overshadows traditional statistical analyses essential for interpretability. Simulation-based inference (SBI) learns the mapping between model outputs and parameters and, given reference data, returns posterior distributions that can be fed into a deterministic model to reproduce the data. However, as the number of parameters increases, required simulations grow rapidly (approximately quadratically with dimensionality), slowing convergence and limiting interpretability. The middle ear, with its complex structure and many parameters, is a prime case: we propose a two-stage strategy that first ranks parameter influence via a global sensitivity procedure and then applies tiered SBI to sequentially tune high-dimensional models (from high- to lower-sensitivity subsets). This enables automated diagnosis and can inform middle-ear reconstructive surgery planning.

Methods: We propose a structured workflow that integrates systematic sensitivity analysis with multi-batch SBI to reduce simulation burden while retaining interpretability. As a case study, we implemented our approach on a lumped-element human middle-ear model that has been experimentally validated. Parameters were first ranked using one-at-a-time sweeps and global methods (Morris and Sobol total-order indices) to identify and order model parameters by their influence on system outcomes. Parameters were grouped into high-, mid-, and low-impact tiers. Multi-batch SBI was then performed iteratively: first inferring high-impact parameters while fixing others at prior baselines, then sequentially unfreezing mid- and low-impact groups. This strategy reduces dimensionality at each stage while updating priors with maximum a posteriori (MAP) estimates.

Results: Sobol ranking with Saltelli’s sampling scheme ($\approx 30,000$ simulations) produced a clear hierarchy of influential parameters. Learning-curve analysis guided the number of simulations needed for each tier, and staged multi-batch SBI yielded stable posteriors and reproducible spectra. In contrast, conventional all-parameter SBI required orders of magnitude more simulations and often failed to converge consistently or reproduce reference experimental data.

Conclusions: Sensitivity-guided, tiered inference reduces the simulation burden of SBI while preserving interpretability. The framework provides a practical workflow for parameter ranking, staged inference, and efficient posterior convergence. Applied here to the middle ear as a case study, the approach demonstrates how complex biological systems with many parameters can be analyzed in a way that identifies the properties most critical to system function while ensuring

that neural network–based diagnosis remains computationally efficient and clinically interpretable rather than a black box.

SU175. A Unified Framework for Spectral Similarity and Parameter Confidence in Neural Network–Based Diagnosis

Amruta Koshe¹, Ehsan Sobhani-Tehrani¹, Kian Jalaie¹, Hamid Motallebzadeh*²

¹*iKinesia inc.* ²*California State University*

Background: Simulation-based inference (SBI) uses neural networks to map model parameters to outputs. This overcomes limitations of deterministic models that rely on fixed parameter sets, as SBI can capture uncertainty and variability. However, two challenges remain: (1) quantifying how well SBI-informed outputs match experimental spectra and (2) assessing confidence in inferred parameters. We propose a general framework that addresses both aspects, demonstrated here using middle-ear wideband immittance spectra.

Methods: Experimental reference data included repeated measurements of stapes velocity, ear-canal impedance, and absorbance (200 Hz–8 kHz) on a temporal bone. A finite-element model was used to generate training datasets with randomized parameter values, and SBI was trained to infer posterior distributions of seven physiologically meaningful middle-ear parameters. Spectral similarity was evaluated using three categories of measures:

- Point-to-point error metrics: MAE, RMSE, weighted RMSE, L1 and L2 norms, and maximum absolute error
- Distributional/divergence metrics: Wasserstein distance, AUC difference, and energy distance.
- Shape/trend metrics: dynamic time warping, cosine similarity, Pearson correlation coefficients.

Posterior confidence was quantified using entropy and distributional width measures (standard deviation, interquartile range (IQR), full width at half maximum (FWHM), mass width). Learning-curve analysis, varying simulation dataset size from hundreds to 10,000, identified the minimum data required for stable convergence of SBI training. Noise-sensitivity analysis evaluated the robustness and narrowness of posterior distributions under experimental variability. A majority-vote scheme integrated all metrics into two composite indices: the Spectral Similarity Index (SSI) and the Parameter Confidence Index (PCI).

Results: The SSI and PCI jointly identified conditions where SBI produced both accurate spectral fits and narrow, well-constrained parameter distributions. Learning-curve analysis revealed diminishing returns beyond a critical dataset size, while noise analysis exposed stability limits of posterior estimates. Importantly, SSI and PCI were calculated simultaneously across stapes velocity, ear-canal impedance, and absorbance, yielding a joint composite index rather than independent similarity scores for each spectrum.

Conclusions: This framework moves beyond single-metric evaluation by combining multiple similarity and confidence measures into unified indices. Although demonstrated here for model-to-data comparisons, it can be generalized to contexts where multiple spectral datasets (e.g.,

data-to-data) are compared. In doing so, it supports more robust model validation and strengthens confidence in parameter-based clinical decision-making.

SU176. Acoustic Measurement of Tympanic Membrane Displacement During Middle Ear Muscle Reflex Activation in Normal Human Ears

Mohammad Ehsan Khalili^{*1}, Jeffery Lichtenhan², Shawn Goodman¹, Stephen Neely³

¹*The University of Iowa*, ²*University of South Florida Morsani College of Medicine*, ³*Boys Town National Research Hospital*

Background: The same acoustic stimulus paradigm that has been used to detect middle-ear muscle reflex (MEMR) may be further analyzed to estimate the distance between the ear-canal probe and the tympanic membrane (TM). This study examines TM displacement in response to MEMR activation to infer contraction of the stapedius and/or tensor tympani muscles.

Methods: A train of acoustic clicks presented to the ear canal served as probes, and a contralateral broadband sound that increased and decreased in sound level served as a putative MEMR elicitor. Analysis of the acoustic response to click stimuli can provide meaningful interpretation when both magnitude and phase are used. Further analysis of the click response using the MEZ(Trademark) method (Merchant and Neely, 2021) provides estimates of middle-ear input impedance and TM displacement. An analog-circuit model of the ear canal and middle-ear was fit to individual click responses. The time-course of model components associated with the ossicular chain suggests how its stiffness and damping are altered by MEMR activation. The direction of TM displacement may indicate whether MEMR activation is dominated by contraction of the tensor tympani (medial) or stapedius (lateral) muscle.

Results: In the subset of measurements where (1) ear-canal impedance and middle-ear impedances were well fit by the model and (2) TM returned to its initial displacement after termination of the contralateral elicitor, TM displacement was about equally likely to be medial or lateral. Distributions of model component values across all well-fit measurements showed a significant decrease ($p < 0.01$) in stiffness of the ossicular chain and no significant change in other components.

Conclusions: Our findings are supported by a recent study of human temporal bones (Puria, 2023), which observed that contraction of the tensor tympani muscle or the stapedius muscle laterally displaces the umbo of the malleus either laterally or medially, respectively. Our approach may provide an avenue to understand the function of the tensor tympani muscle, which has remained poorly understood.

SU177. Leveraging Middle-Ear Input Impedance for Diagnosis of Conductive Pathologies

Anna Kamau^{*1}, Gabrielle Merchant², Hideko Heidi Nakajima³, Stephen Neely²

¹*Harvard University*, ²*Boys Town National Research Hospital*, ³*Harvard Medical School, Mass. Eye and Ear Infirmary*

Background: Machine learning-based classification has the potential to improve the accuracy and efficiency of diagnosing mechanical ear pathologies when applied to audiometric and wideband tympanometry (WBT) data. Previous studies show that pairing the air-bone gap (ABG) with absorbance, the most widely used WBT metric, yields better discrimination between stapes fixation (SF) and superior canal dehiscence (SCD) than either measure on its own. However, absorbance captures only magnitude and omits phase information, limiting its ability to fully characterize middle- and inner-ear mechanics. Impedance offers an advantage in this respect, but variability in ear canal acoustics may obscure its diagnostic value. By using a circuit model of the ear, these ear canal effects can be minimized, allowing the input impedance at the middle ear (ZME) to be estimated.

Methods: 97 ears were included in this study: 27 normal, 32 with confirmed SCD via CT scan, and 38 with SF confirmed via surgery. WBT data were collected with the Interacoustics Titan, and air- and bone-conduction thresholds (0.25-4 kHz) were obtained from patient audiograms. ZME was derived for each ear by fitting a lumped-element model composed of three parallel branches, each containing a stiffness (K), damping (R), and mass (M) element. The ear canal was represented as a transmission line to isolate ZME from the measured input impedance at the ear canal (ZEC). Logistic regression algorithms were trained with dimensionality reduction via PCA, and cross-validation was used to evaluate classification performance.

Results: The combination of ABGs and |ZME| achieved the lowest classification error rate (15%), outperforming ABGs and absorbance (22%). ABGs alone resulted in 20% error. Confusion matrix analyses showed that SF could be classified with perfect accuracy (100%) using ABGs and |ZME|, but SCD remained more difficult to identify, with correct rates under 70% across algorithms.

Conclusions: These findings suggest that impedance, when paired with ABGs, improves diagnostic classification compared to absorbance. Such classification algorithms could reduce reliance on imaging or surgical exploration, particularly for differentiating SF from SCD. Future work includes expanding the dataset, incorporating other conductive pathologies (e.g., ossicular discontinuity, malleus fixation), and exploring alternative model representations. In addition, the role of impedance across static pressure sweeps remains poorly understood. Future work also includes investigating whether the full pressure range from -300 daPa to +200 daPa may serve as an additional tool for distinguishing pathologies.

SU178. High-Frequency Bone-Conduction Thresholds (4–16 kHz) in Children: Feasibility, Reliability, and Early Disease Signatures

Vanessa Zhang^{*1}, Keelin Fallon¹, Barbara Herrmann², Jeffrey Cheng², Amanda Griffin³, Aaron Remenschneider³

¹UMass Chan Medical School, ²Massachusetts Eye and Ear Infirmary, ³Boston Children's Hospital

Background: Bone-conduction (BC) hearing thresholds are rarely measured above 4 kHz in routine practice, despite well-documented examples of high-frequency (HF) conductive hearing loss. Newly characterized BC transducers (Tascam and KLH96) with high output and low distortion permit reliable HF-BC measurement (4–16 kHz) in adults. We implemented HF-BC in

pediatric otology clinic to (i) assess thresholds in normal-hearing (NH) pediatric ears and (ii) explore HF hearing loss signatures of common middle ear disease in pediatric patients.

Methods: Children 5–16 y underwent standard and HF audiometry including air-conduction (AC) and BC thresholds at 4, 6, 8, 9, 10, 11.2, 12.5, 14, and 16 kHz. Contralateral masking was used when HF-AC asymmetry was ≥ 10 dB. Reliability was tested via serial threshold measurement at select frequencies (9 and 12.5 kHz). Audiometer output was converted to force (dB re 1 μ N) and to hearing level (dB HL) using our published HF-BC calibration protocol and adult reference thresholds (18–25 y). Pediatric cohorts included NH, otitis media with effusion (OME; flat tympanogram), and post-middle-ear surgery/disease (“post-surgical”).

Results: HF-BC thresholds were feasible as early as age 5 and measurable at 4–16 kHz. Reliability was typically ≤ 5 dB at 9 and 12.5 kHz. Pediatric median force thresholds were broadly similar to adult NH subjects; but select frequencies (4, 8, 16 kHz) showed pediatric medians ~ 10 –15 dB lower (better). Thresholds obtained with the KLH96 and Tascam in the same subjects were generally similar to test-retest variability with larger differences at 4–6 kHz, indicating a possible need for device-specific reference values.

Disease signatures: In an OME case followed longitudinally, HF-AC improved after tympanostomy tube placement while HF-BC remained stable, consistent with an HF air-bone gap (ABG) due to HF conductive hearing loss. In other post-surgical ears, we observed two patterns: (i) a conductive signature (stable HF-BC with improved HF-AC), and (ii) a sensorineural signature (HF-BC thresholds elevated relative to pediatric NH medians and tracking with AC). These examples illustrate HF-BC’s ability to separate conductive from sensorineural contributions at high frequencies.

Conclusions: HF-BC audiometry (4–16 kHz) is feasible in children, reliable at 8–12.5 kHz, and clinically informative for distinguishing type of HF loss in common pediatric conditions. Pediatric force medians are largely similar to adults but may be lower by ~ 10 –15 dB at select bands; larger datasets are needed to determine whether pediatric-specific RETVFLs are warranted. Findings also motivate parallel investigations in HF-AC references in this population. Overall, HF-BC provides a practical path to quantify HF ABGs and separate conductive from sensorineural effects to guide counseling and improve surgical outcomes.

SU179. Avian Cochlear Nucleus Neurons Exhibit a Tonotopic Developmental Delay of Hcn Current

Mary Kate Tanselle*¹, Kristine McLellan¹, Yuhang Zhang¹, Jason Sanchez¹

¹*Northwestern University*

Background: Functional hearing relies on the precise frequency-specific encoding of auditory stimuli. Nuclei in the auditory brainstem, such as the mammalian cochlear nucleus and the analogous avian nucleus magnocellularis (NM), are organized by different frequency-specific regions known as tonotopy. HCN channels across different frequency regions help support tonotopic tuning by the underlying mediated current known as I_h . While it is known that low-frequency regions of NM exhibit a developmental delay compared to the high-frequency areas,

differences in HCN channel expression and I_h across development and tonotopic regions remain unknown. This study aims to fill this knowledge gap.

Methods: We recorded from high- and low-frequency regions (HF and LF, respectively) of brainstem slices before (embryonic (E) days 12-13), during (E15-16), and after hearing onset (E20-21). Voltage clamp recordings from NM neurons measured I_h from holding voltages between -40mV to -130mV in 10mV increments. I_h was measured with Steady State (SS) and different current techniques and compared. Fast and slow I_h activation kinetics were fit with single and double exponentials to explore HCN channel subunit contribution.

Results: I_h increases significantly across development for all NM neurons. However, in embryos before hearing onset, high-frequency neurons have significantly more I_h than low-frequency neurons. In embryos during hearing onset, HF and LF difference currents are similar, while HF neurons still have a greater inward SS current than LF neurons. Finally, for embryos after hearing onset, there is no significant difference between HF and LF neurons for either SS or difference current. Activation kinetics are similar across the tonotopic axis throughout development.

Conclusions: Results suggest that at the beginning of neural circuit development, HF neurons have more HCN channels than LF neurons. Furthermore, I_h magnitudes increase across development with HF neurons developing sooner than LF neurons with respect to HCN channels. Since activation kinetics do not differ across development or tonotopy, results suggest that subunit composition of HCN channels is not changing during development, nor is it different across the tonotopic axis. Taken together, we conclude that LF neurons experience a developmental delay in the number of HCN channels present, with I_h catching up to HF neurons by the onset of hearing. Characterizing the development of auditory brainstem neurons across the tonotopic axis is a crucial step in elucidating how normal central auditory systems function effectively in vertebrates.

SU180. Auditory-Visual Speech Integration is Supported by Frontal-Cortical Engagement in Older Adults

James Dias^{*1}, Carolyn M. McClaskey¹, Kelly C. Harris¹

¹*Medical University of South Carolina*

Background: Older adults with age-related auditory (AO) and visual (VO) speech perception deficits can often identify audiovisual (AV) speech to a degree of accuracy like that of younger adults. We have previously reported that this enhanced AV speech perception (relative to unisensory deficits) by older adults can be explained by auditory-visual multisensory perceptual benefits that are > in younger adults. Poorly understood, however, are the neural mechanisms that support AV speech perception in older adults with age-related auditory and visual deficits. Cortical activity in inferior-frontal and temporoparietal cortex has previously been found to be a stronger predictor of AV speech encoding in older adults than younger adults, especially in noisy listening conditions, suggesting that higher-level cortical engagement may support auditory-visual speech integration in older adults. Here we examined how the functional connectivity between inferior-frontal cortex and temporoparietal cortex can predict auditory-visual enhancement of AV speech perception in younger and older adults. We hypothesized that

stronger functional connectivity between cortical areas would predict more auditory-visual enhancement in older adults than in younger.

Methods: A group of 10 younger normal-hearing adults (20-30 years of age, 7 female) and 14 older adults (54-80 years of age, 7 female) with normal hearing or mild-to-moderate sensorineural hearing loss completed an audiovisual speech identification task, identifying words spoken in Gaussian noise (-5, 0, +5 dB SNR) presented in AO, VO, and AV conditions. We calculated auditory-visual enhancement from identification performance across conditions [$AVE=AV-(AO+VO)$]. Speech-evoked potentials (SEPs) were recorded separately while participants were passively presented consonant-vowel syllables (/ba/, /da/, /ga/) in audiovisual conditions in silence and in Gaussian noise at 0 dB SNR (240 trials per condition). Each participant's AV SEP and T1 structural image were used to source-constrain their SEPs to inferior-frontal cortex and temporoparietal cortex to measure the response generated in each cortical area. For each participant, metrics of functional connectivity between inferior-frontal and temporoparietal cortex were computed for responses evoked by AV speech (cross-correlations and dynamic time warping distance).

Results: AV SEP response latencies in inferior-frontal and temporoparietal cortex were longer for older adults than younger adults in inferior-frontal and temporoparietal cortex. AV response latencies in inferior-frontal cortex were shorter in noisy listening conditions, but only for older adults. Importantly, greater functional connectivity between inferior-frontal and temporoparietal cortex when listening to AV speech in noise predicted larger multisensory benefits in speech identification (AVE).

Conclusions: These preliminary findings suggest that older adults rely on a functional network between inferior-frontal and temporoparietal cortex when identifying AV speech in noisy listening conditions, more so than younger adults. The results will be discussed with regards to age-related changes in sensory processing and cognition and the potential role of visual input in alleviating age-related deficits in auditory speech communication.

SU181. Mechanisms for Generation and Control of EMREOs (Eye Movement-Related Eardrum Oscillations)

Stephanie Lovich^{*1}, Steven Eliades², David Kaylie¹, Cynthia King¹, Christopher Shera³, Jennifer Groh¹

¹Duke University, ²Duke University School of Medicine, ³University of Southern California

Background: Accurate information about eye movements is necessary for audiovisual integration because such movements shift the positions of the eyes with respect to the head/ears. We have recently reported an eardrum oscillation, time-locked with eye movement onset and occurring in the absence of outside auditory stimuli, that suggests eye movement information is sent by the brain to the ears (Eye movement-related eardrum oscillation, EMREO; Gruters et al. PNAS 2018; Lovich et al. PNAS 2023). But what is the proximal and neural mechanism producing such eardrum oscillations? The chief suspects are the middle ear muscles (MEMs) and the outer hair cells (OHCs).

Methods: We recorded eye movements and associated eardrum oscillations in rhesus monkeys before and after surgical intervention involving the MEMs -- specifically, stapedotomy and

tensor tympani tenotomy. Such transections of the tendons connecting the MEMs to the ossicles are typically done in human patients suffering from otosclerosis or MEM myoclonus, and the procedures were adapted here for the monkey. The procedures served to eliminate the contribution of the particular MEM in question to the EMREO.

Results: Sectioning MEM tendons did not eliminate the EMREO. Following stapedotomy, the EMREO was reduced in amplitude but still occurred. Following tensor tympani tenotomy, the EMREO was actually increased in amplitude. When stapedotomy and tensor tympani tenotomy were combined, the EMREO still occurred, and was again increased in amplitude. Together these findings suggest the MEMs are not the sole cause of the EMREO, but rather regulate its amplitude likely in a push-pull fashion. These results from animals are largely consistent with related preliminary data in human clinical patients who have undergone similar procedures.

A general caveat to the interpretation of the MEM surgical interventions is that the procedure may change the mechanical load on the eardrum such that interpretations of changes in amplitude of the EMREO signal should be confirmed by additional research. However, that the EMREO continued to exist even after both MEMs were disconnected from the ossicles indicates that there must be an additional source of force contributing to the signal. The most likely such source is the OHC, which could potentially generate this signal by oscillating in concert throughout the cochlea. It is also possible that in the event of OHC dysfunction, the signal can be generated by MEMs acting alone, a possibility not tested here.

Conclusions: We interpret these findings in the context of how eye movements may alter sound localization cues. Recent work has shown that forces applied by the MEMs to the eardrum in a cadaver model could alter both interaural timing and level difference cues in an eye movement-dependent way (Cho et al., Hearing Research 2023).

SU182. Component Analysis of Distortion Product Otoacoustic Emissions in Children for f2 up to 12 kHz

Uzma Akhtar^{*1}, Ana Paula Bruner², Renata Mota Mamede Carvalho², Shawn Goodman³, Sumitrajit Dhar⁴, Alessandra Spada Durante⁵

¹*Rush University Medical Center*, ²*FMUSP, São Paulo - Brasil*, ³*The University of Iowa*,

⁴*Northwestern University*, ⁵*UNIFESP, FCMSCSP, São Paulo – Brasil*

Background: Distortion product otoacoustic emissions (DPOAE) recorded in the ear canal are mixtures of non-linear distortion and linear reflection components. Each component has its own hypothesized generation source and mechanism based on its phase-frequency behavior. However, little is known about the components' behavior in the first decade of life particularly for $f_2 > 8$ kHz. Here we report on individual DPOAE components measured using low stimulus levels, which are more sensitive to cochlear status yet difficult to measure in noisy ears. Thus, multiple signal cleaning strategies for handling noisy recordings are described.

Methods: 94 children between the age of 6 weeks and 11 years were recruited from a maternity hospital in São Paulo, Brasil. With the Etymotic Research 10X system, DPOAE were measured using fixed ratio of 1.22 for f_2 frequencies between 1.5 and 12 kHz and $L1/L2 = 55/40$ dB FPL using a 96 kHz sampling rate. Time domain waveforms were sent through a multi-step artifact rejection protocol followed by a least-squares-fit based frequency analysis and weighted

averaging procedure. The complex level and phase were then processed using continuous wavelet transform, during which the complex signals were convolved with an array of mother wavelet basis functions and resulting coefficients were filtered into different latency bands according to Moleti et al (2008). The filtered signals were separated as zero-latency distortion components and non-zero-latency reflection components. The time-frequency representations as well as level and phase behaviors were compared for three signal cleaning methods.

Results: 76 ears had recordable DPOAE above the noise floor at primary levels of 55/40 dB FPL. Nine ears with the highest quality recordings as determined by 9 dB SNR criteria across 90% of the spectrum were used as the gold standard for our analysis. The time-frequency representations of these nine ears demonstrated DPOAE energy hotspots that were constrained in the first and second latency bands with little to no signal outside of these bands. In contrast to these nine exemplar recordings, the time-frequency representations of noisier recordings displayed energy at latencies outside of the expected frequency-latency function at randomly distributed spectral regions. Furthermore, phase behavior of the total DPOAE and distortion component occasionally varied with frequency, a phenomenon not consistent with the fixed phase of distortion emissions in fixed-ratio recordings.

Conclusions: The influence of physiological and environmental noise on DPOAEs evoked by low stimulus levels must be considered when separating individual components. Advanced signal processing methods such as SNR-weighted averaging, multi-step artifact rejection, continuous wavelet transform that can numerically quantify the unwanted noise residuals, and time-frequency representations that can visually display noise contributions may be useful and will be discussed. Future studies are warranted to examine the utility of these methods for improving detection of DPOAE responses at low stimulus levels.

SU183. A Transmission Line Model of the Cochlea Under Noise Produces Four Distinct Categories of Spontaneous Emissions

Dani Agramonte*¹, Julien Meaud¹

¹*Georgia Institute of Technology*

Background: Spontaneous Otoacoustic Emissions (SOAEs) are indicative that cochlea is an active, nonlinear system. Existing research has shown the transmission line models of the cochlea with roughness can predict narrow band peaks in the absence of any external stimulus, i.e. SOAEs; however, these models are limited to only describing narrowband bimodal peaks. Existing human SOAE experimental data show that SOAEs include not only narrowband bimodal peaks but also broadband unimodal peaks.

Methods: The cochlea is studied using a modified version of the Ku and Elliot model, which is a 1D transmission line model. Roughness is introduced by adding small (0.25%) perturbations to the activity parameter γ . Full spectrum white noise is applied to the basilar membrane and is uncorrelated in time and space. The nonlinear dynamics of the model are simulated numerically in the time-domain before analyzing the spectrum of the response at the stapes and evaluating how the key characteristics of the spectrum are linked to the linear stability analysis of the model. Spectral peaks are characterized by their quality factor (tuning sharpness), level, and their time domain distribution.

Results: The model with noise predicts a series of spectral peaks with a wide range of levels, quality factors, and Hartigan dip statistic values. Comparison of the SOAE spectrum to the linear stability diagram (eigenvalues of the state-space matrix) helps to interpret the numerical results. Our analysis suggests that SOAE peaks can be naturally divided into four categories: (1) Primary SOAE Type A peaks; (2) Primary SOAE Type B peaks; (3) Filtered noise peaks; (4) and Distortion product SOAE (DPSOAE) peaks. Primary SOAE Type A and B peaks are associated with unstable eigenvalues; Type A appear in the noiseless case and the case with noise, and Type B appear only in the case with noise. Filtered noise peaks are associated with nearly unstable eigenvalues and act as lightly damped harmonic oscillators. Distortion product SOAE peaks are peaks which are distortion products of primary SOAE peaks.

Conclusions: With an extension to the existing linear stability analysis and the introduction of noise into the transmission line model of the cochlea, we demonstrate how the shortcomings of existing transmission line models can be overcome, and we observe additional phenomena from the introduction of noise which was not previously predicted. The presence of different categories of SOAE peaks provides a novel lens through which to understand SOAE spectra through.

SU184. Growth of DPOAEs Evoked by the Fixed L1 Stimulus Paradigm

Julia Roemen^{*1}, M. Ehsan Khalili¹, Mary E. Meskan², Parisa Jalilzadeh Afshari², Jeffery T. Lichtenhan³, Sumit Dhar², Shawn S. Goodman¹

¹*The University of Iowa*, ²*Northwestern University*, ³*University of South Florida*

Background: Distortion product otoacoustic emission (DPOAE) magnitudes measured across a range of stimulus levels as level growth functions (LGFs) may be useful for assessing cochlear function and health. The observed LGF shapes depend on the variety of stimulus paradigms that have been reported in the literature. Recent work has suggested that the slopes of LGFs from the fixed L1 paradigm may differentiate types of cochlear hearing loss; however, normal LGF growth in this paradigm is not well understood. LGFs are typically fitted with mathematical functions from which slopes can be derived and (behavioral) thresholds can be predicted. However, fitting LGFs at low stimulus levels is challenging, due to poor signal-to-noise ratios (SNRs). Here, we describe a generalized linear statistical model (GLM) appropriate for fitting LGFs at varying SNRs, including portions of the LGF that fall below the noise floor. The primary aim of this study was to characterize fixed L1 LGFs at low-to-moderate levels in young listeners. A secondary aim was to evaluate the hypothesis that functions fit to these LGFs accurately predict DPOAE magnitude at low stimulus levels ($L2 = 5$ dB FPL), which produce responses that are typically below measured noise floors.

Methods: DPOAE LGFs were recorded from 12 young, healthy adult participants (9 female, mean = 22.9 yr) using an ER10X probe system and custom software. L1 was held constant at 65 dB FPL, while L2 swept in level from 0 to 70 dB FPL in 9 seconds. Each test consisted of 24 nine-second sweeps for a total test time of 216 seconds. For evaluating the fit at low levels, discrete measurement was also obtained at $L2 = 5$ dB FPL, a low stimulus level eliciting DPOAEs well below the typical noise floor. This low-level DPOAE was recorded for a long period of time (~26 minutes averaging time) to reduce the noise floor to near -40 dB SPL. A phenomenological model was used to generate simulated data for comparison with human data.

Results: Data from healthy young adult listeners, along with simulations from a phenomenological model, established that at low to moderate L2 and a fixed L1, LGFs grow as polynomials dominated by the linear term, with smaller but important contributions from the quadratic and cubic terms. The GLM predicted DPOAE magnitudes at low stimulus levels with a mean error < 0.4 dB (SD = 2.2 dB).

Conclusions: This improved understanding of expected LGFs in healthy ears provides a foundation for future studies of the relationship between fixed L1 LGFs and cochlear health.

SU185. Auditory Novelty Detection Impairment in Rats Treated With the Nmda Receptor Antagonist MK-801: A Model of Schizophrenia

Ana Belén Lao Rodríguez*¹, Lucia Licerán¹, Martina Mansilla¹, Ángela M. López¹, Manuel Malmierca¹

¹*Cognitive and Auditory Neuroscience Laboratory*

Background: Animals are constantly exposed to a wide range of environmental sounds. While many of these are irrelevant, the detection of novel stimuli is crucial for survival. Behavioral habituation, a fundamental form of learning, is characterized by the progressive reduction of responses to repeated stimuli and provides the foundation for detecting unexpected changes (Rakin, 2009; Netser et al., 2011; Quintela-Vega et al., 2023). This ability is closely linked to mismatch responses observed at both neuronal and behavioral levels, which have been conceptualized within the predictive coding framework. These responses rely on repetition suppression to predictable stimuli and prediction error signals when expectations are violated. Importantly, reduced mismatch responses have been consistently associated with schizophrenia and glutamatergic dysfunction in humans. To investigate this, we used a pharmacological model based on the NMDA receptor antagonist MK-801, which reproduces schizophrenia-like features by disrupting neuronal adaptation and associative learning mechanisms (Parras et al., 2017; Ishishita et al., 2019).

Methods: We trained eight freely moving female Long Evans rats to discriminate deviant tones in an oddball paradigm. Animals learned to nose-poke in response to deviants, which were rewarded with food pellets. A pair of frequencies within the auditory range (8.0–11.3 kHz) was used, and discrimination was tested across inter-stimulus intervals (1.0, 1.5, and 2.0 s) with a 10% deviant probability. A many-deviant paradigm was also applied to control for predictive coding indices: mismatch (iMM), prediction error (iPE), and repetition suppression (iRS). Behavioral performance was quantified using d' index. Once the animals reached reliable performance (d' > 1), they were divided into two groups: control and MK-801. Both saline and MK-801 (0.075 mg/kg) were administered subcutaneously 45 min before the behavioral deviance detection task. Finally, neuronal activity was recorded in the auditory cortex and the inferior colliculus using multi-channel probes and equivalent paradigms to study neuronal responses.

Results: Preliminary results show that saline-treated animals continued to improve in the deviance detection task during treatment, whereas MK-801-treated rats exhibited a significant impairment in performance after drug administration.

Conclusions: These findings suggest that NMDA receptor blockade with MK-801 disrupts auditory novelty detection at both behavioral and neural levels. This pharmacological model provides valuable insights into the mechanisms underlying sensory and cognitive deficits in schizophrenia.

SU186. Serotonergic Modulation of Auditory Cortical Circuits

Mary Chaves^{*1}, Carolyn Sweeney², Christine Junhui Liu², Lucas Vattino², Anne E. Takesian²

¹*Harvard University*, ²*Massachusetts Eye and Ear/Harvard Medical School*,

Background: Auditory experience powerfully shapes the functional organization of the developing auditory cortex (ACtx), but this plasticity declines in adulthood. Neuromodulator release can reinstate robust plasticity in the adult brain, offering potential to promote recovery from neurological disorders or peripheral hearing loss. However, the mechanisms by which distinct neuromodulators act within cortical circuits to drive plasticity remain incompletely understood. For example, serotonin (5-HT) modulates tonotopic plasticity in the adult ACtx, but the underlying cellular and circuit mechanisms are unknown. Prior studies, including our own, have mapped serotonergic axons throughout ACtx and localized diverse 5-HT receptor mRNAs to distinct populations of excitatory pyramidal neurons and GABAergic interneurons. Specifically, subsets of deep-layer somatostatin-expressing (SST) inhibitory interneurons predominantly express transcripts encoding inhibitory 5HT1A receptors and may therefore serve as key targets of serotonergic modulation. We hypothesize that 5-HT selectively suppresses SST inhibitory interneurons to dynamically sculpt network activity.

Methods: To identify the effects of 5-HT on SST interneurons, we combined whole-cell electrophysiology and two-photon (2-P) imaging in thalamocortical slices of mouse ACtx.

Results: Local 5-HT application reliably hyperpolarized layer 5 (L5) SST interneurons and suppressed spike amplitude, which was abolished by bath application of a selective 5-HT1A antagonist. Given that subsets of SST interneurons expressing the 5-HT1A receptor form local projections, we employed optogenetic activation of SST interneurons to probe serotonergic modulation of SST inhibitory output onto L5 pyramidal neurons. We observed that bath-applied 5-HT reduced SST-mediated inhibition onto the majority of these neurons.

SST interneurons have been previously shown to curtail runaway excitation during periods of prolonged cortical activity. Using 2-P imaging to interrogate the effects of 5-HT on the cortical network, we demonstrated that 5-HT prolongs calcium responses evoked by repetitive thalamic

stimulation in subsets of L5 pyramidal neurons, consistent with reduced SST-mediated inhibition.

Conclusions: Ongoing work is examining whether serotonergic actions on specific SST interneuron subclasses mediate layer-specific modulation. L5 serves as the principal output layer of the cortex, suggesting that 5-HT may gate information flow from primary ACtx to higher-order cortical and subcortical targets. Together, these studies provide new insight into the cellular and circuit mechanisms by which 5-HT modulates ACtx, informing the development of targeted strategies to induce layer-specific neuronal changes that may enhance adult cortical plasticity.

SU187. Decision-Making Shapes Auditory Cortical Responses to Harmonic Complex Tones in Noise

Jason Putnam*¹, Nikolas Francis¹

¹*The University of Maryland*

Background: Background noise often presents a challenging acoustic environment for listening. Adaptive plasticity in auditory cortex is thought to facilitate hearing in noise by adjusting the gain of neural responses to behaviorally meaningful sounds. However, it remains unclear how adaptive plasticity facilitates the recognition of auditory perceptual features with masked acoustic components, such as the missing fundamental frequency (F0) of a harmonic complex tone (HCT) in background noise. Since mice have high-frequency hearing, neurons in auditory cortex that are tuned to low F0s encode missing-F0s in HCTs. Thus, we hypothesized that adaptive plasticity in mouse auditory cortex facilitates the recognition of missing-F0s in noise by modulating the activity of F0-selective neurons relative to background noise level.

Methods: Background noise often presents a challenging acoustic environment for listening. Adaptive plasticity in auditory cortex is thought to facilitate hearing in noise by adjusting the gain of neural responses to behaviorally meaningful sounds. However, it remains unclear how adaptive plasticity facilitates the recognition of auditory perceptual features with masked acoustic components, such as the missing fundamental frequency (F0) of a harmonic complex tone (HCT) in background noise. Since mice have high-frequency hearing, neurons in auditory cortex that are tuned to low F0s encode missing-F0s in HCTs. Thus, we hypothesized that adaptive plasticity in mouse auditory cortex facilitates the recognition of missing-F0s in noise by modulating the activity of F0-selective neurons relative to background noise level.

Results: Mice successfully discriminated between target vs. non-target F0s in silence ($d' > 1$), with performance declining as SNR decreased. Average neural responses to HCTs also declined with SNR, however, neural responses depended strongly on behavioral choice. As SNR decreased, neural responses during behavioral hits and false alarms increased and decreased, respectively. In contrast, neural responses during correct rejections and misses were less choice-dependent, generally increasing with noise level.

Conclusions: Our results suggest that during perceptual discrimination of missing-F0s, neural responses to HCTs in noise reflect a combination of sensory coding and decision-making processes in auditory cortex. Together, these mechanisms may facilitate listening in challenging acoustic environments.

SU188. Maturational Changes in Listening Effort During a Degraded Speech Task in Adolescents and Young Adults

Kiara Derbyshire¹, Bruna Mussoi², Jennifer Roche¹, Julia Huyck*¹

¹*Kent State University*, ²*University of Tennessee Health Science Center*

Background: Understanding speech in challenging listening conditions, such as noisy environments or with degraded signals, is a skill that requires intact auditory encoding, deployment of listening effort, and application of cognitive skills. While some studies have indicated that perception of degraded speech continues to mature during adolescence, others have not. Here we examined (1) whether behavioral performance on a degraded speech task changes during adolescence and young adulthood, (2) how adolescents and young adults deploy listening effort during this task, and (3) the relationship between task performance and listening effort over this age range.

Methods: We tested 10- to 23-year-olds (n=76) on 6-band noise-vocoded (NV) speech under two conditions: NV speech immediately followed by a period of silence or NV speech immediately followed by multi-talker babble. Listeners were asked to repeat back what they heard following either the silent period or the babble. Based on Winn and Moore's (2018) prior work with hearing-impaired listeners, we hypothesized that it would require more listening effort for all listeners to comprehend the speech when it was followed by babble, but that these effects would be more pronounced in adolescents. We assessed listening effort using an eyetracker to measure pupil size during pre-trial baseline, the sentence, the babble or silence, and the participant's response (i.e., repeating back the sentence). We analyzed pupil size change relative to baseline over the course of the trial and compared these temporal dynamics between the silence and babble conditions and between the age groups. Consistent with convention in the field, larger pupil size compared to baseline was interpreted as indicative of greater listening effort.

Results: The temporal dynamics of listening effort differed between the age groups and the two listening conditions. In addition, the adolescents demonstrated greater listening effort despite poorer performance on the degraded speech comprehension task.

Conclusions: These data suggest that degraded speech perception continues to mature during adolescence. Poorer performance by teenagers occurred despite higher levels of listening effort, indicating that their prolonged perceptual development is not attributable to poor engagement. Other factors that may contribute to this late maturation include developmental changes in auditory encoding and cognitive processing.

SU189. Ideal Observer Analysis of the Effects of Medial Olivocochlear Gain Control on Neural Coding of Sound Level and Amplitude Modulation

Daniel R. Guest*¹, Laurel H. Carney¹

¹*University of Rochester*

Background: The medial olivocochlear (MOC) system reduces cochlear gain in response to sound. One hypothesis for the MOC system's role is that it adjusts cochlear gain to improve

sound coding at moderate sound levels. For example, when detecting amplitude modulation (AM) of a mid-level signal, a reduction in cochlear gain could reduce the deleterious effects of cochlear compression and/or synaptic saturation and enhance AM detection. This gain reduction could be elicited by sound preceding the AM stimulus (precursor). Some psychophysical data on level discrimination and AM detection with precursors appear qualitatively consistent with this hypothesized role of the MOC system. However, due to nonlinearities present in the auditory periphery, it is difficult to predict how much cochlear gain changes should be expected to change behavioral thresholds.

Methods: To quantitatively predict the effects of MOC gain control on level discrimination and AM detection, we used a model of the auditory periphery and midbrain modified to include a simple MOC reflex driven by stimulus energy. We simulated responses in this model to level discrimination and AM detection stimuli with and without precursors and then used ideal observer analysis to determine theoretical bounds on the effects of cochlear gain changes on task performance. Both rate-based and temporal coding schemes were evaluated, and we applied the framework to several stages in the model to better understand how the effects of MOC gain control manifest along the ascending auditory pathway.

Results: Ideal observer analysis revealed that, at moderate sound levels in single model channels, reductions in cochlear gain enhance level discrimination and AM detection, consistent with classical theories of MOC gain control. However, effect sizes for level discrimination and AM detection were small in peripheral model stages for both rate-based and temporal codes. For example, at 60 dB SPL in low-spontaneous-rate auditory-nerve fibers, a 10-dB change in cochlear gain resulted in a predicted change in level discrimination thresholds of only ~1 dB and AM detection thresholds of only ~2 dB, raising questions about whether these effects would be detectable behaviorally. Moreover, in contrast to single-channel results, when observers had access to off-frequency channels, predicted effects of cochlear gain on perceptual sensitivity were negligible.

Conclusions: Our simulations support the idea that the MOC system enhances coding of sound level and AM. However, at the same time, our simulations suggest that surprisingly large changes in cochlear gain may be required to produce measurable threshold changes in behavioral tasks designed to explore the MOC reflex.

SU190. Measures of Subclinical Hearing Function: Long-Term Test-Retest Reliability and Relations Between Change Outcomes

Hannah Guest¹, Rebecca Dewey², Karolina Kluk-de kort¹, Rebecca Millman*¹, Kevin Munro¹, Carlyn Murray¹, Garreth Prendergast¹, Stephen Roberts¹, Christopher Plack¹

¹*The University of Manchester*, ²*University of Nottingham*

Background: Noise exposure is the main cause of preventable hearing loss (Rabinowitz, 2000) and recreational noise may pose a particular hazard in young people (WHO, 2015). Studies of hearing health in the younger population (e.g., Henderson et al., 2011; Carter, 2014; Keppler et al., 2015) have tended to focus on pure-tone audiometry (PTA: detection thresholds of pure tones

at different frequencies) but PTA may be relatively insensitive to the early effects of noise damage.

We conducted a longitudinal study investigating changes in auditory function over a three-year period, during which many participants started regularly attending high-sound-level environments (e.g., live music events and nightclubs). Our participants underwent an extensive battery of physiological, psychoacoustic and self-report measures with the aim of identifying early markers of noise damage. Here we report on relations between the various hearing change measures, with particular focus on disentangling the effects of hair-cell damage and synaptic pathology. We also report on the longer-term test-retest reliability of potential early markers of recreational noise damage in young people.

Methods: Participants were 220 teenagers aged 16 or 17 at the time of their baseline test session (Nov 2021 – Dec 2022). Follow-up test sessions took place from Nov 2024 to Jan 2026. At each test session, participants completed a battery of hearing tests:

- Cochlear function: Pure-tone audiometry (0.25-8 kHz), extended high-frequency audiometry (1/3-octave narrowband noise centred at 10 kHz, 12.7 kHz, and 16 kHz), and distortion-product otoacoustic emissions (2f1-f2 amplitude, at f2 frequencies of 3-16 kHz).
- Auditory neural function: Auditory brainstem responses to monaural filtered chirps and ipsilateral middle-ear muscle reflexes with two tonal probes (226 Hz and 1 kHz) and a 4-kHz tonal elicitor.
- Speech perception: Three digits-in-noise tests (monaural digits in speech-shaped noise, diotic digits in spatially separated babble, and diotic digits with two competing, concurrent, spatially separated digit streams).
- Self-report measures: short-lasting and long-lasting spontaneous tinnitus.

Hearing change measures were defined as the difference or the ratio between these outcomes measured at baseline and then again at follow-up (post – pre or post/pre).

Results: At the time of abstract submission, 180 of the 220 participants had been invited to complete the final testing session, of which 170 had attended. The study was powered based on 60% retention, yet participant retention was much higher: on track for ~89% (n = 195) by the close of the study. Data analysis was scheduled for the fourth quarter of 2025.

Conclusions: The large sample size, longitudinal design, and broad array of measures offer novel opportunities to explore the reliability and interrelations of subclinical hearing measures over the course of years. Results will have implications for the interpretation of research reliant on the use of such measures in young adults.

SU191. Identifying the Acoustic Fingerprints of Trigger Sounds and Predicting Discomfort for Misophonia

Alex Clonan¹, Ian Stevenson¹, Monty Escabi^{*1}

¹*University of Connecticut*

Background: Human hearing is critical to everyday communication and the perception of natural auditory scenes. For individuals with misophonia, sounds commonly experienced in daily life can evoke severe discomfort and distress. Aversion is often described in terms of broad

sound categories, such as bodily sounds, but what acoustic features cause specific sounds to be aversive or not, within the same category or across different individuals, remains unclear. Here, we explore whether bottom-up statistical sound features processed in the auditory periphery and midbrain can explain aversion to sounds.

Methods: Using the Free Open-Access Misophonia Stimuli (FOAMS) dataset and a hierarchical model of the auditory system, we find that sound summary statistics extracted from the auditory model can predict discomfort ratings in participants with and without misophonia. The model was fit to each individual using Generalized Perceptual Regression (Clonan et al 2025) which produces individualized transfer functions that pinpoint specific spectrotemporal modulations that contribute towards sound aversion. Model parameters were also compared to diagnostic evaluations of misophonia (Duke Misophonia and S-Five questionnaires).

Results: Overall, the model explains 76% of the variance in discomfort ratings, and we find substantial differences across participants in which sound features drive aversion. An advantage of the approach here is that it is sound-computable – perceptual ratings can be fit from or predicted for any sound. To illustrate applications of sound-computable models, we consider 1) extrapolation to a large set of untested environmental sounds and 2) personalized trigger detection in continuous audio. Model predictions accurately predict aversion to FOAMS sounds and identify untested sound categories, not in the original FOAMS set, that may also be aversive. This suggests that there may be substantial heterogeneity in how aversive specific sounds are within some sound categories. In continuous audio, we show how sound-computable models can identify the timing of potential triggers from sound mixtures. Finally, parameters of the model that account for the listener’s perceptual sensitivity were significantly correlated with diagnostic evaluation scores.

Conclusions: Altogether, our results suggest that acoustic features – spectrotemporal modulations, in particular – can practically be used to characterize the individualized patterns of aversion in participants with misophonia. Future perceptual studies using synthetic sounds and sound sets with more diverse acoustics will allow model predictions to be tested more broadly; however, sound-computable models may already have applications in precision diagnosis and management of misophonia. Funded by NIH (R01DC020097).

SU192. The Contribution of Speech Articulatory and Statistical Sound Features Towards Speech Recognition in Natural Auditory Scenes

Alex Clonan^{*1}, Ian Stevenson¹, Monty Escabi¹

¹*University of Connecticut*

Background: Humans excel at recognizing speech in natural auditory scenes despite large variation in speakers’ voice quality, intonation, and pitch. We previously demonstrated that different types of background sounds and their spectrotemporal statistics can improve or worsen speech recognition accuracy (Clonan et al 2025). However, how foreground speech features, such as fundamental frequency or formants, influence speech recognition accuracy is not well understood.

Methods: Here we explore how different speech articulatory features interact with natural and perturbed background sounds to influence speech recognition abilities. Participants (n=10) were required to recognize digit sequences (e.g., 0-9-1, 2-5-7) generated by adult and adolescent male

and female talkers and then mixed with various natural background sounds (e.g., water, babble, construction noise etc.; SNR= -9 dB) and perturbed background variants with distorted spectrum or modulation statistics. To characterize the unique interactions between the foreground and background sound statistical features, we used a hierarchical model of the auditory periphery and auditory midbrain, paired with generalized perceptual regression (GPR; Clonan et al 2025). GPR models perceptual judgments of single listeners with the neural-acoustic model and allows perceptual outcomes for arbitrary speech-foreground combinations to be predicted using auditory model features.

Results: We found that different spoken digits had different accuracies depending on both the background sound statistics and the speaker's voice. To explore these speech driven effects, we compared recognition abilities across the speech fundamental (F0), first formant (F1), and second formant (F2) frequencies, and harmonicity. Using a generalized linear mixed effects model, we found substantial, statistically significant trends for digit identity, F0, F1, and F2, on recognition accuracy, in addition to background-driven effects. Furthermore, we find that the neural inspired GPR model captures nearly 76% of the perceptual variance across background and digits. This model, based on spectral and temporal modulation statistics, successfully explains differences in recognition accuracy associated with individual talkers and talker identity (male, female, adult, adolescent) as well as differences associated with formant and harmonicity structure.

Conclusions: These results further identify foreground and background sound features that influence speech recognition in natural environmental noise and suggest that auditory computations involving modulations may underlie perceptual outcomes. Funded by NIH (R01DC020097).

SU193. Similarity and Divergence in Human and Machine Speech Recognition

Annika Magaro¹, Erica Shook², Alex Kell¹, Gasser Elbanna³, Mark Saddler⁴, Josh McDermott¹

¹MIT, ²Zuckerman Institute, Columbia University, ³Harvard University, ⁴Technical University of Denmark

Background: Advances in machine learning have yielded machine systems that often approach human levels of performance on real-world perception tasks. For instance, models trained to recognize speech in noise reproduce some characteristics of human speech recognition. However, human and model speech behavior have not been extensively compared, leaving the extent to which such models can account for human speech perception unclear.

Methods: We measured word recognition abilities in humans and models across 37 types of speech distortions, spanning natural sources of distortion (e.g. background noise and reverberation) and artificial distortions (e.g. noise vocoding and audio filtering). We evaluated a set of industry speech recognition models along with in-house models. To investigate the factors that might give rise to human-like performance, we manipulated the architecture and the variability of training data for the in-house models. We measured the match between human and model performance across distortions.

Results: Two recent industry speech recognition models trained on hundreds of years of labeled speech (Whisper and Parakeet) exhibited high rank correlations with the pattern of human performance, but in absolute terms were superhuman on most types of distortion, and as a consequence were poor quantitative models of human speech recognition. In-house models with transformer-based architectures trained on a dataset that was intended to be more realistic in size (around 1400 hours) and variability produced better quantitative matches to humans. The match to human behavior was worse for models trained on less variable speech data, and for models that had exclusively convolutional architectures, even when they were matched in number of parameters.

Conclusions: The results are consistent with the idea that the robustness of human speech recognition results from the variability of real-world experience, but suggest that the computational architecture contributes to obtaining human-like generalization. Overall, the results show that superhuman performance is possible with systems that are optimized over enough data, and indicate that accurate models of human speech recognition can be obtained by optimizing models over the amounts and types of speech audio that humans are plausibly exposed to over developmental timescales.

SU194. Benchmarking Artificial Neural Network Models of Human Auditory Processing With Sound Similarity Judgements

Aidan Seidle^{*1}, Jenelle Feather², Malinda McPherson¹

¹*Purdue University*, ²*Carnegie Mellon University*

Background: With the increasing use of artificial neural networks (ANNs) in psychology and neuroscience, it is critical to pick appropriate benchmarks to assess how well such networks capture aspects of human perception and cognition. Most of this development has occurred in the visual domain, thus the generalizability of these visual model benchmarks to other sensory domains remains unclear. Here, we explored one possible benchmark: the extent to which human similarity judgments could be used to predict model-brain alignment across a broad range of ANNs trained on auditory tasks.

Methods: From a set of 20 ANNs, we computed cosine similarity scores between model activations for pairs of sounds. Sounds came from a dataset we compiled to be representative of sounds encountered in daily life. Models varied in architecture, training data, and training task, however none were trained on a similarity task. We calculated Spearman correlation between each models' similarity scores and sound pair similarity judgements from human participants. Additionally, we compared these correlations to a neural model-brain alignment metric from fMRI data to investigate whether models that best captured human similarity judgments also explained the most variance in neural data.

Results: The strength of correlation between similarity metrics computed from ANNs and human similarity judgements varied across models, though some ANNs did approach the human-to-human correlation ceiling. In general, ANNs trained on multiple tasks or trained on audio event categories had higher correlations to human similarity measures. Furthermore, the extent to which a given ANN captured human-like similarity judgements was strongly correlated with how well the ANN captured neural firing in its layer activations, but there was some unique variability in each measure.

Conclusions: The correlation between model similarity structure and human similarity judgments offers a task-agnostic benchmark for evaluating brain-model alignment. The variability across different models suggests that the metric has sensitivity to distinguish different models. Much like networks trained on vision tasks, some auditory ANNs captured human similarity judgements to a high degree, suggesting that these models share some auditory representational features with humans. Brain-model alignment measured with this similarity benchmark was positively correlated with a model's ability to capture neural firing patterns in its activations; therefore, this benchmark could potentially be used as an exploratory precursor for cortical brain-model alignment studies.

SU195. Hearing-In-Noise Problems Within a Large Online-Recruited Cohort

Niklas Isserstedt^{*1}, Lena Schell-Majoer², Nori Jacoby³, Birger Kollmeier², Mathias Dietz⁴

¹*Carl von Ossietzky university Oldenburg*, ²*Carl von Ossietzky Universität Oldenburg*³*Max Planck Institut for Empirical Aesthetics*, ⁴*University of Oldenburg*

Background: The primary clinical measure for hearing loss is the audiogram. However, suprathreshold hearing-in-noise problems only correlate moderately with absolute hearing thresholds. Consequently, audiometric thresholds fail to capture enough information for an individual's hearing performance characterization (Kollmeier, 1999, *Psychophysics, physiology and models of hearing*, pp. 211-218). There is even a considerable percentage of the population that has hearing-in-noise problems despite clinically normal audiometric thresholds, loosely categorized by terms such as "hidden hearing loss" or "central auditory processing disorder" (Schaette and McAlpine, 2011, *J Neurosci.*, 31(38), pp. 13452-7; Tremblay et al., 2015, *Ear and hearing*, 36(6), e290-e299). We ran a lab study measuring audiometric thresholds as well as hearing-in-noise to characterize an individual's hearing to find emerging measurements or model parameters for hearing characterization. In a further step, we introduced remote testing with a large participant cohort (N = 627, 4 different languages) measuring the same hearing-in-noise tests as in the lab experiments to enlarge sample size and to meaningfully identify types or principal components of suprathreshold hearing and to evaluate online testing procedures in a broader test battery.

Methods: Audiometric thresholds, loudness growth functions and tone- as well as speech-in-noise thresholds in 50 participants with age-typical or mild hearing loss who had no hearing aid experience were measured in the lab. 24 participants from the lab study also participated in remote testing to form a validation group to compare lab and remote test results. Moreover, 627 participants took part in remote testing.

Results: Correlations and RMS error-analysis revealed tone-in-notched-noise- and N0S π thresholds as potential candidates to characterize an individual's hearing by predicting numerous tone- and speech-in-noise measurements with high accuracy in the lab study. A single 500-Hz N0S π threshold explains 61% of the variance in diotic speech-in-noise performance (RMS error = 0.80 dB). Including remote test results revealed a highly significant increase for all tone-in-noise thresholds for the 24 participants taking part in both the lab and remote experiments. Largest differences were found in the aforementioned most diagnostic stimuli: tone-in-notched noise as well as dichotic tone-in-noise detection. On a population level, results were similar for personally recruited compared to online-recruited participants.

Conclusions: Tone-in-notched-noise and N0S π thresholds turned out to be promising candidates for a quick screening of hearing-in-noise abilities in clinical practice. Significantly worse remote tone-in-noise thresholds indicate the need for additional care when designing online hearing tests, especially for the most cue-specific stimuli. Nonetheless, similar remote testing results for known and unknown test participants indicate the usefulness of online recruitment for epidemiological studies of hearing problems. These results showcase the possibilities of remote hearing testing using tone-in-noise thresholds for a qualitative diagnostic of suprathreshold hearing in an efficient and cost-effective way.

SU196. Exploring the Link Between Frequency Selectivity and Temporal-Coherence–Based Speech Segregation in Sensorineural Hearing Loss

Courtney Shepler^{*1}, Barbara Shinn-Cunningham², Hari Bharadwaj¹, Vibha Viswanathan²

¹*University of Pittsburgh*, ²*Carnegie Mellon University*

Background: Individuals with hearing loss commonly report trouble hearing in noise despite using prescriptive amplification. Listening in noise depends on our brains' ability to parse an auditory scene and segregate different sound sources. A key mechanism thought to support segregation is grouping of across-frequency acoustic elements that are temporally coherent (in-phase or comodulated) to form unified perceptual streams or objects. Prior computational modeling work suggests that reduced frequency selectivity, as is common in sensorineural hearing loss (SNHL), can degrade temporal-coherence-based segregation. However, whether broader tuning in SNHL covaries with temporal-coherence-based masking release for speech from background noise has not been directly tested.

Methods: We collected the following measures from native speakers of North American English aged 18-65 years across the continuum of normal-hearing and symmetric SNHL: (i) psychophysical tuning curves (at 4 kHz), (ii) comodulation masking release (CMR) measured for 4 kHz tones in narrow bands of noise, and (iii) speech-in-noise scores while manipulating the temporal coherence between frequency bands containing speech and noise. To date, 5 normal-hearing participants and 6 SNHL participants have completed this study. Importantly, all psychophysical measures used stimuli that were amplified to restore normal loudness perception using a linear hearing aid (Moore and Glasberg, 1998).

Results: Preliminary data suggest that CMR for tonal targets is smaller in listeners with SNHL compared to those with normal hearing. Furthermore, individuals with SNHL also exhibit broader psychophysical tuning-curve tips and reduced tip-to-tail ratios. With data collection and analysis ongoing, individual tuning-curve metrics will be compared to individual temporal-coherence-based masking release data for both speech-based and tone-based stimuli.

Conclusions: We seek to collect data from N=30 participants to test the hypothesis that reduced frequency selectivity covaries with temporal-coherence-based masking release even when audibility is restored.

SU197. Neural Changes After Insc Transplantation Into the Scala Tympani in an Auditory Neuropathy Model

So-Young Chang^{*1}, Jae Yun Jung², Hosup Shim², Ji Eun Choi², Min Young Lee²

¹*Beckman Laser Institute Korea, Dankook University*, ²*College Of Medicine, Dankook University*

Background: Studies investigating cochlear hair cell regeneration have been conducted worldwide. However, only a few have been successful, and the clinical application of these therapeutic approaches remains uncertain. Recent advances in cochlear implant techniques are impressive, but maintaining cochlear neural health to improve cochlear implant outcomes remains challenging due to secondary degeneration. Recent studies have demonstrated the direct conversion of mouse somatic cells into induced neural stem cells (iNSCs), which may provide an unlimited source of neuronal cells for autologous transplantation in patients with neurological disorders.

In this study, we evaluated the effects of iNSC transplantation on auditory neural connections in an animal model of auditory neuropathy induced by ototoxic drugs.

Methods: Mongolian gerbils aged 8–9 weeks and GFP-tagged human iNSCs kindly donated by Prof. Shim³ were used. For auditory nerve denervation, 1 mM ouabain solution soaked in gelfoam was placed on the round window (RW) for 30 minutes. Two weeks after ouabain application, human iNSC-GFPs at a density of 6×10^4 cells per 3 μ L were injected into the scala tympani (ST) using a cannula. Auditory function was assessed via auditory brainstem response (ABR) before and after ouabain treatment and surgery. Two weeks after hiNSC transplantation, ABR and electrical ABR (eABR) were recorded, and animals were sacrificed. Hematoxylin and eosin (H and E) staining, epifluorescence analysis of GFP, NF, TuJ, CtBP2, and VGLUT1, as well as quantification of spiral ganglion neurons (SGNs) in the cochlea, were performed.

Results: Ouabain application resulted in hair cells loss and increased ABR thresholds compared to controls. Two weeks after hiNSC transplantation, transplanted iNSCs were located in Rosenthal's canal and increased the neural cell population. ABR thresholds showed no improvement at this time point. The organ of Corti displayed less organized nerve fibers and synaptic structures, with wider intercellular gaps. The average distance between nerve fibers and presynaptic puncta was significantly greater in the hiNSC group. In the central auditory pathway, VGLUT1 expression was significantly increased in both cochlear nuclei, and eABR recordings revealed delayed action potentials in the hiNSC group, indicating partial recovery of afferent neural connections.

Conclusions: Human iNSC transplantation restored neural structures after degeneration, significantly enhancing synaptic connections toward the central auditory pathway, although peripheral synapses were not improved. These findings suggest that combining autologous stem cell transplantation with cochlear implants may improve outcomes and enable cochlear implant use in patients with long-term hearing loss.

SU198. Epigenetic Regulation of EDNRB2, a Key Regulator of Transdifferentiation of Supporting Cells Into Hair Cells, in Explants of Chick Auditory Epithelia

Mami Matsunaga^{*1}, Marie Takeuchi¹, Kei Ida¹, Koji Nishimura¹, Yosuke Tona¹, Koichi Omori¹, Takayuki Nakagawa¹

¹Kyoto University

Background: Our previous studies demonstrated that EDNRB2 regulates fate determination of reprogrammed supporting cells during transdifferentiation of supporting cells into hair cells in collaboration with ATOH1 in chick basilar papilla explants (Takeuchi et al., 2025). This study aimed to elucidate the upstream signals for EDNRB2 expression during hair cell regeneration in chick basilar papilla explants using ATAC sequencing.

Methods: We performed RNA- and -ATAC seq using our explant culture model, in which HCs are entirely lost by exposure to streptomycin (SM) for 48 h. Time course samples for RNA- and ATAC-seq are SM0 (before SM exposure), SM24 (24-h exposure to SM), and SM48 (48-h exposure to SM). For sampling, 25-35 basilar papillae were used for one batch and prepared in duplicate for both analyses. We performed transcription factor (TF)-binding motif scanning for detected enhancer-candidate loci. Based on this, in situ hybridization or immunostaining was done to examine the expression patterns of candidate TFs.

Results: RNA-seq identified 24,888 genes, and ATAC-seq identified 80,366 open chromatin lesions. We identified three candidate loci for EDNRB2 enhancer lesions. TF-binding motif scanning revealed 98 candidate motifs. Filtering by the expression levels of candidate TFs in RNA sequencing data, 23 candidate TFs were identified. Previous studies (Matsunaga et al., 2020; Janesick et al., 2022) have demonstrated upregulation of JAK-STAT signaling pathways in the initial process of hair cell regeneration in chick basilar papillae. Based on this, we chose a couple of TFs, which are associated with JAK-STAT signaling, from 23 candidate TFs for histological evaluation. Phosphorylated STA3 exhibited a similar distribution to EDNRB2 expression.

Conclusions: We conducted an integrated analysis of RNA and ATAC sequencing to explore candidate upstream TFs for EDNRB2. Based on histological findings, functional analyses of candidate TFs will be done in the near future.

SU199. Reducing Sox2 Increases Cochlear Supporting Cell Reprogramming Efficiency

Richard Seist^{*1}, Melissa McGovern², Janelle Gleim², Andrew Groves¹

¹Washington University in St. Louis, ²University of Pittsburgh School of Medicine

Background: Sox2 is dynamically expressed in the developing inner ear and expressed in mature supporting cells but not in hair cells. Germline Sox2 haploinsufficiency induces supernumerary hair cells and enhances natural hair cell regeneration in the neonatal cochlea. Mature supporting cells can be reprogrammed to hair cell like cells by combined expression of the transcription factors Atoh1, Gfi1, and Pou4f3 (GAP). To test whether Sox2 influences reprogramming efficiency, we activated GAP and reduced Sox2 in mature supporting cells.

Methods: We bred GAP overexpressing mice to mice carrying either a Sox2 allele flanked by LoxP sites or wild-type Sox2 and crossed these with Pou4f3-DTR mice, to kill hair cells, and Ai3 reporter mice, to track cell lineage. Cre was introduced by intra-labyrinthine AAV-Lfng-CreER or by crossing with Lfng-CreER transgenic mice. Cre recombination with tamoxifen at 3 or 6 weeks induced GAP reprogramming, as well as knocking out of a Sox2 allele. Hair cells

were killed with diphtheria toxin. Mice were euthanized 2 or 9 weeks after hair cell death, and their inner ears harvested for quantitative immunofluorescence microscopy.

Results: Simultaneously reducing Sox2 and overexpressing GAP significantly increased the number of reprogrammed hair cells by 50% at 2 weeks, and by 100% at 9 weeks compared to GAP controls. Reprogrammed hair cells appeared immature and quantifying stereocilia with phalloidin staining showed no difference between genotypes.

Conclusions: Reducing Sox2 in supporting cells at the time of GAP activation significantly increased the number of reprogrammed hair cells. Future therapies for sensorineural hearing loss relying on reprogramming supporting cells could incorporate Sox2 decreasing strategies to increase reprogramming efficiency.

SU200. Exploring Spontaneous Regeneration of Spiral Ganglion Neurons Post-Ablation

Joshua Lin^{*1}, Nhi Nguyen¹, Priya Shah¹, Seiji B. Shibata¹

¹*Keck School of Medicine of USC*

Background: The current consensus suggests that spiral ganglion neurons (SGN) do not spontaneously regenerate in mammals. A recent study has reported spontaneous SGN regeneration following ouabain treatment in adult mice, demonstrating the upregulation of glia markers Sox2/Sox10 within cells expressing the neuronal marker Tuj1. Yet, the precise origin of the spontaneously regenerated SGNs remains unclear. As such, we utilized an inducible Sox2Cre-ER mouse model to enable lineage tracing following SGN ablation with diphtheria toxin (DT).

Methods: Wild-type (C57) and Sox2Cre-ER crossed with Ai9-TdTomato Cre-reporter mice (Sox2Cre-ER+/Td+) obtained from the Jackson Laboratory were used. A single injection of AAV-retro encoding diphtheria toxin receptor gene with GFP (AAV-DTR) was injected via the posterior semicircular canal (PSCC) at P1-2 to express DTR in the SGN. We observed near-total SGN transfection without transfecting the hair cells as early as 7 days post-injection. At 7 or 28 days post-AAV-DTR inoculation, neonatal (P9) and adult (P30) mice were administered DT at 5ng/g and 20ng/g, respectively. Distortion-product otoacoustic emissions (DPOAEs) and auditory brainstem responses (ABRs) were measured before histological assessment and immunohistochemistry of harvested cochleae at 14 days after DT administration. We performed lineage tracing experiments in Sox2Cre-ER+/TdTomato+ mice injected with AAV-DTR at P1-2. At 7 or 28 days post-AAV-DTR inoculation, Tamoxifen was introduced to activate Cre recombinase expression with DT. AAV-DTR-injected, age-matched, saline-administered mice served as controls.

Results: The AAV-DTR-injected wild-type mice, receiving 5ng/g DT at P9 (neonate) and 20ng/g DT at P28 (adult), showed normal DPOAE and increased ABR thresholds at 14 days, consistent with auditory neuropathy. Saline-administered controls demonstrated normal DPOAE and ABR thresholds. Subsequent histology demonstrated a 94% reduction in Tuj+ SGN density (203.86 cells/mm²) in neonates and a 78% reduction in Tuj+ SGN density (894.43 cells/mm²) in adults. Immunohistochemistry indicated co-localization of Tuj and Sox2 signals in 6% of the surviving SGNs in both wild-type deafened neonatal and adult mice, consistent with previous literature. Our preliminary lineage tracing experiment in AAV-DTR-injected Sox2CreER+/Td+

mice demonstrated similar levels of SGN ablation by 14 days after DT administration (92% in neonates and 91% in adults). Consistent with the wild-type immunohistology, we observed TdTomato signals in the few surviving Tuj+ cells in both neonatal and adult mice, indicating spontaneous transdifferentiation from the glial cell lineage to exhibit a neuronal phenotype.

Conclusions: We established a new auditory neuropathy model with temporal control: introduction of 5 and 20ng/g of DT in AAV-DTR-injected mice was sufficient to ablate 78-94% of SGN in neonatal (P9) and adult (P30) mice, sparing the hair cells. Our preliminary fate-mapping experiments in AAV-DTR-injected Sox2Cre-ER+/TdTomato+ mice indicate that spontaneous SGN regeneration from Sox2-positive glial cells occurs in both the neonatal and adult mice following DT-induced SGN ablation. We will further quantify and characterize the regenerated SGN in future experiments.

SU201. Exploring Genes that Enable Hair Cell Regeneration in Zebrafish

Andrea Meza Hernandez*¹

¹*Johns Hopkins University*

Background: Hair cells are mechanosensory receptors of the inner ear that are essential for hearing and balance. Damage or loss of these cells in mammals results in permanent hearing loss and vestibular dysfunction due to limited regenerative capacity. In contrast, zebrafish and other non-mammalian vertebrates are able to robustly regenerate hair cells following injury. Understanding the molecular mechanisms that enable hair cell regeneration in these systems may reveal

conserved genetic pathways that could be therapeutically targeted to restore hearing in mammals.

Recent in vitro studies using mammalian inner ear organoid cultures have identified a set of genes implicated in hair cell regeneration through bulk RNA sequencing and single-cell RNA sequencing approaches (Li et al., 2022). These analyses revealed six key regulatory factors: Trim71, Arid3a, Jarid2, Rprm, Nfix, and Zbtb20. These factors are enriched under regenerating conditions compared to controls. They are proposed to play roles in reprogramming supporting cells and promoting hair cell regeneration. While these findings provide important insight, the functional roles of these candidate genes in vivo remain largely unexplored.

This project aims to investigate the in vivo function of zebrafish homologs of selected candidate regeneration genes using the zebrafish larval lateral line system. In addition to possessing hair cells in the inner ear, zebrafish have external accessible hair cells located along their body surface in the lateral line, making them a powerful model for studying hair cell damage and regeneration. Hair cells in the lateral line can be selectively ablated by exposing larval zebrafish to ototoxic compounds such as copper sulfate without damaging surrounding tissues.

Methods: To assess the role of candidate genes in hair cell regeneration, CRISPR/Cas9 mediated mutagenesis will be used to generate zebrafish larvae with targeted gene disruptions. Five-day old CRISPR injected larvae will undergo a standard lateral line regeneration assay in which hair cells are ablated by a one-hour exposure to copper sulfate. Following ablation, larvae will be washed and allowed to recover for two days, a time point at which robust regeneration normally occurs. Regenerated hair cells will then be labeled using the vital dye YO-PRO-1 and quantified to identify defects or enhancements in regeneration relative to wild type controls.

Results: Hair cells count from copper treated CRISPR injected mutants will be compared to untreated CRISPR injected larvae, copper treated wildtype larvae, and untreated wildtype controls. Following phenotypic analysis, genomic DNA will be isolated from individual larvae and analyzed by PCR and sequencing to confirm CRISPR-induced insertions or deletions at the targeted loci.

Conclusions: Together, this work seeks to define the functional roles of conserved regeneration_x0002_- associated genes in vivo and to identify genetic regulators that enable hair cell regeneration.

These findings may advance our understanding of sensory regeneration and inform future strategies for restoring hearing in mammals.

SU202. Processing of Salient Vocalizations in Auditory Cortical Regions Cell Types

Zahra Ghasemahmad^{*2}, Elliot Chin¹, Maryse Thomas³, Carolyn Sweeney³, Jeffrey Wenstrup³, Anne Takesian²

¹Harvard College, ²Massachusetts Eye and Ear/Harvard Medical School, ³Northeast Ohio Medical University

Background: Mice produce a rich repertoire of complex vocalizations across diverse behavioral contexts, such as mating and stress. Playback of these calls elicits distinct behavioral responses and neuromodulator release patterns that vary with the listener's state and the context in which the calls occur. The auditory cortex is thought to relay information about these vocalizations to motor and limbic centers, thereby shaping context-appropriate reactions. However, how such salient vocalizations are represented across cortical subpopulations, and how this representation depends on behavioral state, remain unclear.

Methods: We measured vocalization responses in multiple auditory cortical cell types, including pyramidal excitatory neurons and a subset of inhibitory interneurons expressing Neuron-Derived Neurotrophic Factor (NDNF). These interneurons receive strong neuromodulatory inputs and are thought to modulate cortical activity in a state-dependent manner. Using transgenic mice expressing GCaMP in either pyramidal neurons or NDNF interneurons, we performed widefield and two-photon calcium imaging across auditory cortical regions in awake, head-fixed mice. Mice listened to playback of vocalization syllables recorded during negative (stress), positive

(mating), or neutral (isolation) contexts, while we simultaneously monitored pupil dynamics and locomotion.

Results: Vocalizations evoked robust, widespread responses across primary auditory cortex (A1) and multiple higher-order regions. Two-photon recordings revealed region- and cell type-specific response patterns, with subsets of L2/3 and L4 pyramidal neurons, and NDNF interneurons displaying strong selectivity for specific vocalizations or call classes (e.g., mating versus stress). Notably, many neurons responded robustly to natural vocalizations but not to synthetic sounds with matched spectral content, and small ensembles of vocalization-selective neurons could reliably decode call identity. Ongoing analyses are evaluating how behavioral state modulates the selectivity of these responses.

Conclusions: Together, these findings suggest that auditory cortical circuits encode behaviorally relevant vocalizations in a region- and cell-type-specific manner, and highlight a role for NDNF interneurons in shaping state-dependent processing. By identifying circuit mechanisms for encoding natural communication sounds, this work advances our understanding of auditory perception and lays a foundation for future studies of how internal state and experience shape communication.

SU203. Deep-Neural-Network-Based Hearing Loss Compensation Methods: Personalization and Patient Benefit

Sarah Verhulst¹, Chuan Wen¹, Marjoleen Wouters¹, Morgan Thienpont¹, Nele De Poortere¹, Attila Fráter¹, Guy Torfs¹

¹*Ghent University*

Background: Deep neural network (DNN)-based approaches are increasingly being used to design hearing-loss compensation algorithms. These methods offer low-latency, end-to-end processing suitable for deployment on resource-constrained devices, and they provide greater flexibility in addressing various aspects of sensorineural hearing loss (SNHL) compared to traditional techniques. Their nonlinear structure and ability to optimize via backpropagation make them particularly effective in compensating for deficits caused by cochlear synaptopathy (CS) and outer hair cell (OHC) damage.

Methods: We propose a closed-loop framework for developing augmented-hearing algorithms by minimizing the loss between outputs of differentiable biophysical models simulating normal and impaired auditory-nerve responses. The resulting CoNNear-HA algorithms are personalized using the individual's audiogram and CS profile inferred from auditory physiology. We first benchmark these personalized algorithms against conventional methods using standardized tests, including transfer functions and step/impulse responses. We then evaluate their impact on speech intelligibility in noise while ensuring sound quality remains acceptable. **Results:** We report speech recognition thresholds (SRTs) to 70-dB Flemish Matrix sentences in stationary noise for 20 subjects treated with either CS-specific or combined CS-OHC CoNNear-HA algorithms. While not all participants showed improvement, individual outcomes were analyzed in relation to their audiogram and envelope-following response strength. Post-hoc analysis revealed that the greatest benefit occurred in individuals whose baseline SRTs deviated most from the normal-hearing reference group. To assess performance in a more challenging listening scenario, we tested 40 subjects (20 older normal-hearing and 20 hearing-impaired) on a word recognition task

in babble noise using a signal-to-noise ratio corresponding to their unprocessed SRT. In this condition, most participants benefited from the CoNNear based processing.

Conclusions:

These findings support the integration of DNN-based algorithms alongside conventional methods to enhance hearing in individuals with early to advanced SNHL.

Molecular Drivers of Directional Regeneration of Spiral Ganglion Neurites and Their Therapeutic Application in Synaptopathy

3:00 p.m. - 3:15 p.m.

Volkan Ergin¹, Wei Wei¹, Chenxi Jin¹, Yi-Zhou Quan¹, Wan Du¹, Stewart Silver¹, Natalie Pelon¹, ZhengYi Chen^{*1}

¹*Massachusetts Eye and Ear, Harvard Medical School*

Background: Spiral ganglion nerve (SGN) degeneration underlies word recognition deficiency and poor cochlear implant (CI) outcomes. While neurotrophic factors, such as BDNF and NT3, promote general neurite growth, their roles in the directional regeneration of spiral neurites and their effect on synaptopathy have been limited. In adult cochlea, while the detachment and retraction of spiral neurites from inner hair cells is generally permanent, we found that adult SGN can regrow their neurites in response to regenerated hair cells (HCs) to form connections. We hypothesized that regenerated HCs secrete molecules to promote this directional regeneration of adult neurites and their identification holds great promise for treating synaptopathy and improving CI performance.

Methods: We used single-cell RNAseq (ScRNAseq) to study transcriptomes in regenerated HCs via reprogramming and ATOH1 overexpression. Bioinformatics was used to identify molecules secreted by regenerated HCs. SGN explant culture assays were used to assess neurite regeneration induced by individual and combined candidates. Dose response and antibody blockade were used to study specificity and potency. In vivo effect on neurite regeneration was studied using noise-exposed and ouabain-treated mouse models with permanent spiral nerve degeneration. AAV-mediated gene therapy was used to deliver the candidates into mice exposed to noise or during aging. ABR thresholds and wave 1 amplitudes were measured with synapses labeled and quantified.

Results: ScRNAseq identified 70 molecules secreted by regenerated HCs, which were reduced to 14 high-probability candidates by bioinformatics analysis. Testing showed a three-molecule combination of Col18a1, Sparc, and Igfbp2 (CSI) to be potent on neurite growth that is dose-dependent and can be specifically blocked by C, S and I antibodies. In adult cochlear explant culture, CSI successfully promoted neurite regeneration and connections with regenerated HCs. Biochemically, C, S and I were shown to interact intracellularly but not as secreted forms. AAV-CSI delivery in adult cochlea, after noise exposure or ouabain treatment, led to potent, directional neurite regeneration toward HCs to form connections. Significantly, AAV-CSI injection into adult inner ear, after noise-induced synaptopathy or with age-related synaptopathy, rescued wave 1 amplitudes and synapses. This rescue effect was mediated by neurite growth and synapse preservation.

Conclusions: Our work, stemming from adult HC regeneration, identified a new class of extracellular molecules COL18A, SPARC and IGFBP2 with potent roles in directional regeneration of damaged neurites in vitro and in vivo. CSI gene therapy achieved therapeutic outcomes in mouse models of NIHL and ARHL. We identified a target-initiated mechanism for neurite regeneration distinct from developmental mechanisms and revealed the regeneration capacity of damaged adult neurites. CSI represents a promising strategy to treat auditory synaptopathy, improve CI outcomes and enhance the treatment of transplanted neuro-stem cells for auditory neuropathy.

Selective Alterations in Intrinsic Excitability of Neurons in the Superior Olivary Complex in a Rat Model of Autism

3:15 p.m. - 3:30 p.m.

Samantha Lauby¹, Aaron Hardman¹, Shaam Anand¹, Nace Golding¹

¹*University of Texas at Austin*

Background: Auditory processing difficulties are often reported from individuals with neurodevelopmental disorders, including autism spectrum disorder. Changes in auditory brainstem functioning, including auditory brainstem responses (ABRs), precede other symptoms of autism spectrum disorder and thus may be a useful biomarker for early detection and intervention. However, the underlying biological mechanisms underlying these changes in ABRs in human infants is largely unknown. Prior research in the autistic brain, especially the cortex, has consistently reported alterations in excitatory/inhibitory balance as a potential biological mechanism underlying the disorder and alterations in auditory brainstem nuclei have also been reported.

Methods: We used a prenatal valproic acid (VPA) exposure model of autism in rats to examine changes in ABRs at postnatal days 35-37. Waveform amplitudes were measured as well as the dB threshold for broadband click and tone stimuli (4-48kHz). Ex vivo patch clamp recordings were made in whole neurons in the superior olivary complex of the auditory brainstem from postnatal days 29-35. Intrinsic membrane properties, including rheobase, input resistance, and time constant were measured in current clamp mode. HCN channel functioning via sag ratio was also assessed in current clamp and their conductance and biophysical properties were assessed in voltage clamp mode. The morphology of the patched neurons was also assessed.

Results: We found that prenatal VPA-exposed offspring have an elevated ABR threshold at all tone stimuli (but not clicks). We also found stimulus-dependent changes in Wave III amplitudes and increased Wave IV/I ratio at all stimuli. At the single-cell level, we found an elevated rheobase, shorter time constant, and higher sag ratio in principal neurons in the medial nucleus of the trapezoid body. This was associated with a higher maximum conductance of HCN channels, suggesting an increase in the total number of HCN channels. We did not find any major alterations in intrinsic membrane properties in principal neurons in the lateral superior olive.

Conclusions: Our results suggest that prenatal VPA-exposed offspring have alterations in central gain and excitatory/inhibitory balance at the superior olivary complex, which can be identified through ABRs. VPA can alter the expression of many genes, so the increase in the maximum conductance of HCN channels in the medial nucleus of the trapezoid body might reflect an underlying mechanism that links prenatal VPA exposure to impaired inhibition in this brain region. Deficits in the detection of speech patterns in challenging listening environments are well-known hallmarks of autism spectrum disorders in humans. The changes we have identified in the sound localization circuitry of the lateral superior olive of rats may provide mechanistic insight into these deficits, and help guide potential strategies for remediation.

A Vestibulothalamic Relay to Posterior Parietal Cortex Defines a Canonical Vestibular Neuraxis

3:30 p.m. - 3:45 p.m.

Todd Mowery*¹, Mark Aziz¹, Justin Yao¹

¹*Rutgers University*

Background: The striatum is the primary input nucleus of the basal ganglia, integrating dense corticostriatal and thalamostriatal projections to regulate action selection and learning. Extensive comparative neuroanatomical work across rodents, nonhuman primates, and carnivores has revealed robust sensorimotor substrates for motor, somatosensory, auditory, and visual processing. In contrast, vestibular sensory pathways remain comparatively unexplored. Our recent work identified a major vestibulothalamic relay from the medial vestibular nucleus (MVN) to the parafascicular nucleus, revealing extensive sensorimotor overlap and a compartmentalized projection zone in the dorsoventral striatum.

Methods: Using retrograde and anterograde AAV tracing in adult Mongolian gerbils, we systematically mapped a second ascending vestibular pathway. Retrograde AAV-GFP (350 nL) was pressure-injected (50 nl/minute) using a Nanoject III at stereotaxic coordinates targeting the center of the lateral dorsal (LD) thalamic nucleus and posterior parietal cortex (PPC). The pipette was left in place for 20 minutes following injection. Anterograde AAV1-GFP (350 nL) was similarly delivered to the center of LD. After three weeks of viral expression, animals were perfused, and brains were extracted, post-fixed, and sectioned coronally at 50 μ m. Sections were float-mounted onto pig-gelatin-coated slides and coverslipped with DAPI-containing mounting medium. All sections were imaged on an Echo Revolve R4 fluorescence microscope using matched exposure and gain settings. Mean fluorescence intensity (arbitrary units) was quantified using the ImageJ histogram tool and exported to Excel. Fluorescence levels were measured

across brainstem, thalamus, cortical, and striatal regions and analyzed in JMP using one-way ANOVA with Tukey's HSD post-hoc comparisons.

Results: We find that projections from MVN target the lateral dorsal (LD) nucleus of the thalamus, which provides a robust thalamocortical input to the posterior parietal cortex (PPC). In turn, PPC corticostriatal projections terminate in a compartmentalized region of the dorsolateral striatum, mirroring the organizational features of the previously described MVN→PF→striatum pathway. A PPC specific compartment just dorsal to auditory and visual inputs to the dorsolateral striatum could represent vestibular striatum.

Conclusions: Together, these results identify a previously unrecognized vestibular circuit linking brainstem, thalamus, parietal cortex, and striatum—defining a canonical vestibular neuraxis in rodents. This pathway provides a new framework for studying vestibular contributions to basal ganglia physiology, cross-modal plasticity, and behavior across species.

Nonclinical Development of a Therapeutic for Usher Syndrome Type 3A Associated Hearing Loss

3:45 p.m. - 4:00 p.m.

Katherine Gribble*¹, Yuan Gao¹, Ye-Hyun Kim¹, Matthew McGill¹, Yukako Asai¹, Lars Becker¹, Vikrant Borse¹, Junaid Syed¹, Janmaris Marin Fermin¹, Izra Hernandez Rivera¹, Michael McKenna¹, Brian Lin¹, Neda Masoudi¹, Bifeng Pan¹, Jean Phillips¹, Kathleen Lennon¹, Danielle Lenz¹, Eva Andres-Mateos¹, Michelle Valero¹

¹*Eli Lilly and Company*

Background: Usher Syndrome Type 3A (USH3A) is an inherited genetic condition affecting hearing and vision. Individuals with USH3A experience progressive bilateral loss of hearing and vision, with clinical diagnosis typically occurring by the age of 10 years. Hearing loss in USH3A is typically symmetric, sensorineural, and progressive, often reaching the level of bilateral profound sensorineural hearing loss (SNHL) by the third or fourth decade of life.

Although USH3A is believed to be caused by a defective clarin-1 protein (individuals with variants in the clarin-1 gene present with USH3A), there are currently no approved pharmacologic therapies for treating either the progressive hearing or vision loss associated with USH3A. The only treatment options for USH3A-associated hearing loss are hearing aids and cochlear implantation, neither of which provide the opportunity to recover lost physiologic hearing nor to halt further progression of physiologic hearing loss. We have developed a therapy that can be delivered to the cochlea to address USH3A hearing loss as discussed below.

Methods: Here we present nonclinical data from mice and non-human primates (NHPs) supporting development of an USH3A therapy for hearing loss. Our USH3A therapy is designed for local delivery to the cochlea. We first characterized the auditory phenotype and disease progression of a mouse model to evaluate its relevance to the USH3A-mediated hearing loss phenotype in humans. Auditory and cochlear function were assessed with auditory brainstem response and distortion-product otoacoustic emission testing, respectively. Cochlear histologic

evaluations were performed to evaluate hair cell survival and sub-cellular hair bundle dysmorphology. We then evaluated the potential for efficacy and otic tolerability of our USH3A therapy across multiple doses when administered at an age when the murine cochlea is mature but before substantial degeneration of hair cells occurs. In NHPs with mature cochleae, we evaluated otic tolerability of our USH3A therapy across multiple doses.

Results: In a mouse model of USH3A-associated hearing loss, we observed a dose-dependent improvement in auditory and cochlear function following administration of our USH3A therapy. Additionally, we observed that increasing doses of our USH3A therapy are well tolerated in the mouse and non-human primate cochlea.

Conclusions: Our results in mice and NHPs support the development of our USH3A therapy as a potential treatment for individuals with USH3A-associated hearing loss.

Symposium 2: New Neurostimulation Strategies for Auditory Restoration

3:00 p.m. - 5:00 p.m.

Ballroom B, Floor 3

New Neurostimulation Strategies for Auditory Restoration

Brice Bathellier, *Institut Pasteur, Institut Audition*

Symposium Description: The cochlear implant (CI) is by far the most successful sensory restoration device, putting the hearing research at the forefront of neurostimulation device development. CI have shortcomings, including their restriction to patients with preserved auditory nerve, and their poor spectral accuracy. Intense research is currently on-going to solve these issues encompassing new algorithms or stimulation methodologies for CI, as well as the conception of brain targeted implants addressing the cochlear nucleus or the even the cortex. The aim of this symposium is to highlight recent progresses made on these fronts, including pre-clinical and clinical research. To account for the diversity of options considered in present research effort we will cover approaches developed at the level of the cochlea, brainstem and auditory cortex. Moreover, we will discuss a large range of research focuses including the impact of AI-based algorithms improving information transfer for CI users, or shaping information at higher level of the auditory system, the development of new electrical stimulators, microfabricated and flexible for higher resolution of stimulation and current progresses in the implementation of optogenetic stimulations techniques for auditory rehabilitation. The symposium will include established specialists and younger researchers demonstrating striking results that prefigure important technological steps with significant improvement of auditory rehabilitation, and will be organized into 6 talks of 15 min and one 30min talk (Moser).

Tania Barkat, *University of Basel*

New and Old Neurostimulation Strategies for Auditory Restoration

Julie Arenberg, *Massachusetts Eye and Ear Infirmary, Eaton Peabody Laboratory*

Individual Abstract: Our research addresses two main challenges that likely limit the speech perception outcomes for individuals with cochlear implants. The first challenge is providing temporal fine structure information. Current implants are primarily encoding the envelope of the acoustic signal, thereby discarding the fine temporal information. There is one strategy that attempts to encode this, but the evidence is mixed about how effective temporal fine structure is transmitted. The second challenge is providing spectral detail by stimulating more localized populations of auditory neurons. Current implants employ the monopolar electrode configuration that induces a broad spread of excitation and more unwanted channel interaction than can be achieved with focused electrical stimulation and potentially with magnetic stimulation through micro-coil arrays. This talk will demonstrate data from animal models demonstrating two approaches to solving these challenges. To provide temporal fine structure, we have applied continuous analog stimulation, which is how cochlear implants were stimulated when they were first developed, but we do this in combination with highly focused electrical fields. Results show that neurons in the inferior colliculus phase lock to the stimulus frequency, and two channels of simultaneous stimulation show small degrees of channel interaction as assessed by quantifying the degree of overlapping neural activation. To provide more spectral detail, we also explore magnetic stimulation from micro-coils of the auditory nerve. Intracochlear magnetic stimulation via a micro-coil produced robust IC activation; the spread of activation was significantly narrower vs. that from monopolar/bipolar electrical stimulation from implanted electrodes. These new stimulation approaches will be discussed within the context of standard cochlear implants in use today.

Bionic Hearing in Mammalian Species Through a Soft Auditory Cortex Implant

Alix Trouillet, *Centre hospitalier universitaire vaudois*

Individual Abstract: By 2050, nearly 700 million people will require hearing rehabilitation according to the World Health Organization. Cochlear implants (CI) are the first line of treatment for severe deafness and they restore meaningful sound perception and speech comprehension to both children and adults. However, significant limitations remain and underscore the urgent need for innovation: 1) CIs do not convey complex hearing experiences such as music or speech in noisy environments, 2) Outcomes are variable across patients with some poor responders with limited improvements, 3) CIs are not indicated for individuals with cochlear and auditory nerve abnormalities as well as central disorders. Direct electrical stimulation of the auditory cortex through an Auditory Cortex Implant (ACI) provides an alternative therapeutic approach tackling some of these challenges. We developed animal models enabling systematic assessment of ACI performance from electrophysiology and behavioral readouts. Applying this framework to rodents, minipigs and non-human primates (NHP), we demonstrated how ACI activates the auditory pathway in a tonotopic fashion, resembling acoustic stimulation. In NHP, the ACI electrode pitch determined the resolution of acoustic percepts enabling a rich encoding capacity of the device. Finally, we measured the behavioral responses to ACI and quantified the auditory nature of the percepts with its acuity and dynamic range. These results reveal the potential of auditory cortical stimulation to restore high-resolution hearing in patients with severe deafness.

Leveraging AI to Improve Speech Information Transmission With Cochlear Implants

Tobias Goehring, *University of Zurich*

Individual Abstract: Cochlear implants (CIs) help many people with severe-to-profound hearing loss hear better, but perceiving speech in a noisy or reverberant environment remains a major challenge for them. I will discuss the limitations in CI hearing responsible for these perceptual difficulties and then describe several avenues to leverage artificial intelligence (AI) to improve speech transmission and perceptual outcomes with CIs. AI methods for the CI frontend processor have shown unmatched potential for enhancing the intelligibility of speech in noisy situations. Our results from several studies using deep learning to improve speech-in-noise perception, include AI systems that can generalise to realistic acoustic situations, benefit from spatial information and let the user choose a specific speaker of interest at runtime. These deep-learning systems achieved meaningful and statistically significant improvements in speech intelligibility even in difficult situations with unseen noise and reverberation or with up to 3 concurrent speakers in background noise. I will present further work on AI-based approaches to tailor these systems specifically for CI speech processing and perception. A hybrid combination between computational models of the auditory system under electrical stimulation and their application as predictors and loss functions for the training of AI-based speech enhancement models is presented. Training such domain-aware speech enhancement models has the potential to further improve performance. Finally, the recent success of powerful speech foundation models in tasks such as automatic speech recognition and translation opens new venues to utilize large-scale speech models to directly assess and compare CI speech processing strategies. First results indicate the potential and feasibility of this approach by applying large speech models to probe speech information transmission in the context of CI simulation and speech processing strategies.

Toward Optogenetic Hearing Restoration

Tobias Moser, *University Medical Center Goettingen*

Individual Abstract: When hearing fails, cochlear implants (CIs) provide open speech perception to most of the currently more than a million CI users. CIs bypass the defective sensory organ and stimulate the auditory nerve electrically. The major bottleneck of current CIs is the poor coding of spectral information, which results from wide current spread from each electrode contact. As light can be more conveniently confined, optical stimulation of the auditory nerve presents a promising perspective for a fundamental advance of CIs. Developing optogenetic stimulation for auditory research and future hearing restoration requires concerted efforts toward development and characterization of appropriate channelrhodopsins, their viral gene transfer to cochlear neurons, as well as medical device engineering. The presentation will summarize the current state of the art and plans for developing gene therapy of the auditory nerve and optical CI as well as their combination for improved hearing restoration by optogenetic sound coding.

Cortical Implants for Hearing Restoration

Tania Barkat, *University of Basel*

Individual Abstract: Hearing loss affects half a billion people worldwide, significantly impairing communication and quality of life. While hearing aids provide adequate support for mild cases, severe hearing loss often requires cochlear implants. Despite their success, cochlear implants suffer from poor spectral accuracy, low acoustic resolution, and ineffectiveness in patients with auditory nerve damage. This study investigates whether cortical implants offer a more effective alternative for auditory restoration.

We implanted surface electrode arrays with 32 contacts (175 μm spacing) onto the auditory cortex of mice and compared them with cochlear implants featuring 4 electrodes (500 μm spacing). To ensure a direct comparison, we analyzed responses from four cortical electrodes, four cochlear implant electrodes, and four frequency-matched acoustic stimuli in normal-hearing mice. Mice were tested on single- and multi-frequency categorization tasks, amplitude modulation categorization, and amplitude modulation in noise categorization. Across all tasks, cortical implants led to superior auditory performance compared to cochlear implants, although learning took longer and followed distinct learning curves. Notably, mice trained with natural sounds could perform the tasks with cortical stimulation without additional training and vice versa, suggesting that cortical stimulation evokes percepts that closely resemble natural hearing.

To investigate the neural basis of these differences, we recorded in vivo electrophysiological responses in the auditory cortex to cortical stimulation, cochlear stimulation, and natural sounds. Neuronal responses scaled with stimulus strength across all conditions. Dimensionality reduction analyses (PCA, t-SNE) revealed that cortical stimulation responses resembled natural sound-evoked responses more closely than cochlear stimulation responses. Linear decoder analyses trained on natural sounds and tested on cortical and cochlear stimulation showed higher classification accuracy for cortical stimulation. Additionally, three-way decoder analyses confirmed that cortical stimulation responses were more similar to natural sounds than to cochlear stimulation, aligning with behavioral findings.

These results suggest that cortical stimulation not only provides better auditory performance but also more faithfully mimics natural auditory processing. The ability of mice to generalize between natural sound and cortical stimulation further supports this claim. While cortical implants show promise as an alternative for hearing restoration, future studies should further investigate learning dynamics, perceptual fidelity, and translational feasibility for clinical application.

A Generic Deep Learning Architecture for Bio-Inspired Encoding of an Auditory Cortical Implant

Brice Bathellier, *Institut Pasteur, Institut Audition*

Individual Abstract: Cochlear implants (CIs) are the most successful sensory neuroprosthesis and help almost a million patients to recover functional hearing. However, their relatively poor spectral and temporal accuracy limits speech intelligibility in noise and music perception. Moreover, CIs do not address pathologies involving auditory nerve loss or cochlear malformation. Because auditory cortex stimulation leads to sound perception, a possible approach to circumvent these issues could be to implant the neuroprosthesis at this level. However, cortical implants would require high-level encoding models to transfer information in a format similar to sound representations in the auditory cortex. To address this challenge, we have developed an AI-based encoder allowing us to recreate and map key features of the

biological auditory code observed in the cortex while ensuring a high information throughput, which is closely measured by reconstructing the waveforms of the encoded sounds. Our approach uses an autoencoder whose latent space matches the number of electrodes on the stimulator and the temporal resolution of auditory cortex activity. The autoencoder is combined with a classifier of human-labelled sound categories that enables the generation of structured pre-semantic representations. The encoder and decoder are based on modern 1D convolution layers explicitly developed for sound processing, yielding efficient training and excellent performance. We demonstrate that this novel hybrid architecture trained on millions of natural sounds can perform sound encoding on hundreds of channels with almost no information loss while generating stimulation patterns matching multiple neural code properties of the auditory cortex. Preservation of information is established by the high perceptual similarity of reconstructed sounds compared to original sounds, for speech, music and natural sounds. The similarity with natural auditory cortex representations is established by using representational similarity analysis on cortical data and on the representation of our encoder. In addition, specific constraints in the training process allow us to reproduce tonotopy. In addition, we demonstrate that single channel activities for well-known sounds have temporal profiles similar to cortical neurons with a variety of onset, offset and sustained responses, as well as tuning properties observed commonly in vivo. Finally, we show that mice can perceive and use the representations generated by our models with good precision. Hence, our approach allows for precisely delineating the design of a potentially successful auditory cortical implant for auditory restoration.

Distinct Cortical Neuronal Populations Are Tuned to Electrical and Acoustic Stimuli in a Chronic Soft Abi Mouse Model

Daniel Lee, *Massachusetts Eye and Ear Infirmary and Harvard Medical School*

Individual Abstract: The auditory brainstem implant (ABI) was developed to restore sound perception in individuals who are not candidates for cochlear implants (CI) due to retrocochlear hearing loss, such as those with Neurofibromatosis type 2 (NF2). Despite its initial promise, ABI performance remains limited—most users continue to experience significant difficulty understanding speech. One potential issue is that neurons in the auditory cortex do not respond to ABI stimulation in the same way as they respond to auditory stimulation. To study this issue, we used a novel chronic ABI model in mouse, allowing us to directly compare neural activation in the contralateral auditory cortex (ACtx) in response to sound and to electrical ABI stimulation.

The model used a flexible three-electrode ABI array to electrically stimulate the dorsal subdivision of the cochlear nucleus (DCN) in awake mice. The strain of mice used in this study express a genetically-encoded calcium indicator in cortical excitatory pyramidal neurons (Thy1-GCaMP6s or VGlut1-GCaMP8s). Two-photon imaging was performed through a cranial window over ACtx to measure sound and ABI electrically-evoked responses at both the single-neuron and populational levels. Neurons studied were within L2/3 (~250µm depth) of ACtx. Responses to amplitude modulated (AM) sounds and ABI stimulation were compared across a range of modulation depths.

ABI stimuli elicited diverse calcium responses in ACtx, including neurons with rapid transient activation, delayed sustained responses and stimulus-evoked suppression – response profiles

broadly similar to those evoked by sound. Approximately 30% of neurons responded to ABI and a similar proportion to sound stimuli, however only a small fraction responded to both, suggesting largely non-overlapping populations. Although many neurons displayed sharp tuning to specific modulations in acoustic and electrical stimuli, tuning preferences for AM-ABI and AM-sound were often mismatched at the single-neuron level. These findings suggest that although the ACtx is capable of decoding ABI inputs, these signals may not be immediately aligned with natural auditory coding strategies. This mismatch may contribute to the limited perceptual performance of ABI users and highlights the potential for cortical plasticity to enhance outcomes—aligning with clinical reports that ABI performance improves with continued device use. Ongoing work aims to determine whether behavioral training can reshape cortical tuning to ABI stimuli and enhance perceptual performance.

Podium 7: Neural Correlates of Tinnitus

3:00 p.m. - 5:00 p.m.

Meeting Room 208ABC, Floor 2

Moderators: Joel Berger and Nour Alsabbagh

Integrating Afferent and Efferent Auditory Assessments to Explore Central Gain and Hidden Hearing Loss in Tinnitus

3:00 p.m. - 3:15 p.m.

Pauline Devolder^{*1}, Hannah Keppler², Sarah Verhulst¹

¹*Hearing Technology at WAVES, Ghent University*, ²*Ghent University, Ghent, Belgium*

Background: Tinnitus is a symptom that is often associated with aging or excessive noise exposure. Emerging evidence suggests that interactions between peripheral hearing loss and central gain changes can alter central auditory and non-auditory regions, potentially contributing to tinnitus. Peripheral and central imbalances may affect both upward neural encoding and downward feedback pathways. This study combines novel afferent and efferent auditory measurements to examine how these factors interact and shape auditory encoding in individuals with tinnitus.

Methods: To assess afferent neural encoding from the cochlea to the inferior colliculus, the protocol included auditory brainstem responses (ABRs), envelope-following responses (EFRs), and frequency-following responses (FFRs) to low-frequency harmonic complex tones and speech syllables. Low-frequency FFRs allow us to differentiate between envelope and temporal fine structure encoding. The efferent reflex pathways were assessed using wideband click-evoked middle-ear muscle reflexes (MEMR) and wideband medial olivocochlear reflexes (MOCR). Additionally, several behavioural and tinnitus-related measurements were implemented. 120 participants were included: sixty with chronic tinnitus (noise-induced or idiopathic) and sixty age-matched controls, subdivided into young (18 – 35 y/o) normal-hearing, older (45 – 65 y/o) normal-hearing, and older hearing-impaired groups. Group comparisons evaluated the effects of tinnitus, age, and hearing loss on auditory processing.

Results: Participants with tinnitus had enhanced neural envelope encoding and improved behavioural low-frequency vowel discrimination. While typical listeners, as reported in previous studies, usually rely on envelope information to encode speech in noise, participants with tinnitus showed a correlation between neural temporal fine structure encoding and low-pass speech-in-noise scores. As expected, older listeners showed reduced responses on almost all measurements, which interacted with tinnitus-related enhancements. MEMR analyses revealed significant age-related effects but no direct tinnitus-related differences. This suggests that efferent function alone is insufficient to explain tinnitus-related enhancements and central gain.

Conclusions: These findings highlight the importance of considering interactions between peripheral damage, aging, and central gain in tinnitus research. By integrating afferent and efferent measures, this study establishes a comprehensive framework for interpreting changes in subcortical auditory encoding related to tinnitus. This framework also paves the way for future research on central gain in relation to aging, tinnitus, and hyperacusis.

Neural Plasticity Following Restricted Peripheral Cochlear Deafferentation in Ferrets

3:15 p.m. - 3:30 p.m.

Victoria Bajo*¹, Joshua R. Gold¹, Sara Rolle Sonora¹, David N. Furness², Linus Milinski¹, Andrew J King¹, Fernando R. Nodal¹

¹*University of Oxford*, ²*Keele University*

Background: Subjective tinnitus is the perception of a sound in the absence of an environmental source, and is thought to derive from maladaptive plasticity following hearing impairment. Our aim was to investigate whether primary auditory cortex has a causal role in a model of trauma-induced tinnitus.

Methods: Our longitudinal experimental design comprised gap-in-noise behavior using positive operant conditioning and auditory brainstem response (ABR) recordings to detect the presence of tinnitus before and after making a restricted unilateral mechanical lesion in the cochlea. Normal hearing ferrets underwent behavioral testing on a two-alternative forced choice paradigm and ABR measurement prior to spiral ganglion lesion. Post-lesion, the animals were re-tested behaviorally and ABRs were recorded at two time points (1 week and 3 months). Animals were tested again in the gap-in-noise task after deficient replicant AAV virus containing ArchT tagged with GFP was injected bilaterally in the primary auditory cortex (A1) and 200 μ m optical fibres were implanted at the surface of A1 to silence cortical activity. Pulses of green light ($\lambda = 532$ nm, 8-10 mW) from a compact diode-pumped solid-state (DPSS) laser were randomly paired with the sound stimuli and applied to A1 on the right, the left or both sides of the brain in 50% of the trials presented. To investigate neuroplasticity in A1 neurons, recordings were performed using Neuronexus probes in the two hemispheres and compared with recordings from naïve animals.

Results: Spiral ganglion lesion resulted in a heterogeneous change in gap-in-noise detection behavior across animals, with some ferrets displaying temporal processing impairments and

others showing post-lesion adaptation. These behavioral outcomes correlated with particular ABR features, indicating a possible predisposition towards adaptation/maladaptation. Interestingly, optogenetic silencing of A1 contralateral to the lesioned cochlea showed a rescue effect on the behavioral markers of impairment.

Spiral ganglion lesions appear to reduce the afferent drive to the A1 with recorded units showing lower spontaneous firing rates than in naïve controls. Importantly, when behavioral status was considered, the spontaneous firing rate of A1 neurons from cases that did not show a behavioral impairment was significantly lower and more synchronized than that in animals that showed a behavioural impairment. Frequency remapping in A1 was not observed following spiral ganglion lesions, though in control cases, the right hemisphere showed a greater representation of low frequencies than the left hemisphere, whereas this inter-hemispheric asymmetry was not observed in the lesioned cases, where A1 units were significantly more narrowly tuned than those in control animals.

Conclusions: These results suggest that A1 shows evidence for behaviorally-relevant deafferentation-related neuroplasticity, suggesting possible targeted strategies for remediation of the maladaptive processing potentially underpinning tinnitus in humans.

Development of a New Tinnitus Model Using Designer Receptors Exclusively Activated by Designer Drugs (DREADD)-Based Chemogenetic Technology

3:30 p.m. - 3:45 p.m.

Joseph Pinkl^{*1}, Giovana Da Silva², Harry Wang², Jianxin Bao¹

¹Gateway Biotechnology Inc., ²Duke University

Background: Tinnitus research at the preclinical stages is difficult to manage due to a lack of understanding of its neurological mechanisms and limited reliable tests to identify tinnitus in animal models. Evidence obtained from both animal and human studies suggest that tinnitus results from the dysfunction of several neuronal networks. Here, we aimed to develop a new pathological model of tinnitus by directly modulating neuronal activity of the inferior colliculus (IC) in mice using Designer Receptors Exclusively Activated by Designer Drugs (DREADD)-based chemogenetic tools, a class of engineered proteins that are activated by synthetic ligands. Validation measures were completed using a behavioral-based tinnitus detection method called sound-based avoidance detection (SBAD). Additionally, we supplement SBAD data with deep learning video tracking analyses to profile tinnitus-associated passive behavior.

Methods: Eight adult C57BL/6J mice received bilateral stereotaxic micro-injections of AAV8-CaMKIIa-hM3D(Gq)-mCherry (AAV) at 50-150 nL doses in the central nucleus of the IC (AP: -5.00 mm, ML: +/- 1.00 mm, DV: -1.50 mm). After one month of recovery, animals underwent 15 days of SBAD training followed by 6 consecutive days of SBAD testing. On every other day of testing, animals received intraperitoneal (i.p.) injections of clozapine-N-oxide dihydrochloride (CNO), a chemogenetic actuator, at a dose of 5 mg/kg, one hour before testing. On all other days of testing, animals received .5ml injections of .9% saline as a control. Video tracking was completed using an overhead camera capturing animal movement within a 15inx8inx5in cage. Video recordings were obtained from each animal individually under two conditions – 1 hour post i.p. CNO injections and 1 hour post i.p. saline injections.

Results: For AAV injected animals, there was a significant main effect of injectant type (saline vs CNO) for the SBAD silent trials only. However, there was no significant main effect of AAV dose and no significant interaction between injectant type and AAV dose for both silent and sound trials. Silent trial scores post-CNO injection ranged from approximately 50-100% with seven of the eight IC AAV injected animals yielding scores that indicated tinnitus-associated behavior. Video tracking analyses indicated 9 distinct metrics of animal behavior that yielded significant differences between injectant type (saline vs CNO).

Conclusions: SBAD scores suggest that selective modulation of IC excitatory neurons via chemically activated DREADDs can lead to tinnitus-associated behavior. Video tracking analyses identified 9 behavioral metrics that may be associated with tinnitus percept. Future studies will continue to build these tinnitus-associated behavioral profiles. Because IC hyperactivity is implicated in many tinnitus studies, excitatory DREADD applications in auditory pathways could be reliable experimental tools for tinnitus research.

Identify Tinnitus-Related Neural Activity With a Machine Learning Classification Model

3:45 p.m. - 4:00 p.m.

Jinsheng Zhang^{*1}, Na Zhu², Hao Luo³

¹Wayne State University, ²University of Michigan, ³Henry Ford Health

Background: Tinnitus is a prevalent medical condition that affects many millions of people. Efforts have been made to better understand its underlying mechanisms and develop treatment. However, there is a lack of reliable biomarker for diagnosing tinnitus. In animal studies, it has been shown that behavioral evidence of tinnitus is associated with hyperactivity often in the forms of higher firing rate. However, there is a significant difference among individuals. That is, firing rates alone may not be the only factor in determining the presence or absence of tinnitus. In this study, we adopted an integrated approach, leveraging machine learning (ML) to examine spike rates and spike patterns, in order to separate animals with and without tinnitus. Ultimately, our goal is to develop a ML tool that can reliably identify biomarkers for tinnitus by evaluating waveform measurements from neural activity.

Methods: In this study, spontaneous activity was recorded in the auditory cortex (AC) of seven rats with known tinnitus status using gap prepulse inhibition of the acoustic startle paradigm: four displaying behavioral evidence of tinnitus, and three without tinnitus. During the signal processing, local field potentials were analyzed to determine the mean and standard deviation, providing data's values and range. Statistical measures were used to detect spikes in the time domain. A short segment of the waveform was extracted at each spike location, ensuring the segment capturing the entire spike waveforms. A total of 10,000 spike samples were used to train and test a supervised ML model.

For the ML process, a model was developed using four input features: spike firing rate, spike amplitude, prominence, and width. The output prediction was a binary value: "0" indicating no tinnitus, and "1" indicating tinnitus was observed. Seventy-five percent of the data were used for model training, while the remaining 25% was used for validation. The ML algorithms included

decision trees and support vector machines (SVM), and their validation accuracy was compared. The importance of the four features in model building was assessed using various ranking algorithms, such as Minimum Redundancy Maximum Relevance (mRMR) and the Chi-squared test.

Results: Our results demonstrated that the ML can identify the presence of tinnitus with an accuracy of approximately 90% in several methods, including the SVM, k-nearest neighbors (KNN), and tree-based models. Among these, the bagged tree algorithm demonstrated the highest accuracy. Additionally, the firing rate, spike amplitude, and prominence are the three most important input features.

Conclusions: The machine learning model may be further developed to an effective tool for identifying a biomarker of tinnitus.

Neuroinflammation of Central Auditory and Limbic System Induced by Blast Exposure

4:00 p.m. - 4:15 p.m.

Wei Sun^{*1}, Li Li¹, Guangdi Chen¹

¹*University at Buffalo*

Background: Tinnitus and memory deficits are commonly seen in veterans who have traumatic brain injury (TBI) during their service. There is supporting evidence suggesting that blast-caused neuroinflammation may underline these symptoms.

Methods: Two-choice paradigms of the operant conditioning tests were used to test tinnitus and hyperacusis in adult Sprague Dawley rats induced by blast exposure. Immunocytochemistry was used to detect brain inflammation signals in the central auditory system and hippocampus using microglial cell markers. To isolate blast induced brain injury affected by peripheral auditory damage, the ear canals of the rats were plugged during the blast exposure. Rats without blast exposure were used as controls.

Results: Rats in the TBI group with ear protection did not develop hearing loss. The reaction time showed a significant decrease, indicating increased sound sensitivity, in blast exposed rats with ear protection. In the TBI groups, increased neural inflammation expression of IBA-1 and CD-68 signals were detected in both the hippocampus and auditory pathways, compared to controls.

Conclusions: Our data found blast-induced neuroinflammation in the central auditory system and hippocampus area may be linked to tinnitus and memory deficits after blast exposure.

Sound-Evoked Pain Behavior Analyzed by Machine Learning Exceeds a Threshold Set by a Known Pain Model

4:15 p.m. - 4:30 p.m.

Benjamin Seicol^{*1}, Amelie Valles², Bryan Djunaidy², Elisabeth Glowatzki¹, Megan Wood³

¹*Johns Hopkins School of Medicine*, ²*Johns Hopkins University*, ³*Vanderbilt University School of Medicine*

Background: The auditory pain threshold in humans is commonly reported to be ~120 dB (Sherlock and Formby, 2005). This threshold was thought to be similar in mice, and loud sound exposure has been routinely employed for noise-induced hearing loss in rodent models. To investigate whether high-intensity sound evokes behaviors that indicate pain, calcitonin gene-related peptide (CGRP) was used to induce migraine-like pain as a comparative tool to validate our sound-evoked behavior assay. CGRP was selected as the painful stimulus of interest due to its known expression in the auditory system (Cabanillas and Luebke, 2002; Schrott-Fischer et al., 2005), its ability to lower auditory thresholds (Rahman et al., 2025; Le Prell et al., 2021), and its association with phonophobia (heightened auditory sensitivity or pain), a symptom frequently reported by migraine sufferers (Lipton et al., 2024).

Methods: C57BL/6J mice aged 6 – 10 weeks old were recorded inside a custom-built clear container in a sound chamber. CGRP protocol: Mice were first recorded for 10 minutes to establish baseline behavior. Behavioral recordings were conducted following CGRP injection (100 µg/kg, i.p.) or saline during the middle of the migraine period (20–40 minutes post-injection), which included the expected peak at approximately 30 minutes post-injection (Rea et al., 2018). Sound protocol: Mice were recorded for 10 minutes to establish a baseline and then exposed to 2 – 20 kHz sound for 2 minutes ranging from 70 – 120 dB SPL interleaved with 2 minutes of no sound. Deep learning was applied to automatically place thirteen pose-estimated points and connecting skeletons on the face and body of the mice. Six facial grimace measurements (La Moëne and Larson, 2023) and four new body positions parameters were separately added together to calculate two cumulative scores.

Results: After CGRP injection, both Facial Grimace and Body Position Scores were statistically distinct from baseline recordings, indicating pain. Saline-injected controls did not show a significant change in Facial Grimace or Body Position Scores. Pain thresholds for sound were similarly defined by a significant difference from baseline in both additive Facial Grimace and Body Position Scores. Normal hearing mice were found to have auditory pain thresholds of 100 dB SPL based on these criteria that also exceeded the magnitude of change in CGRP-injected mice. Animals returned to baseline behavioral levels during periods of no sound following sound presentations, except for post 120 dB SPL-exposure.

Conclusions: This study highlights the need for caution when exposing animals to sound levels above 100 dB without appropriate anesthesia or analgesia to mitigate potential pain. Machine learning analysis of video recorded mice during sound presentation proved to be an effective approach to measuring auditory pain in mice and could be applied to hyperacusis models.

Use of Opm-Meg for Identification of the Neural Correlate of Tinnitus

4:30 p.m. - 4:45 p.m.

Marlies Knipper^{*1}, Rodrigo Donoso-San Martín², Stephan M. Wolpert³, Stefan Fink³, Paul Delano², Christoph Braun⁴, Lukas Rüttiger³

¹*University Hospital Tuebingen*, ²*Laboratorio Neurobiología de la Audición, Facultad de Medicina, Universidad de Chile*, ³*Tübingen Hearing Research Centre, University of Tübingen*,

⁴*MEG-Center, University of Tübingen, Otfried-Müller-Straße. and Hertie Institute for Clinical Brain Research*

Background: Acquired auditory processing disorders including age dependent hearing loss, speech discrimination deficits, tinnitus or hyperacusis, require a personalized diagnosis to assign the individual cause within the auditory hierarchy to either the periphery, subcortical, or distinct cortical or cortico-fugal neuronal dysfunctions. The good functioning of the feedforward and feedback PV-IN network is an essential precondition for audition that above all senses relies on high-speed information flow (Zajac IT and Nettelbeck T, 2018). Therefore, we hypothesize disease-specific deficits in temporal intracortical network function in auditory circuits.

Methods: We studied fast auditory processing in tinnitus subjects with or without the comorbidity of hyperacusis using auditory stimuli evoking time-sensitive cortical responses. These responses were recorded using a time-sensitive OPM-MEG.

Results: We expect this method to become an efficient diagnostic strategy to fathom peripheral or central contribution of the distinct auditory impairments in the future to improve individualized targeted interventional therapies.

Conclusions: Here we will present preliminary results demonstrating the usability and function of the OPM-MEG for hearing research in a clinical setting.

Acknowledgment and funding: This work was supported by ERA-NET NEURON JTC 2020: BMBF 01EW2102 CoSySpeech and the Tübingen Research Take off Program (TRT) of the Brasilien-Lateinamerika Zentrum, University of Tübingen.

Permanent Reversal of Noise-Induced Tinnitus by 28-Days of Ebselen Treatment is Related to Significant Reductions in Outer Hair Cell Loss

4:45 p.m. - 5:00 p.m.

Kushal Sharma¹, Annie Jia¹, Rende Gu¹, Sao-Mai Gahr¹, Ryan Longenecker¹, Jonathan Kil*¹

¹*Sound Pharmaceuticals, Inc.*

Background: Noise-induced hearing loss (NIHL) is a major risk factor for developing noise-induced tinnitus (NIT). Prior human studies have shown that 4-days of ebselen can prevent acute NIHL in young adults and 21-28 days of ebselen can improve hearing and tinnitus in aged adults with Meniere's disease. We previously showed in young and old mice that 4 or 14-days of ebselen treatment can temporarily reduce or partially reverse NIT. The goal of this current study was to determine if 28-days of ebselen treatment can permanently reverse NIT in young (3 to 4-month) and old mice (12 to 15-month) and if it is related to outer hair cell (OHC) loss.

Methods: Two ages of CBA/CaJ mice (N=60) were utilized: 3 to 4-month-old (N=30) and 12 to 15-month-old (N=30). Each age group was further divided: Group 1: 3-6 month (N=6) and 12-15 month (N=6) served as an unexposed controls with no ear occlusion; Group 2: 3-4 month (N=24) and 12-15 months (N=24) received a temporary unilateral occlusion of an external ear canal before a brief narrowband noise exposure (awake, 112 dB, two hours, octave-band noise centered at 8-kHz). Baseline ABRs and Gap-Induced-Prepulse-Inhibition of the Acoustic Startle Reflex (GPIAS) were assessed prior to and three months after noise to determine changes in

GPIAS ratios (behavioral marker for NIT). The mice that developed NIT were treated with 28-days of ebselen (10/mg/kg/d/ip) and reassessed at 1, 10, and 30-days post-treatment. Cochlear histopathology was performed using Myosin-7a immunolabeling to identify OHC loss.

Results: Three months after noise exposure, permanent threshold shifts were observed in the open ears of all noise-exposed mice across three tested frequencies (16-32 kHz). GPIAS showed frequency specific changes (NIT) in a subset (N=13) of the noise-exposed mice (N=48). After 28-days of ebselen, gap detection deficits were significantly reduced to pre-exposure levels in 12 of the 13 (92%) NIT mice at 1-day, in 10 of 12 (83%) NIT mice at 10-days, and in 9 of 11 (82%) NIT mice at 30-days post-treatment. Mice with permanent reversal of NIT showed significantly less OHC loss (3 complete rows) than those with temporary reversal: 0.073 ± 0.07 mm vs 0.660 ± 0.06 mm, respectively ($p=0.0013$).

Conclusions: 28-days of ebselen treatment can permanently reverse gap detection deficits to baseline or pre-noise exposure in 82% of mice that developed NIT, 3-months after noise exposure and the development of NIHL. In addition, the significant reduction in complete OHC loss suggests a broad therapeutic window by which to prevent injured OHCs from dying. This work is the first demonstration of an anti-inflammatory drug permanently reversing NIT after the development of age-related hearing loss. These data further support ebselen as a treatment for NIHL and NIT in young and old adults.

gEAR Session: Advanced Workshop

4:15 p.m. - 5:15 p.m.

Meeting Room 209ABC, Floor 2

Join us for an exciting workshop where you'll learn directly from leading investigators how to harness the power of the **gEAR platform** to explore cutting-edge, newly generated **multi-omic datasets** in our field—and accelerate your own research. We'll kick off with a brief introduction from the gEAR team, followed by three, brief, expert-led sessions:

- **Brian Herb** - Showcasing the **Hearing Restoration Project's new collection** of multi-omic datasets now available in gEAR. Brian will demonstrate how to use the **gEAR projection tool** for transfer learning and for identifying shared molecular features across diverse datasets.
- **Matthew Kelley** - Presenting the **first release of CoMAP**, the NIDCD's cochlear multi-omic and spatial transcriptomic atlas. Matthew will guide you through co-exploring **transcriptomic and spatial transcriptomic data** using gEAR's integrated tools.
- **Celia Bloom** - Sharing a **new gene regulatory network** from the lab of Litao Tao and demonstrating how to use the **new epigenomic viewer** in gEAR. Celia will walk through how to visualize and connect **DNA accessibility, epigenetic marks, CUT&RUN, and Hi-C data** with transcriptomic datasets—all within the platform.

Advanced gEAR Workshop

Brian Herb, *University of Maryland School of Medicine*

Presenting the First Release of CoMAP, the Nidcd's Cochlear Multi-Omic and Spatial Transcriptomic Atlas. Matthew Will Guide You through Co-Exploring Transcriptomic and Spatial Transcriptomic Data Using Gear's Integrated Tools

Matthew Kelley, *NIH/NIDCD*

Sharing a New Gene Regulatory Network from the Lab of Litao Tao and Demonstrating How to Use the New Epigenomic Viewer in Gear. Celia Will Walk Through How to Visualize and Connect Dna accessibility, Epigenetic marks, CUT&RUN, and Hi-C Data with Transcriptomic datasets—all within the Platform.

Celia Bloom, *Creighton University*

Inner Ear Courses

6:30 p.m. - 7:30 p.m.

Formins and Ankle-Link Complexes Regulate Stereocilia Length in Auditory Hair Cells

8:00 a.m. - 8:15 a.m.

Chun-Yu Tung¹, Xiayi Liao¹, Benjamin Perrin*¹

¹*Indiana University - Indianapolis*

Background: Stereocilia are actin-based protrusions that form a staircase-like bundle on auditory hair cells, essential for mechanotransduction. Their cores consist of long, unbranched actin filaments whose barbed ends reside at the tips. Formins nucleate unbranched actin filaments and elongate them from their barbed ends, so we hypothesized that formins drive stereocilia elongation.

Methods: We treated cochlear explants with the pan-formin inhibitor SMIFH2, then assessed stereocilia morphology by scanning electron microscopy (SEM), examined protein localization by immunofluorescence, and measured actin incorporation using phalloidin labeling. Finally, we performed injectoporation of EGFP-PDZD7 or EGFP-MYO7A constructs to test functional relevance.

Results: If formins elongate the F-actin in the core, then inhibition would result in shorter stereocilia. Instead, SMIFH2 induced stereocilia elongation, suggesting formin inhibition enhanced actin assembly at tips. FMN1 and DAAM1, the most abundant formins per mRNA sequencing, localized at stereocilia bases with ankle-link proteins PDZD7 and MYO7A. SMIFH2 disrupted this localization, redistributing these proteins along stereocilia and to tips. EGFP-PDZD7 overexpression mirrored SMIFH2, causing PDZD7 and MYO7A tip accumulation and elongation. Wild-type EGFP-MYO7A had minimal effects, but a Myo7a mutant with increased activity that is associated with hearing loss did increase stereocilia length.

Conclusions: FMN1 and DAAM1 anchor ankle-link complexes that restrain tip-ward actin polymerization. Disruption of this anchoring, either pharmacologically or by PDZD7 overexpression, released the restraint and increased stereocilia elongation, likely via altered MYO7A activity. This novel regulatory pathway connects ankle-link organization to stereocilia length control.

Tip Link Re-Assembly and Re-Anchoring During Stereocilia Cytoskeleton Remodeling in Inner Ear Hair Cells

8:15 a.m. - 8:30 a.m.

Ana I. Lopez-Porras^{*1}, Sara Gonzalez-Velez¹, Patricia Quiñones², Abigail Dragich¹, Sebastiaan Meenderink³, Luis Rendon-Orozco¹, Dolores Bozovic⁴, Gregory Frolenkov¹, A. Catalina Velez-Ortega¹

¹*University of Kentucky*, ²*University of Southern California*, ³*VA Long Beach Healthcare System*,
⁴*California NanoSystems Institute, UCLA*

Background: Apical surfaces of inner ear hair cells feature stereocilia bundles, formed by highly organized microvilli-like projections arranged in rows of increasing height. The tips of shorter stereocilia are connected to the sides of taller neighbors via tip links. Deflection of these bundles increases tip link tension, activating mechano-electrical transduction (MET) channels. Even at rest, tip links remain tensioned, maintaining optimal mechanosensitivity and allowing a small influx of cations. It has been shown that changes to this resting MET current influence stereocilia cytoskeleton morphology (Velez-Ortega et al., eLife, 2017), and that auditory hair cells can modulate their mechanosensitivity through such cytoskeleton remodeling (Dragich et al., in review, 2025). These findings, however, assume an upper tip link anchoring point with limited mobility. Here, we induced exaggerated stereocilia remodeling (> 150 nm shortening) in the shorter rows of the hair bundle to investigate whether tip links break (and reform) or slide down during this dynamic process, and to further test the mobility capacity of the upper tip link insertion site.

Methods: The organ of Corti from mice, as well as the sacculus and amphibian papilla from bullfrogs, were dissected and incubated with pharmacological blockers of MET channels to initiate stereocilia remodeling. Samples were then processed for scanning electron microscopy (SEM) to visualize/quantify tip links or embedded for focused ion beam (FIB)-SEM to assess upper tip link densities (UTLDs). We also assessed MET currents via whole-cell patch-clamp recordings and mechanical stimulation of hair bundles.

Results: During initial stages of stereocilia remodeling (~150 nm of shortening), there was a significant reduction in tip link counts in all hair cell types evaluated, accompanied by changes in the appearance of surviving tip links and reduced MET currents. Consistent with Grati and Kachar (PNAS, 2011), the UTLD remained at or near its original position, and thus significantly far from the tips of shorter stereocilia. At later time points (up to 500 nm of stereocilia shortening), tip link counts, their appearance, and MET amplitudes were fully restored. In addition, the UTLD was observed significantly lower from its original location, at a position consistent with the new tip link insertion site.

Conclusions: We show that tip links and their associated structures can remodel in response to significant changes in stereocilia morphology. The initial stages of stereocilia shortening disrupt tip links, likely due to limited mobility of the UTLD. After extensive stereocilia shortening, however, new tip links form and UTLDs are found at the new tip link insertion points. These findings indicate that the UTLD can reform/relocate when the tip link reassembles at a new location, revealing a previously unrecognized mechanism of plasticity of the upper tip link insertion point in hair cells.

The Role of MYO7A Isoforms in Tuning Hair Cell Function

8:30 a.m. - 8:45 a.m.

Sihan Li^{*1}, Jinho Park², Andrew Mecca³, Giusy Caprara³, Natchanon Sittipongpittayaemail¹, Gloria Sheynkman¹, Edward Egelman¹, Anthony Peng³, Jonathan Bird², Jung-Bum Shin¹

¹*University of Virginia*, ²*University of Florida*, ³*University of Colorado Anschutz Medical Campus*

Background: In auditory hair cells, tip-link tension is essential for the sensitivity of the mechano-electrical transduction (MET) process. Our previous study provided evidence that the unconventional Myosin VIIa (MYO7A) is essential for tensioning the tip-link MET complex. We further discovered two MYO7A isoforms with unique N-terminal extensions in inner and outer hair cells (IHCs and OHCs), with their expression pattern correlating with reported differences in tip-link tension. The goal of the present study was to explore the hypothesis that the differential expression of functionally distinct MYO7A isoforms directly affects hair cell physiology such as tip-link tension and resting open probability, and hearing sensitivities across hair cells at different frequencies.

Methods: Kennix long-read sequencing by PACBIO was performed on cochlea cDNA to identify new transcript isoforms. MET currents were recorded in response to fluid jet stimulations, and hair bundle motion was monitored by a high-speed camera. SEM and immunofluorescence microscopy were used to investigate hair bundle morphology. ATPase hydrolysis assay and actin gliding assay were conducted to determine the motor activities of MYO7A isoforms. Cryo-EM was applied to resolve the structure of mouse MYO7A isoforms.

Results: Kennix sequencing identified two major isoforms of Myo7a in the auditory system: a widely studied canonical isoform (MYO7A-C) and a previously unreported novel isoform (MYO7A-N). Analysis of isoform-specific HA KI mice revealed that IHCs predominantly express MYO7A-C, and a significantly lower level of MYO7A-N. In OHCs, MYO7A-C and MYO7A-N showed an opposing gradient along the tonotopic axis. Simultaneous deletion of both MYO7A-C and MYO7A-N abolishes MYO7A immunoreactivity in all hair cells, accompanied by disorganized hair bundles and profound hearing loss. Therefore, we conclude that MYO7A-C and MYO7A-N are the major isoforms in hair cells. We previously reported that IHCs in mice lacking MYO7A-C showed a significant reduction in resting open probability in IHCs, consistent with the proposed role of MYO7A in generating tip-link tension. We now show that deletion of MYO7A-N results in progressive hearing loss and OHC loss. ATPase hydrolysis assays demonstrated that MYO7A-N exhibits significantly lower ATPase activity than MYO7A-C, consistent with a proposed role in maintaining a higher tip-link tension in OHCs. Cryo-EM analysis revealed structural divergences between MYO7A isoforms, with loop-2—a key actomyosin binding interface—showing significant differences that likely underlie their distinct ATPase activities. These structural and biochemical distinctions suggest that MYO7A-N functions as a slower, high-tension motor, specialized for sustaining elevated tip-link tension in OHCs.

Conclusions: In summary, our studies reveal the isoform diversity of MYO7A in the cochlea and highlight their essential roles in tensioning the MET complex. The differences in motor activity between the two isoforms are consistent with their proposed role in fine-tuning the tip-

link tensions, with potential importance for establishing the remarkable frequency range of mammalian hearing.

Taperin Bundles F-Actin at Stereocilia Pivot Points Enabling Optimal Lifelong Mechanosensitivity

8:00 a.m. - 9:00 a.m.

Inna Belyantseva^{*1}, Chang Liu², Abigail Dragich³, Takushi Miyoshi⁴, Sayaka Inagaki¹, Ayesha Imtiaz¹, Risa Tona¹, Karen Sofia Zuluaga-Osorio³, Shadan Hadi³, Elizabeth Wilson¹, Eva Morozko¹, Rafal Olszewski¹, Rizwan Yousaf¹, Yuliya Sokolova¹, Gavin Riordan¹, Andrew Aston¹, Atteeq Rehman¹, Cristina Fenollar Ferrer¹, Jan Wisniewski¹, Shoujun Gu¹, Gowri Nayak⁵, Richard J. Background: Pathogenic variants of TPRN are associated with nonsyndromic prelingual deafness DFNB79 (Rehman et al., 2010) or progressive hearing loss (Bashir et al., 2013; Li et al., 2010). Taperin protein (TPRN) is located at the tapered base of each stereocilium where it pivots in response to sound (Rehman et al., 2010). TPRN deficiency in mouse results in stereocilia degeneration (Chen et al., 2016; Liu et al., 2018; Men et al., 2019; Qi et al., 2024). However, the exact functions of taperin and molecular mechanisms of stereocilia degeneration in Tprn mutants are unknown.

Methods: We generated two Tprn-deficient mouse models: Tprn^{-/-} has the entire Tprn gene deleted using Crispr/Cas9 and Tprn^{Δ260-749} lacks the sequence encoding residues 260 to 749. ABR and DPOAE were assessed. Whole cell patch clamp recordings evaluated mechano-electrical transduction (MET) in cochlear hair cells. Structural abnormalities in hair cells were investigated with Airyscan confocal and super-resolution STED fluorescence microscopy and various electron microscopy techniques, including FIB-SEM. Finally, the ability of taperin to cross-link F-actin was explored using mouse TPRN heterogeneously expressed in E. coli and purified for biochemical assays.

Results: In wild-type hair cells, native TPRN encircles the F-actin core along stereocilia tapers forming funnel-like patterns like those reported by Qi et al. (2024). TPRN interacts with membrane receptor PTPRQ, connecting stereocilia F-actin to the plasma membrane. Localization of TPRN partially overlaps with TRIOBP-5 and ANKRD24. Overexpression of TPRN in wild-type hair cells results in over-elongation of stereocilia, indicating that TPRN may directly regulate F-actin dynamics. Consistent with this idea, in mice with progressive deafness due to total or partial deletions of Tprn, TRIOBP-5 and ANKRD24 disappear from rootlets of the shortest third row stereocilia beginning at P3, leading to excessive pruning of stereocilia, dysmorphic rootlets and prominent abnormalities in the actin core of stereocilia and rootlets

around stereocilia pivot points. However, MET current before the onset of hearing is unaffected. By P30, these structural abnormalities of stereocilia become accompanied by synaptic rearrangement and excessive accumulation of endosome-like vesicular aggregates in inner hair cells (IHCs) reflecting vesicular trafficking dysfunction along with re-appearance of IHC axo-somatic synapses, indicative of affected MET. This likely exacerbates the progression of hearing loss to profound by two months of age, revealing complex molecular mechanisms underlying deafness due to TPRN deficiency. Biochemical experiments show purified TPRN cross-links F-actin forming flexible bundles with smaller interfilamentous space than F-actin bundles cross-linked by espin isoform 1. Similar whorl-like bent bundle formations are observed in live COS-7 cells. We show that TPRN has multiple actin-binding sites, while its N-terminal portion is essential and sufficient to bundle F-actin.

Conclusions: TPRN bundles F-actin at stereocilia pivot points to reinforce rootlets, stabilizing stereocilia structure and augmenting sustained pivot-point flexibility for optimal mechanosensitivity.

PIP2-Tmie Interactions Drive Mammalian Hair Cell Slow Adaptation Independently of Myosin Motors

9:00 a.m. - 9:15 a.m.

Giusy Caprara¹, Ye-Ri Kim², Sujin Jun¹, Sihan Li³, Un-Kyung Kim⁴, Jung-Bum Shin³, Anthony Peng^{*1}

¹*University of Colorado Anschutz Medical Campus*, ²*University of Colorado*, ³*University of Virginia*, ⁴*Kyungpook National University*

Background: Auditory stimuli are transmitted to the inner ear, eliciting vibrations within the cochlear partition, comprised of hair cells and supporting cells situated atop the basilar membrane and covered by a tectorial membrane. Hair cells serve as auditory mechanoreceptors utilizing apically located hair bundles to transform sound-induced mechanical vibrations into electrical activity, a phenomenon referred to as mechano-transduction. This process is pivotal for cochlear amplification, which underlies exceptional sound level sensitivity, wide dynamic range, and notable frequency discrimination. This mechano-transduction is similar in the vestibular hair cells within the inner ear, which are responsible for balance. With a sustained step-like displacement, the hair-cell receptor current peaks followed by a decrease in the receptor current, termed adaptation. Among these adaptation mechanisms, slow adaptation, characterized by time constants typically ranging from 10-100 milliseconds, was previously hypothesized to operate via a motor model of adaptation. This form of adaptation relies on Ca²⁺ influx through MET channels modulating the attachment of myosin motors along the stereocilia core. Our recent investigations have challenged the motor model of slow adaptation, proposing instead a novel model reliant on the phosphoinositide PIP2.

Methods: We used whole-cell patch clamp electrophysiology coupled with mechanical stimulation with a fluid jet while imaging the hair bundle at 10,000 frames per second to study the slow adaptation process.

Results: We found that the reduction of hair bundle PIP2 levels using PAO results in a reduction of slow adaptation. Previous work by others and us have shown that when the Myo1c motor is

inhibited in vestibular hair cells, slow adaptation is reduced. Strikingly, we could rescue slow adaptation during Myo1c inhibition with exogenous PIP2, indicating that PIP2 is the critical component to slow adaptation, and that the myosin motors may have a secondary role in slow adaptation. Slow adaptation in cochlear hair cells could also be rescued with PIP2 when slow adaptation was reduced with myosin motor inhibition using intracellular sulfate. Our hypothesis is that PIP2 directly modulates the MET channel complex as other ion channels, like the structurally similar TMEM16a, are directly modulated by PIP2. Interestingly, TMIE, an MET channel complex protein, was shown to bind PIP2. Using a point mutation in TMIE that reduces PIP2 binding, we found these hair cells exhibit reduced slow adaptation.

Conclusions: Our results provide the first data describing a new mechanistic model of slow adaptation in mammalian hair cells.

Sensory Transduction Defects Alter Development and Maturation of Auditory Inner Hair Cells

9:15 a.m. - 9:30 a.m.

Thibault Peineau^{*1}, Stephanie Mauriac¹, Lauren Celardo², Benjamin Tibbetts², Jeffrey Holt¹, Brikha Shrestha², Gwenaelle Geleoc¹

¹*Boston Children's Hospital, Harvard Medical School*, ²*Mass Eye and Ear/Harvard Medical School*

Background: We hypothesize that acquisition of mechanosensory transduction plays a pivotal role in the development and maturation of the peripheral auditory system. However, the extent to which alterations in sensory transduction affect downstream pathways and the reversibility of these changes are poorly understood.

Methods: We performed experiments in several mouse models with altered sensory transduction: mice lacking Transmembrane Channel (TMC) proteins one or two (Tmc1 Δ/Δ , Tmc2 Δ/Δ , respectively), mice lacking both proteins (Tmc1 Δ/Δ ; Tmc2 Δ/Δ) and mice carrying recessive mutations in Tmie (Tmiesr/sr, Spinner mice). We assessed electrophysiological properties of inner hair cells (IHCs) before (P12) and after the onset of hearing (P21) to characterize hair cell biophysical profiles and exocytosis. Single-cell transcriptomic profiles were collected from organs of Corti harvested from each mouse model (P24-P28) to determine changes in IHC gene expression. Finally, we performed gene replacement therapy in Tmc1 Δ/Δ mice and assessed recovery of physiological and transcriptional features.

Results: We demonstrate preservation of potassium currents and synaptic properties in Tmc2 Δ/Δ mice. In mice lacking sensory transduction (Tmc1 Δ/Δ , Tmc1 Δ/Δ ; Tmc2 Δ/Δ and Tmiesr/sr mice), we observed alterations in potassium currents, voltage-dependent calcium currents and exocytosis. These changes were associated with alterations in synapse morphology, consistent with previous results. Single cell RNA sequencing revealed different transcriptomic profiles in IHCs of the various mouse models with trends consistent with our physiological assessments. Lastly, we showed that neonatal gene replacement therapy in Tmc1 Δ/Δ mice restored developmental features of hair cell physiology, afferent synapses and gene expression.

Conclusions: The data demonstrate that sensory transduction plays a critical role in the development and maturation of the peripheral auditory system.

Protein-Protein Interactions of TMEM145 in Outer Hair Cell Stereocilia

9:30 a.m. - 9:45 a.m.

Dennis Derstroff¹, Marisa Flook Pereira², Antonia Löhnes³, Sherylanne Newton², Vijay Renigunta⁴, Saskia Hanemaaijer⁵, Carlos Aguilar², Jeffrey R. Holt⁶, Michael R Bowl², Dominik Oliver⁴, Katrin Reimann^{*7}

¹University Hospital Marburg, Philipps-University Marburg, ²UCL Ear Institute, University College London, ³University Hospital Marburg, Philipps-University Marburg, ⁴Institute of Physiology and Pathophysiology, Philipps-Universität Marburg, ⁵Mammalian Genetics Unit, MRC Harwell, ⁶Boston Children's Hospital, Harvard Medical School, ⁷University Hospital Marburg, Philipps-University Marburg

Background: In outer hair cells (OHCs), mechanosensory transduction (MET) relies on physical coupling of the stereocilia bundle to the tectorial membrane (TM). This connection is mediated by tectorial membrane attachment crowns (TM-ACs) at the tips of the tallest stereocilia. Additionally, OHC stereocilia are interconnected by horizontal top connectors (HTC). Both structures are assembled from the same proteins, but their molecular architecture remains incompletely defined. Here, we characterize the interactions of Tmem145, a GPCR-related transmembrane protein, with known TM-AC and HTC components.

Methods: Protein interactions were assessed in-vitro using co-immunoprecipitation, and in cells by pull-down assays (Nano SPD). This in-cell approach is based on intracellular trafficking of bait protein along filopodial actin filaments enforced by association to a myosin motor. Molecular interactions are then quantified by the degree of co-trafficking of fluorescently labelled prey protein to filopodial tips, using confocal microscopy. Interaction interfaces were probed by mutagenesis and deletion of protein domains. Subcellular localization was investigated by super-resolution TauSTED microscopy, while SEM was used to examine hair bundle morphology and TM-AC imprints.

Results: Using CoIP we demonstrate direct physical interactions between TMEM145 and tubby, as well as between TMEM145 and STRC, but not between tubby and STRC, establishing TMEM145 as a molecular bridge linking the intracellular protein tubby with the extracellular protein STRC.

To evaluate direct protein-protein interactions of Tmem145 in live cells we used the nanoscale pulldown technique (NanoSPD). When tubby was co-expressed with Tmem145 fused to GFP-labelled myo10MD, it was significantly enriched in filopodial tips. Enrichment was not observed in the absence of TMEM145 as the bait, indicating binding of tubby to Tmem145. Truncation analyses further suggested potential binding sites mediating the TMEM145–tubby interaction specifically for the intracellular domain of TMEM145.

All three proteins display a ring-like distribution at the tips of the tallest OHC stereocilia, precisely outlining the localization of TM-ACs. Quantitative analysis of ring diameters supported localization of tubby in an innermost layer, an intermediate localization of TMEM145, and the localization of STRC in an outermost layer. Depletion of the lipid co-ligand of tubby, PI(4,5)P2 from the inner leaflet of stereocilia membrane led to dissociation of tubby from the TM-AC complex, supporting its intracellular association to the complex.

Conclusions: Our findings identify Tmem145 as a key organizer of outer hair cell (OHC) stereocilia attachment complexes, bridging intracellular and extracellular components. Through its C-terminal domain, Tmem145 interacts with the intracellular partner tubby, while its extracellular Golgi-like domain anchors the secreted protein STRC. These results uncover a central role for Tmem145 in coordinating protein–protein interactions within TM-ACs as well as HTC. Future work will address the precise binding motifs and assembly principles of these complexes, possible additional components of the complexes, thereby advancing our understanding of OHC stereocilia architecture.

Nherf1 Directs PCDH15-CD2 Trafficking to the Hair Bundle via a Phospho-Dependent Interaction

9:45 a.m. - 10:00 a.m.

Aray Adylkhan^{*1}, Anna Andreeva², Xufeng Qiu³, Alison Lim¹, Phillip Wilson¹, Bao-Tich Nguyen¹, Ulrich Mueller³, Xiaowei Lu⁴

¹*University of Virginia*, ²*Nazarbayev University*, ³*Johns Hopkins University, School of Medicine*,

⁴*University of Virginia School of Medicine*

Background: The architecture of hair bundles (HBs) is crucial for hearing and relies on extracellular links composed of Protocadherin-15 (PCDH15) and Cadherin-23 (CDH23). The CD2 isoform of PCDH15 (CD2 hereafter) is essential for kinociliary links and tip links; its absence during development leads to kinocilium detachment and HB shape and orientation defects, while its absence in mature hair cells (HCs) impairs mechanotransduction (MET) and causes profound deafness. Despite its importance, the molecular mechanisms regulating CD2 trafficking and function in stereocilia are unclear. We hypothesized that CD2 localization to stereocilia is regulated by interactions of its C-terminal PDZ-binding motif (PBM) with PDZ-domain-containing chaperones. This is tested by identifying CD2-interacting proteins and functional analysis of novel CD2-protein interactions in vitro and in vivo.

Methods: To identify CD2 binding partners, we performed a CD2 pull-down assay against P0 mouse brain lysates, followed by mass spectrometry (MS). We confirmed direct binding and determined key residues in CD2 essential for the interaction using in vitro GST pulldown assays and AlphaFold structural modeling. We investigated the physiological relevance of the identified protein-protein interaction (PPI) by analyzing mouse lines carrying mutations that disrupted the PPI, including evaluations of CD2 localization, HB morphology using immunofluorescence, HC MET function using FM1-43 uptake and whole-cell patch-clamp recordings, and ABR hearing thresholds at different stages.

Results: We identified the PDZ-scaffold protein Nherf1 as a CD2 binding partner. In vitro, Nherf1 showed a strong, direct interaction with PCDH15-CD2 and CD1 isoforms. In P0 Nherf1-KO HCs, CD2 localization to stereocilia was significantly reduced and shifted towards the tips, whereas localization of CDH23 was unaffected. Thus, Nherf1 is specifically required for stereocilia trafficking of PCDH15.

We also identified three C-terminal phosphorylation sites in CD2 expressed in heterologous cells. We have generated antibodies that specifically detect phospho-S1771. Importantly, CD2-S1771 phosphorylation was detected in postnatal HBs, suggesting that phospho-regulation of

CD2-Nherf1 interaction is important for CD2 function in vivo. In support, in vitro binding assays demonstrated that a phospho-deficient mutant of CD2 (CD2-4A) has significantly reduced affinity for Nherf1. Moreover, AlphaFold modeling revealed that the 4A mutations disrupt critical hydrogen bonds between the Nherf1 PDZ and CD2 PBM domains.

We next generated corresponding CD2-4A knock-in mice, which phenocopied Nherf1-KO mice. Specifically, CD2-4A HCs at P0 showed reduced CD2 stereocilia localization and mild HB orientation defects. Interestingly, CD2-4A HCs displayed decreased FM1-43 dye uptake, although MET channel currents appeared normal at P5. By one month of age, CD2-4A mice showed high-frequency hearing loss. MET channel recordings at different ages and in different conditions, and ultrastructural analysis of CD2-4A adult HBs are underway.

Conclusions: Disruption of CD2-Nherf1 interaction leads to CD2 stereocilia trafficking defects and compromised MET in adult HCs, with mild effects on HB development.

Podium 9: Auditory Cortex and Thalamus: Human and Animal Studies

Auditory Training Enhances Speech Perception in Noise With Enhanced Cingulo-Opercular Network Activation

8:00 a.m. - 8:15 a.m.

Leeseul Shim¹, Jahee Kim², Gibbeum Kim¹, Hyo-Jeong Lee^{*3}

¹Hearing, Balance and Integrated Neuroscience (HBIN) Lab, Hallym University College of Medicine, ²Hallym University Sacred Heart Hospital, ³Hallym University College of Medicine

Background: The ability to perceive speech-in-noise (SiN) is essential for human social interaction and remains a significant challenge for individuals with hearing loss. Such ability cannot be sufficiently restored by amplification through hearing aids alone but has been shown to improve with auditory training that targets auditory–cognitive functions. Neuroimaging evidence further suggests that speech-in-noise perception is closely associated with higher-order networks supporting auditory attention and cognitive control, such as the cingulo-opercular network (CON). In this study, neurophysiological changes associated with improvement in speech-in-noise performance were evaluated in hearing aid users who underwent auditory training, using functional MRI.

Methods: An fMRI experiment with a SiN task was conducted, and the Korean Matrix Sentence Test (K-MST) served as a behavioral measure. Participants were fifteen adults with moderate to moderately severe hearing loss and sixteen age- and gender-matched normal-hearing controls. The hearing-impaired group was assessed twice, at one month and three months after initial hearing aid fitting, with one subgroup receiving auditory training (HA+AT) and the other using hearing aids only (HAonly). Controls were tested once. Statistical analyses were performed in R, and neuroimaging data were processed with SPM12.

Results: In the normal-hearing controls, the speech-in-noise task elicited significant activation in the bilateral auditory cortices as well as in the cingulo-opercular network (CON), with the latter showing a linear increase in activity as task difficulty increased. Among the hearing-impaired participants, significant improvement in speech-in-noise performance was found in the HA+AT group, whereas no improvement was observed in the HA-only group. In the fMRI results, no group differences were evident at the initial measurement; however, at follow-up a significant group difference and a group $\times$ time interaction were identified in the paracingulate cortex, part of the CON. The interaction reflected a significant increase in activity in the HA+AT group.

Conclusions: We identified that the cingulo-opercular attention network plays a critical role in speech-in-noise processing, with its activity varying according to task difficulty. In hearing aid users, this network was further implicated in the improvement of speech-in-noise perception following auditory training. These findings suggest that auditory training should not be limited to bottom-up auditory approaches, but should also incorporate top-down strategies targeting auditory attention and related cognitive functions.

Invariance to Extrinsic Acoustic Variation is Accomplished by Hierarchical Anatomical and Temporal Computations Selective for Speech-Specific Structure

8:15 a.m. - 8:30 a.m.

Background: Coding information in speech is computationally challenging in part because factors extrinsic to the sound source (e.g., reverberation, background sounds) substantially alter the sound's acoustics. Successful communication requires listeners to rapidly encode speech information in a manner that is "invariant" to such acoustic variation. Invariant coding has been studied for decades in the visual system and is thought to be achieved by hierarchical anatomical computations that increase invariance across hierarchically organized brain regions, as well as hierarchical temporal computations that increase invariance across time within a region, partly reflecting recurrent computations. By comparison, less is known about the neural computations that underlie invariant representations of speech in the human auditory cortex. Much of the prior research has been conducted in non-human animal models, which lack speech-specific computations present in human auditory cortex, and non-invasive neuroimaging methods lack the precision needed to measure invariant representations of speech.

Methods: We measured responses to speech presented with many common types of extrinsic acoustic variation using spatiotemporally precise intracranial recordings from throughout the human auditory cortex. We developed a novel paradigm that directly measures the timing and strength of invariance relative to the onset of speech information. The paradigm provides a straightforward, model-free, and time-varying measure of invariance that accounts for the fact that noise in the neural measurements will inevitably cause responses to differ even if the noise-free responses were invariant to acoustic variation. In a separate experiment, we measured

responses to a diverse set of natural sounds without any added acoustic variation, which enabled us to identify speech-selective regions of human non-primary auditory cortex.

Results: We observed neural populations whose responses to speech were nearly completely unaltered by many distinct types of extrinsic acoustic variation (reverberation, background sounds, spectral variation). These neural populations clustered in speech-selective regions of non-primary auditory cortex, suggesting the importance of hierarchical anatomical and speech-specific computations. Invariance also rapidly increased over time in many electrodes, in a manner that could not be explained by generic delays in the neural response, consistent with hierarchical temporal computations. As a consequence, neural responses in speech-selective regions required approximately 200 ms to become strongly invariant to extrinsic acoustic variation.

Conclusions: Collectively, these findings suggest that invariant representations of speech are produced by speech-specific computations that rapidly increase invariance across both time and the auditory cortical hierarchy. The fact that many neural populations become more invariant over time suggests that invariant representations are computed by hierarchical temporal computations that iteratively refine an initial, more acoustically sensitive representation of sound. This type of dynamic process might, for example, reflect recurrent connections within or between regions.

Investigating Human Brain Synaptic Plasticity Through AMPA Receptor PET Imaging in Hearing Loss and Restoration With Cochlear Implantation

8:30 a.m. - 8:45 a.m.

Toshihito Sahara*¹, Akinori Kashio¹, Yasuhiro Arai², Katsuyuki Ishida³, Masahiro Takahashi⁴, Nobuhiro Nishiyama⁵, Hidehiko Takeda⁶, Shujiro Minami⁷, Keisuke Aizawa², Takashi Wada⁸, Hajime Koyama¹, Nobuhiko Oridate², Hiroki Abe⁹, Kenji Kondo¹, Takuya Takahashi⁹

¹*Faculty of Medicine, University of Tokyo*, ²*Yokohama City University Hospital*, ³*Chigasaki Chuo Hospital*, ⁴*International University of Health and Welfare Mita Hospital*, ⁵*Tokyo Medical University Hospital*, ⁶*Toranomon Hospital*, ⁷*National Institute of Sensory Organs, National Hospital Organization Tokyo Medical Center*, ⁸*Yokohama City University Medical Center*, ⁹*Yokohama City University Graduate School of Medicine*

Background: Cortical plasticity in the auditory system could underlie the recovery process after cochlear implantation (CI) for hearing loss. However, the molecular basis of experience-dependent neuronal, and synaptic plasticity in the human brain remains elucidated. AMPA receptors are fundamental molecules of synaptic plasticity, and the amount of AMPA receptors at synapses underlies long-term potentiation (LTP) and long-term depression (LTD), a fundamental mechanism of experience-dependent plasticity such as learning and memory. In this study, we evaluate synaptic plasticity in vivo by visualizing AMPA receptors, using the novel PET tracer [¹¹C]K-2, recently developed in Japan, the only technology to visualize and quantify AMPA receptor in living human brain (Miyazaki et al., *Nature Medicine* 2020) during the recovery of CI. The tracer only depicts AMPA receptors on the cell surface which are the physiologically crucial fraction. The objective of this study was to assess AMPA receptor-mediated synaptic plasticity in the human brain through cross-sectional comparisons with

healthy controls, and longitudinal evaluation before and after cochlear implantation using [¹¹C]K-2 PET.

Methods: This single-arm, multicenter, prospective study enrolled 30 adult CI candidates with acquired bilateral severe-to-profound hearing loss (jRCTs031230617). All participants underwent preoperative [¹¹C]K-2 PET scanning, and 22 completed six-month follow-up imaging after CI surgery. Analyses focused on (1) longitudinal comparison of pre- and postoperative scans, and (2) cross-sectional comparison of preoperative candidates with a cohort of age- and sex-matched healthy controls. Voxel-wise statistical analyses were conducted using SPM12, and regional binding was quantified using SUVR (standardized uptake ratio) with white-matter as a reference (quantitative value of ‘absolute’ AMPA receptors density) and SUVR with whole-brain reference normalization (‘relative’ AMPA receptors density).

Results: In the CI group (63.5±15.7 years), 29 were right-handed and 1 was left-handed, and the surgery side was right in 14 and left in 16 participants. White-matter–referenced analysis showed that, compared with healthy controls, preoperative CI candidates exhibited globally elevated AMPA receptor density. In contrast, longitudinal analysis demonstrated a global decrease from the preoperative to postoperative state. Still, AMPA receptor density in postoperative CI patients tended to remain globally higher than in healthy controls. Whole-brain–referenced analysis revealed postoperative relative increases in AMPA receptor density within the left superior temporal gyrus region, including primary auditory cortex and Wernicke’s area, along with relative decreases in bilateral parietal regions.

Conclusions: This study provides the first in vivo molecular evidence of synaptic plasticity in the human brain after hearing loss and cochlear implantation, revealing dramatic absolute changes in AMPA receptor density and postoperative relative increases within the language-dominant auditory cortex. These findings highlight [¹¹C]K-2 PET as a powerful tool to investigate the molecular mechanisms of auditory plasticity. Overall, these findings underscore the fundamental importance of auditory input for human brain function.

The Nexpo Study: Behavioural, Physiological, and Neuroimaging Measures to Assess the Effects of Noise Exposure on the Auditory Pathway

8:45 a.m. - 9:00 a.m.

Rebecca Dewey*¹, Sofya Koryagina¹, Hannah Guest², Michael Asghar¹, Rebecca Millman², Garreth Prendergast², Susan Francis¹, Christopher Plack²

¹*Sir Peter Mansfield Imaging Centre, University of Nottingham*, ²*Manchester Centre for Audiology and Deafness, The University of Manchester*

Background: The NExpo study aims to determine the effects of noise exposure, relative to those of age and audiometric threshold elevation, on the human auditory nervous system. We hypothesize that measures of auditory function and health will be reduced in noise-exposed individuals. The data collection protocol was presented at the ARO 2024 Midwinter Meeting and has been published.

Methods: Participants: We recruited 200 healthy participants into four groups of n=50 based on age, pure tone audiometry (PTA), and Noise Exposure Structured Interview (NESI) score. Group 1: 18-19 years, low noise exposure, normal hearing; Group 2: 30-50 years, low noise exposure,

normal hearing; Group 3: 30-50 years, high noise exposure, normal hearing; Group 4 30-50 years, high noise exposure, elevated 3-8 kHz PTA.

Data collection: Participants underwent extended high-frequency (EHF) audiometry, speech in noise testing, and measurement of distortion product otoacoustic emissions (DPOAEs), middle ear muscle reflexes (MEMRs), and the electrophysiological auditory brainstem response (ABR). MRI measures included whole-brain anatomical MPAGE data, T1 myelination mapping, and Diffusion Tensor Imaging (DTI), as well as resting-state fMRI of the auditory network, and neurography and Diffusion Tensor Imaging (DTI) of the auditory nerve.

Results: Participant demographics: The mean ($\pm$ stdev) age for Groups 1-4 was 19 ± 1 , 40 ± 6 , 41 ± 6 , and 41 ± 6 years, and NESI scores were 1 ± 2 , 4 ± 4 , 71 ± 68 , and 180 ± 310 units.

Audiological results: Tinnitus Functional Index (TFI) scores significantly differed across groups ($p < 0.001$), with noise-exposed individuals exhibiting significant tinnitus. Group audiometric differences were significant ($p < 0.001$) at 3-6 kHz and EHF. Mean DPOAE amplitude ($p < 0.001$), and speech reception threshold in speech-shaped noise ($p=0.04$) and multi-talker babble ($p < 0.001$) varied significantly with group, while MEMR threshold did not. In chirp-evoked ABRs, wave I amplitude ($p=0.023$), wave V amplitude ($p < 0.001$), wave V latency ($p < 0.001$), and mean inter-peak interval ($p < 0.001$) differed significantly with group (uncorrected for multiple comparisons). Post-hoc tests showed significant differences to be driven by Group 4, with no significant differences between Groups 2 and 3.

MRI results: MPAGE data were quantified using FreeSurfer to estimate group differences in cortical thickness (CT) and grey matter volume (GMV). Our results show a main effect of noise exposure related to decreased CT and GMV in both middle temporal gyrus regions and higher-order cognitive areas, including the frontal, parietal, and temporal lobes. A main effect of hearing loss also related to a more focal reduction in CT and GMV in middle temporal gyrus and superior frontal and inferior parietal regions. Analysis of the remaining MRI measures is underway.

Conclusions: There is no evidence from these data that noise exposure in the absence of threshold elevation affects physiological or behavioral measures of hearing. We aim to determine if MRI measures will facilitate the identification of individuals at risk of neural damage resulting from noise exposure.

A Hierarchically Organized Sound Discrimination Pathway in Auditory Cortex

9:00 a.m. - 9:15 a.m.

Steve Lomber^{*1}, M. Charlotte Kruger¹, Amee Hall², Andres Carrasco², Paul Cornwell³

¹McGill University Faculty of Medicine, ²University of Western Ontario, ³The Pennsylvania State University

Background: Electrophysiological, behavioural, and connectional studies have identified a ventral or “what” processing stream within extrastriate visual cortex of the human, monkey, and cat. This pathway arises in occipital cortex and projects anteroventrally across the temporal lobe. Furthermore, studies have shown that visual areas along this pathway become tuned to increasingly complex visual stimuli. Similarly, in auditory cortex, electrophysiological studies

suggest that areas beyond primary auditory cortex (A1) exhibit a hierarchical organization with responsiveness increasing for more complex acoustic stimuli along the sylvian gyrus of the feline temporal lobe. To examine this idea, we tested the hypothesis that ventral, but not dorsal, areas of the cat's temporal lobe have greater specificity for complex acoustic stimuli.

Methods: We trained four mature cats to discriminate sounds in a two-alternative forced-choice apparatus. The animals concurrently learned to discriminate three classes of sounds: tones, narrow-band bursts, and conspecific vocalizations (“meows”). After training, we implanted cooling loops bilaterally over primary auditory cortex (A1), second auditory cortex (A2), temporal cortex (area T), and insular cortex (area IN) to permit their temporary and reversible deactivation. The animals were then tested while each of the areas was bilaterally or unilaterally deactivated. Presentation of the three classes of stimuli was randomized within each testing session.

Results: With criterion performance of 70% correct on three consecutive days, we identified that conspecific vocalizations were learned the fastest, while tonal discriminations often required twice as much time to master. Bilateral deactivation of A1 resulted in discrimination deficits on all three stimulus classes. Bilateral deactivation of A2 caused deficits only for the narrow-band burst and conspecific vocalization classes. Bilateral deactivation of area T resulted in deficits restricted to the conspecific vocalizations. Bilateral deactivation of area IN did not produce deficits on any of the three stimulus classes tested. Unilateral deactivation of left, but not right, area T caused deficits exclusively during conspecific vocalization discriminations.

Conclusions: The present investigation provides evidence for the lateralization of conspecific vocalization discrimination in the left hemisphere. Overall, specificity for increasingly complex acoustic stimuli was identified along the temporal lobe of the cat. The results of this study indicate a “what” processing pathway in auditory cortex of the cat that arises in primary auditory areas and radiates down the temporal lobe through A2 and into area T.

A Topographic Protomap in Subplate Neurons Precedes and Persists Through Onset of Sensory Experience

9:15 a.m. - 9:30 a.m.

Travis Babola*¹, Minzi Chang¹, Rachel Jun¹, Marina Cardoso de Oliveira¹, Jessica Messier², Yunru Chen¹, Lillian Choi¹, Dave Gutierrez¹, Patrick Kanold¹

¹*Johns Hopkins University*, ²*Division of Neonatal-Perinatal Medicine, Johns Hopkins University School of Medicine*,

Background: The establishment of precise sensory maps in the neocortex requires accurate topographic relay of inputs from the thalamus to layer 4 (L4) neurons. Before reaching L4, thalamocortical axons (TCAs) pause within the subplate and form transient connections with subplate neurons (SPNs), a developmentally enlarged population located beneath the cortical plate. Classical ablation studies in cats and rodents suggest that SPNs are essential for guiding TCAs and for the proper formation of cortical maps. However, the functional organization of

SPNs, the nature of their thalamic inputs, and their activity patterns during the critical pre-sensory period remain poorly defined, largely due to a lack of genetic tools that specifically access SPNs. Understanding how SPNs integrate thalamic input and participate in early network activity is critical for defining their role in establishing cortical circuitry.

Methods: To overcome limitations in SPN labeling, we generated a tamoxifen-inducible Cplx3-CreER mouse line, taking advantage of the specific expression of Complexin 3 in SPNs. This model enabled selective genetic access to SPNs in auditory, visual, and somatosensory cortices. We crossed Cplx3-CreER mice with fluorescent and calcium indicator reporter lines to monitor SPN activity and morphology. Widefield and two-photon calcium imaging were used in vivo to assess spontaneous and sensory-evoked responses before and after ear and eye opening. Complementary whole-cell recordings in acute thalamocortical slices characterized intrinsic properties and thalamic inputs to SPNs. Together, these approaches provided a cellular- and circuit-level view of SPN activity across development.

Results: We found that Cplx3-CreER specifically and efficiently labeled SPNs, which persist as L6b neurons into adulthood. Electrophysiological recordings revealed early postnatal maturation of intrinsic properties and demonstrated reliable glutamatergic input from TCAs both before and after ear canal opening. Prior to sensory experience, SPNs exhibited robust spontaneous calcium transients tightly correlated with ascending thalamic activity. These spontaneous events were spatially organized into a protomap aligned with future tonotopic and retinotopic axes. In the auditory cortex, spontaneous organization at P8 resembled future tonotopy, while in visual cortex, SPNs were entrained by propagating retinal waves. Before ear canal opening, SPNs did not respond reliably to sound, but after opening they exhibited frequency-dependent responses with a coarse tonotopic gradient. Compared to L4 neurons, SPN maps were broader and less precise, consistent with a role in establishing cortical organization.

Conclusions: Our findings demonstrate that SPNs receive functional thalamic input, integrate spontaneous peripheral activity, and form an early topographic scaffold prior to sensory experience. After sensory onset, they exhibit coarse but reliable sensory responses. These results identify SPNs as key organizers of early thalamocortical activity, supporting the hypothesis that cortical maps emerge in the subplate before L4 innervation and are subsequently refined by experience-dependent mechanisms.

Auditory Cortical Manifold in Normal and Impaired Hearing

9:30 a.m. - 9:45 a.m.

Satyabrata Parida^{*1}, Jonah Stickney¹, Brad Buran¹, Stephen David¹

¹*Oregon Health and Science University*

Background: Listeners with sensorineural hearing loss (SNHL) exhibit perceptual deficits in everyday communication, which are not fully remediated with modern hearing aids. A key contributing factor to this problem may be central neural plasticity following peripheral hearing loss, which can dramatically affect perception. Studies using simple stimuli (e.g., tones, noise) have revealed changes in the auditory cortex consistent with perceptual deficits. However, because cortical neurons show tremendous heterogeneity in response to natural sounds, it remains unclear how these changes affect the encoding of real-world natural stimuli.

Methods: To comprehensively capture cortical tuning properties across real-world sound statistics, we recorded single-unit activity in the auditory cortex of awake ferrets in response to > 50 hours of natural sounds (pooled across all sessions). Data were from ferrets with normal hearing (N=4, ~3500 neurons) or noise-induced hearing loss or NIHL (N=1, 260 neurons), induced using 2.8–5.6 kHz noise (116 dB SPL, 2 hours). Hearing loss was validated with ABRs.

To characterize cortex-wide tuning properties, we trained a convolutional neural network (CNN) to predict neural responses from sound for each animal. The CNN-based encoding models identified a neural manifold, an efficient, low-dimensional space that is most predictive of cortical population activity. Data were also recorded for an environmental sound corpus (ESC50) to quantify how sound categorization is affected with hearing loss, measured with linear spike-count-based population decoders.

Results: CNN-based models explained over 50% of the explainable variance in neural responses, outperforming previous state-of-the-art encoding models. The manifolds were highly similar between normal-hearing ferrets and captured several key cortical tuning properties, such as spectrotemporal tuning and contrast gain control. In contrast, the NIHL manifold was less similar to normal-hearing manifolds and was lower dimensional, suggesting reduced information processing capacity following hearing loss. Sound categorization performance for the ESC50 dataset was also significantly reduced following hearing loss.

Conclusions: These results establish the neural manifold as a comprehensive, quantifiable framework to characterize the tuning properties that shape cortical responses to real-world sounds within and across individual listeners. These results also provide new insight into how NIHL degrades cortical sound representations and how encoding manifolds capture the underlying plasticity-related changes. This framework opens up important avenues for research to develop new classes of hearing-aid algorithms that mitigate deficits elucidated by degraded manifold representations.

Inhibitory Inputs From SST and PV Neurons in the Thalamic Reticular Nucleus Exert Differential Control Over Frequency Tuning in the Auditory Thalamus

9:45 a.m. - 10:00 a.m.

Audrey Drotos^{*1}, Solyman Rolon-Martinez¹, Julie Haas², Maria Geffen¹

¹*University of Pennsylvania Perelman School of Medicine*, ²*Lehigh University*

Background: A primary role of the brain is filtering out irrelevant sensory information from the continuous stream of inputs in our sensory environments. The thalamic reticular nucleus (TRN) is a thin sheet of GABAergic neurons that envelops the thalamus and provides targeted inhibition to thalamic sensory regions, gating which information reaches cortex. The TRN is comprised of multiple types of inhibitory neurons, including somatostatin-positive (SST) and parvalbumin-positive (PV) inhibitory neurons. We recently showed that SST and PV neurons within the auditory TRN provide direct inhibition to distinct anatomical regions of auditory thalamus. In addition, these neurons exhibit differential control of the thalamocortical relay: inhibition of PV neurons can cause facilitation or suppression of MGB neurons, but SST inhibition primarily

results in MGB suppression. However, how these TRN neuron populations specifically exert control over frequency tuning within MGB has not been explored.

Methods: We analyzed the data from in vivo recordings from MGB neurons in SST-cre or PV-cre mice expressing the Cre-dependent inhibitory opsin GtACR in the TRN, which allowed selective inhibition of SST or PV neuron populations, and examined frequency response functions of MGB neurons in both light-on and light-off conditions.

Results: We first selected neurons with good ($R^2 > 0.6$) Gaussian fits to their frequency response functions. We defined the best frequency as μ (mean of Gaussian fit), and frequency tuning width as σ (standard deviation of the Gaussian fit). There were no significant changes in the best frequency of MGB neurons for either PV or SST inactivation. In MGB neurons that were facilitated by PV inactivation, we found an increase in σ , suggesting that inactivating PV neurons broaden tuning. In MGB neurons inhibited by PV inactivation (potentially via a dual inhibitory synapse) we found the opposite effect: σ decreased in the light-on condition, suggesting that inactivating PV drives sharpening of frequency tuning in facilitated neurons. SST inactivation largely resulted in MGB neuronal response suppression, potentially acting via a dual inhibitory synapse. For these neurons, σ decreased, suggesting that without SST inputs, the tuning sharpens in suppressed neurons.

Conclusions: These results suggest that PV and SST neurons exhibit differential control over MGB tuning that is dependent both on TRN cell type and projection pattern within the MGB. This differential control may help TRN neurons to control sound processing depending on the behavioral context, providing mechanisms to both sharpen and widen tuning in an experience-dependent fashion.

Symposium 3: No SOX, No Shoes, No Service: Critical Roles for Sox in the Inner Ear

Chair: Melissa McGovern, *University of Pittsburgh School of Medicine*

Co-Chair: Brad Walters, *University of Mississippi Medical Center*

8:00 a.m. - 10:00 a.m.

Meeting Room 208ABC, Floor 2

Symposium Description: SOX (SRY-related HMG-box) transcription factors play crucial roles in the development, maintenance, and regeneration of tissue systems in many eukaryotic organisms. Sox genes are expressed at all stages of otic development and are present among non-sensory cells throughout life. From the induction of the otic placode, where the rudimentary structure of the inner ear first forms, Sox genes are involved in directing cell fate. Moreover, Sox genes are critical for the appropriate differentiation of cochlear progenitors into hair cell and non-hair cell fates in the developing cochlea and vestibule. Beyond development, loss of function mutations in Sox genes have been shown to disrupt stria function and fluid homeostasis and are linked to human deafness and vestibular dysfunction.

Despite the extensive evidence that Sox genes are not only expressed in the inner ear but also affect proper development and cellular identity, our understanding of how SOX factors regulate cellular identity in the inner ear is still limited. This symposium will discuss current and recent work highlighting the importance of Sox family genes in the inner ear. We will have 6 speakers

who will present work from both vestibular and cochlear organs in mice as well as the Zebrafish lateral line. We are requesting 2 hours for this symposium that will include one 30-minute talk by Amy Kiernan to introduce Sox genes and to review the precedent findings in the inner ear. We will then have five 15 minute talks describing recent and ongoing research investigating Sox genes in the inner ear. Following each talk, we will have ~3 minutes of questions.

SoxC Transcription Factors Shape the Epigenetic Landscape to Establish and Maintain Competence for Hair Cell Generation

Ksenia Gnedeva, *University of Southern California, Keck School of Medicine*

Individual Abstract: Hair cell loss in the adult mammalian cochlea is irreversible and leads to permanent hearing deficits. Many non-mammalian vertebrates, however, can naturally regenerate hair cells in their adult hearing organs via transdifferentiation of supporting cells. Importantly, the transdifferentiation of supporting cells to hair cells can also occur in neonatal mice, showing that mammals still possess the genetic programs to regenerate hair cells yet quickly lose these shortly after birth. In recent work, we uncovered a potential mechanism that explains the ability of non-mammalian vertebrates but not adult mammals to regenerate hair cells. Through cross-species multiome analysis of zebrafish, lizard, and mouse inner ear sensory epithelia, we identified a novel class of supporting cell-specific enhancers associated with key prosensory genes such as *Atoh1* (Wang et al., 2023; Shi et al., 2024). We showed that these enhancers remain accessible but inactive in the adult supporting cells of regenerative vertebrates, reinitiating *Atoh1* expression and converting supporting cells to hair cells following damage. In contrast, while these developmental enhancers remain accessible in supporting cells of the neonatal cochlea, they are rapidly closed and silenced in mice during the first week of life, coinciding with the loss of regenerative capacity. These findings implicate continued accessibility of developmental enhancers for *Atoh1*, and likely other prosensory genes, as a key requirement for persistent regenerative capacity. Further, our work on mouse prosensory development and zebrafish inner ear regeneration converged on the SoxC factors, Sox4 and Sox11, as main candidates for maintaining prosensory enhancer accessibility in supporting cells of regenerative vertebrates. In the prosensory domain of the embryonic mouse inner ear, we have shown that Sox4/11 directly bind and are required for the initial gain of chromatin accessibility of a number of syntenic prosensory enhancers, including ones for *Atoh1* and *Eya1* that are maintained in supporting cells of the adult zebrafish inner ear. SOX is the most enriched binding motif in both mouse and fish prosensory enhancers, and we found that disrupting SOX binding sites in the conserved supporting cell-specific *Atoh1/atoh1a* enhancer eliminates its transgenic activity. In addition, we show that expression of Sox4/11 factors is maintained in supporting cells of the zebrafish but not mouse inner ear. Together, these findings demonstrate the pivotal role of SoxC family members as agents of epigenetic and transcriptional changes necessary for establishing and maintaining competence for hair cell generation in the inner ear.

Sox Transcription Factors Drive Hair Cell Regeneration Through Regeneration-Responsive Enhancers in Zebrafish

Erin Jimenez, *Johns Hopkins University*

Individual Abstract: Background: Damage to mammalian inner ear hair cells is irreversible, resulting in permanent hearing loss or vestibular defects. This lack of regenerative capacity sets mammals apart from most other vertebrates, which can continually produce new hair cells throughout life or regenerate them after trauma. The zebrafish is a non-mammalian vertebrate with a remarkable ability to regenerate hair cells completely. Previously, we reconstructed gene regulatory networks (GRNs) controlling hair cell regeneration by integrating transcriptomic and epigenomic data at single-cell resolution. We identified cell-specific transcription factor (TF) motif patterns in chromatin that opened during regeneration. Correlating emergent enhancer activity with differential gene expression revealed key regulatory networks driving regeneration. Sox-family transcription factors, particularly Sox2, emerged as central factors in initiating regeneration, with chromatin accessibility and gene expression patterns indicating a regenerative enhancer landscape enriched for Sox-binding motifs.

Methods: To identify direct genomic targets of Sox2, we performed CUT and RUN on regenerating adult zebrafish inner ear tissue and integrated these data with scATAC-seq profiles to identify candidate enhancers enriched for Sox2 binding. We then investigated if *sox2*, *sox21a*, *sox4b*, and *sox10*, along with putative regeneration-responsive enhancers containing Sox-binding motifs, were necessary for zebrafish hair cell regeneration by systematically testing function through gene knockouts and enhancer mutagenesis using CRISPR/Cas9. We screened for hair cell regeneration defects using the lateral line as a proxy. Finally, we used fluorescent in situ hybridization to spatially map the expression pattern of *sox* genes in the inner ear.

Results: Sox2 CUT and RUN revealed a network of direct target enhancers during hair cell regeneration. Integration with scATAC-seq identified Sox2-bound loci that overlapped with regions of chromatin accessibility gained only after hair cell injury. Using MIC-Drop, we targeted 48 loci containing either confirmed Sox2 occupancy or predicted Sox-binding motifs and found that 7% of the regeneration enhancers tested were essential for hair cell regeneration. Targeting *sox2*, *sox21a*, and *sox4b* genes showed significant impairment in hair cell regeneration, while *sox10* disruption was lethal. Spatially resolving Sox TFs detected in our scRNA-seq dataset showed their enrichment in supporting cells during regeneration.

Conclusions: Our results identify Sox transcription factors as master regulators of hair cell regeneration in zebrafish. By orchestrating chromatin accessibility and transcriptional reprogramming in supporting cells, Sox factors drive progenitor states essential for regenerative competence. These findings position Sox TFs, particularly Sox2, and their enhancers as key targets for strategies to unlock regenerative potential in the mammalian inner ear.

Single Cell Multiome Analysis Provides New Insights Into Differences Between Type I and Type II Vestibular Hair Cells and Suggests SOX2-Dependent Mechanisms May Play a Role

Jennifer Stone, *University of Washington, Virginia Merrill Bloedel Hearing Research Center*

Individual Abstract: In mammals, type I and II vestibular hair cells have distinct morphologies, molecular markers, physiological properties, and innervation, yet little is known about the genetic regulation of these unique properties. In adult mice, SOX2 expression is confined to type II hair cells. We found that Sox2 deletion from these cells using *Atoh1CreER:Sox2^{f/f}* mice induced a shift toward the type I phenotype along with shedding of bouton afferent terminals and acquisition of full or partial calyceal terminals.

To further investigate the role of SOX2, single nucleus multiome sequencing (snRNAseq and snATACseq, 10x Genomics) was performed on utricles from adult *Atoh1CreER:Rosa26tdTomato:Sox2f/f* mice and *Atoh1CreER:Rosa26tdTomato:Sox2+/+* controls. Transcriptomes were analyzed using Seurat Library for unsupervised clustering and cell type/subtype identification. Selected differentially expressed genes (DEGs) were validated via in situ hybridization chain reaction. Chromatin accessibility data were analyzed using Signac and ArchR. Pseudo-bulk ATACseq data were derived based on transcriptome clusters to analyze cell type/subtype specific gene regulatory elements. Hair cell type-specific enhancer activity was explored using AAV-delivered reporters in utricles in vivo.

snRNAseq analysis identified hundreds of DEGs in type I versus type II hair cells with shared gene ontology linked to synapse structure and function, calcium regulation, and the cytoskeleton. Intriguingly, type II hair cells had enriched expression of genes regulating cell-cell or cell-substrate adhesion and cellular projections or migration. We explored the chromatin status of three DEGs: *Dlk2* (enriched in type II hair cells), *Bmp2* (enriched in type I hair cells), and *Paqr9* (enriched in striolar type I hair cells). We identified putative enhancer sites in these genes and are verifying their cell type-specific expression in vitro. After *Sox2* deletion, type II hair cells shifted their transcriptomic profile toward the type I profile. 109 genes were significantly upregulated in type II hair cells at 1 month after *Sox2* deletion, and 169 genes were upregulated at 8 months. Many upregulated genes were normally enriched in type I hair cells. Conversely, 99 and 97 genes were downregulated in type II hair cells at 1 and 8 months after *Sox2* deletion, respectively. We are exploring the expression and function of genes whose expression is changed after *Sox2* deletion that are strong candidate regulators of hair cell and/or afferent terminal morphology. This approach is revealing novel insights into genes and regulatory elements that may maintain the phenotypes of vestibular hair cells and afferent neural terminals in adult mice.

Sox10 Restricts the Formation of Ectopic Sensory Patches in the Postnatal Mouse Cochlea

Melissa McGovern, *University of Pittsburgh School of Medicine*

Individual Abstract: *Sox10* is a transcription factor that is expressed in the inner ear by embryonic day 9.5 and is expressed in the cochlear duct of mature animals. The loss of *Sox10* was previously linked to a loss of prosensory progenitors, possibly through its direct regulation of the Notch ligand *Jagged1*. Previously, Notch activation through the expression of the Notch1 intracellular domain (N1ICD) in the embryonic cochlea resulted in the formation of ectopic sensory patches in non-sensory regions. This phenotype is restricted to early embryonic stages prior to the differentiation of hair cells in the organ of Corti. Moreover, our preliminary data suggest that the loss of one copy of *Sox10* decreases the threshold for prosensory fate induction by Notch activation of the inner ear.

We investigated whether the loss of a single copy of *Sox10* was sufficient to permit prosensory fate among cochlear cells at birth. We activated Notch signaling in the neonatal cochlea using *Rosa26-LoxP-stop-LoxP-NICD-eGFP* (*Rosa26-NICD*) mice and targeted cells in the cochlear duct with *Sox9-CreER* mice. Finally, we removed one copy of *Sox10* with *Sox10LacZ* mice. We induced Notch activation at postnatal day (P) 0 and collected tissue at P7. In addition, we investigated whether different levels of Notch activation would enhance prosensory fate induction using a Doxycycline inducible model. We activated Notch signaling with TetO-N1ICD and targeted cells of the cochlear duct with *Sox10rtTA*. We activated Notch signaling in

Sox10rtTA:TetO-N1ICD and littermate controls with doxycycline in the diet to nursing mothers from P0 to P7 and doxycycline was injected in pups P1 while cochlea were collected at P7.

We observed ectopic sensory patches containing SOX2+ cells when Notch was activated in combination with Sox10 heterozygosity, but not when Notch was activated alone. We also observed that higher Notch activation increased the number of animals who developed ectopic sensory patches. Prosensory induction characterized by proliferation and Sox2 expression was observed throughout the cochlear duct and foci were observed medial to the organ of Corti that contained ectopic hair cell-like cells.

Our data indicate that Sox10 haploinsufficiency among post-natal cochlear cells permits the formation of ectopic sensory patches following Notch activation. Our findings suggest that SOX10 regulates cell fate among postnatal cells, however, Sox10 is expressed well before and after the first postnatal week. Thus, understanding Sox10's role in cell fate in the inner ear may enhance our understanding of the development, differentiation, and maturation of cochlear cells.

An Introduction to Sox Transcription Factors

Amy Kiernan, *University of Rochester*

Individual Abstract: SOX transcription factors were first identified in 1990 by their founding member, the Sry (Sex-determining Region Y) gene, a sex-determining gene that could specify the male phenotype. Subsequently, related genes were identified based on a shared homology region, the HMG (High Mobility Group) box, and termed SOX, for Sry-related HMG box genes. There are 20 different Sox genes in mice and humans that can be classified into different groups from A to H, based on sequence and structural similarities. In contrast to most other transcriptions factors, structural studies showed that SOX proteins can bind and expand the minor groove of DNA, resulting in a strong bend. The group SoxB1 factor, SOX2, has been of particular interest as it has been shown, along with several other factors, to have the ability to reprogram a somatic cell into an induced pluripotent stem cell (iPSC). In the ear, SOX2 has been identified as an essential factor in the generation of the neurosensory lineage. Members of the SOXC family have also been shown to be required for sensory cell differentiation and regeneration. SOX factors have been identified as 'pioneer' transcription factors, characterized by the ability to bind transcriptionally silent chromatin and recruit other transcriptions factors. This feature may explain why Sox factors have such profound effects on cell fate, including in the neurosensory lineage of the inner ear. It is likely that this pioneering ability imbues some Sox factors with the ability to reprogram differentiated cells, suggesting the tantalizing possibility that these factors can be used to replace depleted cell types in the ear through reprogramming of existing cell types. In this symposium, data will be presented on the roles of different Sox transcription factors in critical cell lineages of the inner ear and future directions will be discussed.

Defining the Role of Soxe Genes During the Development of the Auditory Portion of the Inner Ear

Brigitte Malgrange, *University of Liege*

Individual Abstract: Tightly regulated genetic programs govern the development of the auditory portion of the inner ear. Among the key molecular regulators are the SoxE family transcription factors—Sox8, Sox9, and Sox10—best known for their roles in neural crest development and lineage specification. However, their specific contributions to cochlear development remain incompletely understood. In the developing murine inner ear, we observed that Sox9 and Sox10 are co-expressed in the sensory epithelia beginning at the otic placode stage. As the organ of Corti differentiates, their expression progressively becomes restricted to the supporting cell population.

We employed conditional gene ablation and lineage tracing strategies in mice to elucidate the functional roles of Sox9 and Sox10 during cochlear development. Sox10 was found to be dispensable for otic placode formation but essential for its maintenance. In Sox10-null embryos, the cochlea lacked glial cells, which are critical for providing trophic support to spiral ganglion neurons. Despite this deficit, neuronal survival was preserved, likely due to compensatory upregulation of neurotrophins by the organ of Corti.

In contrast, Sox9 deletion resulted in pronounced defects in cochlear patterning, disrupted sensory cell differentiation, and aberrant neuronal innervation. Transcriptomic profiling further revealed that Sox9 regulates key downstream targets, including *Atoh1* and *Jag1*, implicating it in the modulation of Notch and proneural signaling pathways.

These findings highlight distinct yet complementary roles for Sox9 and Sox10 in orchestrating sensory and neural elements in the cochlea, underscoring their critical involvement in auditory system development.

Podium 10: Patterning and Cellular Specification of the Auditory and Vestibular System

Outer Hair Cell Innervation by Type II Spiral Ganglion Neurons Depends on Eph/Ephrin and Planar Cell Polarity Cues

10:30 a.m. - 10:45 a.m.

Deborah George¹, Nidhee Seernaum¹, Aileen Cui¹, Maeve Hunt¹, Yifan (Paul) Zhou¹, Shubham Kale², Satish Ghimire¹, Michael Deans³, Thomas Coate^{*1}

¹Georgetown University, ²University of Utah, ³Emory University

Background: Type II spiral ganglion neurons (SGNs) are a fascinating, but poorly understood population of cells. During development, type II SGNs show a dramatic pattern of innervation in the cochlea: they extend past inner hair cells (IHCs), turn toward the cochlear base, then travel a few hundred microns before forming synapses with multiple outer hair cells (OHCs). Previously, Planar cell polarity (PCP) signaling was shown to regulate type II SGN turning. Based on current

research from our lab and others, additional sets of molecules are predicted to facilitate type II SGN turning and other aspects of their development.

Methods: In this study, using genetic sparse labeling, 3D single fiber reconstructions, cochlear cultures, and mouse mutants, we investigated Eph/Ephrin signaling in type II SGN development, as well as possible interactions between Eph/Ephrin and PCP signaling.

Results: In situ hybridization and antibody studies indicate EPHRIN-A3 is expressed by developing supporting cells in the organ of Corti, whereas EPHA7 is expressed by type II SGNs. Similar to loss of Vangl2 (a PCP factor), loss of either *Efna3* or *Epha7* increased the percentage of type II SGNs that turn incorrectly toward the cochlear apex. Type II SGN fibers from both *Efna3* and *Vangl2* knockouts showed altered branching patterns, suggesting these factors also regulate later-stage aspects of OHC innervation. EPHRIN-A3-Fc treatment in vitro increased SGN growth cone collapse at E15.5, but enhanced type II SGN branch number at P0. This indicates EPHRIN-A3 may serve different roles in type II SGN development at different stages. Interestingly, loss of *Vangl2* reduced EPHRIN-A3 membrane distribution on supporting cells, suggesting PCP signaling may act upstream of Eph/Ephrin signaling in this process.

Conclusions: These data indicate Eph/Ephrin signaling helps facilitate type II SGN development and that Eph/Ephrin signaling likely interacts with PCP factors in this process. In the future, we will determine the extent to which PCP and Eph/Ephrin signals facilitate aspects of OHC synapse formation.

Irx3/5 Regulate Vestibular and Cochlear Sensory Patterning in the Mammalian Inner Ear

10:45 a.m. - 11:00 a.m.

Xin Weng^{*1}, Tianli Qin², Yuchen Liu³, Bernice Leung³, Mai Har Sham¹

¹*The Chinese University of Hong Kong*, ²*California Institute of Technology*, ³*University of Hong Kong*

Background: In humans, mutations in *IRX5* are associated with Hamamy syndrome, patients display sensorineural hearing loss, suggesting the potential functions of *Irx* genes during inner ear development. In mammalian inner ear, two main compartments, the vestibule and the cochlea, play distinct sensory roles. However, the mechanisms underlying the formation and separation of these two sensory systems remain elusive. This study aimed to study the roles of *Irx3* and *Irx5* in the vestibular and cochlear patterning.

Methods: We utilized genetically mutated mouse models including *Irx3*LacZ/LacZ (*Irx3*^{-/-}), *Irx5*EGFP/EGFP (*Irx5*^{-/-}), and *Irx3*^{-/-}*Irx5*EGFP/EGFP (*Irx3/5*^{-/-}) to investigate the roles of *Irx3/5*. In addition, to investigate the time window during which the functions of *Irx3/5* is required, *Irx3*f/*fIrx5*EGFP/EGFP, *Emx2*Cre, and *Rosa*CreERT2 mouse models were used to generate temporal conditional knockout mutants. Immunostaining and in situ hybridization were performed on whole-mounted and sectioned inner ear to explore expression patterns. Single-cell transcriptomic sequencing data was generated from cochlea and saccule of wildtype and *Irx3/5*^{-/-} inner ears at E14 followed by analysis.

Results: The inner ear morphogenesis of *Irx3*^{-/-} and *Irx5*^{-/-} is slightly affected, while the *Irx3/5*^{-/-} cochlea represented significant phenotype, including enlarged and shortened cochlear lumen.

We observed that *Irx3* and *Irx5* are broadly expressed in cochlea but are absent from the saccular epithelium.

In *Irx3/5*^{-/-}, *Sox2*⁺ saccular and cochlear sensory domains were fused. Notably, ectopic HCs (hair cells) of vestibular-like stereocilia were formed in the medial edge of the cochlea, occupying cochlear GER (greater epithelial ridge) domain.

Removal of *Irx3/5* before E12.5 using a series of temporal conditional mutants, resulted in the presence of ectopic HCs, resembling the phenotype observed in *Irx3/5*^{-/-} cochlea. However, Tamoxifen was administrated at E13.5 and E14.5, cochlear HCs and the organ of Corti developed normally. These observations suggested that *Irx3/5* function was required within a specific time window for inner ear sensory patterning.

To further investigate the roles of *Irx3/5* in the specification of saccular and cochlear sensory patches, we dissected the saccul and cochlea from E14 wild type and *Irx3/5*^{-/-} inner ears for scRNA-seq analysis. It revealed an increased proportion of saccular sensory cells in the mutants, and an up-regulation of saccular-expressing genes in the mutants. Additionally, we identified a vestibular HC-specific marker, *Tnfrsf25*. In *Irx3/5*^{-/-}, we detected an ectopic expression pattern of *Tnfrsf25* overlapped with the supernumerary *Myo7a*⁺ HCs, indicating that these HCs exhibit vestibular identity.

Conclusions: Our findings revealed that *Irx3* and *Irx5* are essential for regulating vestibular and cochlear patterning. They function to segregate the saccular and cochlear sensory regions, and suppress the vestibular identity in the cochlea.

Promoter Accessibility Accounts for Differential Expression of Many Prominent, but Not Most, Genes in Developing IHCs and OHCs

11:00 a.m. - 11:15 a.m.

Chuan Zhi Foo¹, Anne Duggan¹, Bartom Elizabeth¹, Litao Tao², Neil Segil³, Jaime Garcia-Anoveros^{*4}

¹*Northwestern University*, ²*Creighton University*, ³*University of Southern California*,

⁴*Northwestern University Institute for Neurosciences*

Background: We separately collected developing mouse IHCs and OHCs to identify their mRNAs and chromatin states. We examined their transcriptomes by bulk (full coverage) RNA-seq from six biological replicates each to reveal differences in gene expression. We also examined their chromatin conformation by bulk ATAC-seq from two biological replicates each to reveal open vs closed promoter and enhancer elements. We then compared ATAC-seq with RNA-seq datasets to determine if differential chromatin accessibility can account for differential gene expression. Each biological replicate consists of hair cells pooled from multiple neonatal mice of both sexes.

Methods: We separately collected developing mouse IHCs and OHCs to identify their mRNAs and chromatin states. We examined their transcriptomes by bulk (full coverage) RNA-seq from six biological replicates each to reveal differences in gene expression. We also examined their chromatin conformation by bulk ATAC-seq from two biological replicates each to reveal open vs closed promoter and enhancer elements. We then compared ATAC-seq with RNA-seq

datasets to determine if differential chromatin accessibility can account for differential gene expression. Each biological replicate consists of hair cells pooled from multiple neonatal mice of both sexes.

Results: We found that developing IHCs and OHCs have differentially accessible promoters in some of the most important differentially expressed genes. This includes functional genes whose expression is incipient in neonatal hair cells but will be maintained throughout life, and developmental genes which are only expressed transiently. In addition, we also found that HCs express some unique mRNA isoforms and use novel promoters that are not known in other cell types.

Conclusions: Chromatin accessibility plays an important role in regulating differential gene expression between developing IHCs and OHCs. Moreover, HCs express mRNA isoforms not found in other cell types from novel promoters. Here, we provide a comprehensive resource for the identification of promoters and mRNA isoforms of genes expressed by neonatal IHCs or OHCs, which is publicly-accessible for visualization of any gene of interest at <https://igvviewer.s3.us-east-2.amazonaws.com/index.html>.

Tunability of the Insm1 Mutant Phenotype Reveals a Candidate IHC-Inducing Pathway

11:15 a.m. - 11:30 a.m.

Jemma L. Webber^{*1}, Dominika Rogalska², Alyanna Rodelas², Yingjie Zhou³, Jaime García-Añoveros⁴

¹Creighton University, ²Creighton University School of Medicine, ³Northwestern University, Feinberg School of Medicine, ⁴Feinberg School of Medicine and Hugh Knowles Center for Clinical and Basic Science in Hearing and its Disorders, Northwestern University

Background: Inner hair cells (IHCs) and outer hair cells (OHCs), two types of mechanosensory receptors in the cochlea, are essential for hearing and are distinguished by their unique morphology, molecular function, and specialized patterns of innervation. Damage to either population leads to permanent hearing loss, as neither regenerates. Several transcriptional regulators, including Insm1, Tbx2, and more recently Casz1, have been implicated in specifying IHC versus OHC identity, but the upstream signaling pathways driving these specific fates remain unknown.

Methods: We used Insm1 mutant mice, in which approximately half of OHCs lose their fate markers and transdifferentiate into IHCs, as a model to investigate signaling cues that drive IHC differentiation. Organotypic cochlear explants were cultured from Insm1 mutants at embryonic stages and treated with pharmacological activators or inhibitors of candidate pathways to assess their role in transdifferentiation and IHC maturation.

Results: OHC-to-IHC transdifferentiation in explants closely recapitulated in vivo patterns. We identified a candidate signaling pathway that bidirectionally modulates this conversion: pathway inhibition blocked transdifferentiation, whereas pathway activation enhanced it. Additional loss-of-function experiments in vivo targeting a downstream effector reduced the number of transdifferentiated IHCs, decreased expression of IHC markers (Vglut3, Calb2), and altered nuclear morphology.

Conclusions: These findings demonstrate that the *Insm1* mutant phenotype is modifiable and can be tuned by manipulating candidate pathway activity, supporting the hypothesis that a graded morphogen promotes IHC differentiation. Together, these data identify the candidate pathway as a key regulator of IHC fate and highlight it as a promising target for strategies to selectively regenerate hair cell subtypes.

Spatial Hair Cell Patterning During Zebrafish Utricular Development

11:30 a.m. - 11:45 a.m.

Selina Baeza-Loya^{*1}, David Raible¹

¹*University of Washington*

Background: In zebrafish, like in mammalian species, the vestibular sensory epithelia in the otolith organs are organized into central and peripheral zones, called the striola and extrastriola. Striolar and extrastriolar hair cells drive distinct but parallel vestibular sensory circuits and behaviors, which are functionally matured in the fish's first 5 days. In mammals, it has been shown complementary striolar/extrastriolar patterning depends on differential retinoic acid signaling (rich vs deficient, respectively), but hair cell identity during epithelial patterning in development has not been described in detail. We characterized the spatiotemporal development of hair cell types in the growing zebrafish utricle and assessed factors contributing to maturation.

Methods: To determine perinatal hair cell identity, we use hybridization chain reaction fluorescent in situ hybridization (HCR FISH) probes informed by single-cell RNA sequencing in larval zebrafish against genes found in striolar/extrastriolar hair cells 9 (*cabp1b* and *cabp2b*) and retinoic acid synthesizing (*aldh1a3*) or degrading (*cyp26b1*) enzymes. These fluorescent markers identify cellular spatial patterns in the utricular epithelium. We assessed changes in epithelia in wildtype fish (on *myo6b:GFP* or *myo6b:nlEOS* backgrounds) and in fish with a mechanotransduction (*cdh23*) mutation over the course of development and after pharmacological manipulation of retinoic acid. We then used a computational pipeline for cellular segmentation and image analysis to classify cell types and evaluate spatial organization across fish.

Results: In wildtype utricles, hair cells that develop in the first 48 hours express markers for both striolar and extrastriolar hair cells, indicating a surprising transient intermediate hair cell type which eventually becomes extrastriolar. Hair cells added after 2 days are already specified as striolar or extrastriolar. This change is accompanied by complementary expression of *cyp26b1* in the striolar zone and *aldh1a3* in the extrastriolar zone. In *cdh23* mutant fish, where hair cells do not mechanotransduce, intermediate hair cells never transition. However, complementary patterning of *cyp26b1/aldh1a3* in striolar/extrastriolar zones is normal in *cdh23* mutant utricles. Wildtype fish treated with exogenous retinal, which is converted to retinoic acid by *aldh1a3*, showed a decrease in the relative number of striolar hair cells and an increase in intermediate cell types in wildtype fish. Sputnik fish showed an even greater decrease in striolar hair cells and increase in intermediate types after retinal treatment.

Conclusions: We provide evidence that hair cell maturation, and indirectly normal utricular patterning, is dependent on both mechanotransduction-driven activity and molecular signaling mechanisms. Early hair cells born in the first 2 days begin in a transient state that is neither striolar nor extrastriolar and later acquire extrastriolar characteristics, which is dependent on

functional activity. Hair cells born after 2 days develop as either striolar or extrastriolar, depending on retinoic acid signaling. Disruption of both activity and/or retinoic acid signaling results in a loss of normal patterning.

Prox1 Regulates Trophic Function Between Lateral Supporting Cells and Outer Hair Cells

11:45 a.m. - 12:00 p.m.

Braulio Peguero*¹, Mhamed Grati¹, Rafal Olszewski¹, Michael Hoa¹, Wade W. Chien¹, Matthew Kelley¹

¹*National Institute on Deafness and Other Communication Disorders/ NIDCD*

Background: The organ of Corti (oC) in the mammalian cochlea is an organized cellular mosaic that is required for normal auditory function. Normal development of this complex cellular structure requires temporally and spatially coordinated gene expression. This process includes cellular specification, differentiation, and maturation. While some of the genes required for these processes have been identified, the specific effects of many of these genes remain unclear. For instance, the transcription factor Prospero homeobox 1 (Prox1) is transiently expressed in cells located in the lateral compartment of the oC between E15 and birth when its expression begins to decline. The restricted expression of Prox1 suggests that it may regulate specific aspects of development that are unique to lateral oC cell types.

Methods: Prox1-flox and Fgf20-cre alleles were combined to generate viable Prox1-cKO mice in which Prox1 was deleted from the cochlea beginning at E12. We assessed cochlear function by auditory brainstem response (ABR), distortion product otoacoustic emission (DPOAE) and endocochlear potential (EP) measurements. We used standard immunohistochemical protocols and live imaging assay at different ages to evaluate developmental changes in specific oC cell types. Scanning electron microscopy (SEM) was used to visualize the surface topography and cellular structure of Prox1cKO cochleae. Lastly, we used single cell RNA-sequencing (scRNA-seq) to characterize the transcriptomic changes that occur in response to the deletion of Prox1 in different oC cell types.

Results: Our analyses of the Prox1-cKO mice showed similar changes in cochlea morphology to those reported in previous studies, including a malformed tunnel of Corti and greater number of Deiter cells. Initial development of OHCs appeared normal in Prox1-cKO; however, upon closer examination the OHCs begin to die after P15 and are mostly gone by P21. Extra number of Deiter cells that were found at early ages persist through adulthood. The EP doesn't seem to be perturbed in the absence of the tunnel of Corti. Analyses of scRNA-seq indicated that the transcriptomes of OHCs are largely unchanged in the Prox1-cKO mice. Instead, changes in SC transcriptome suggest a partial change in cell fate for pillar and Deiters' cells in which they appear to express some genes consistent with an inner phalangeal identity.

Conclusions: These results provide evidence for a critical role for Prox1 in normal cochlear development. While Prox1 is expressed in the lateral precursors that will give rise to both OHCs and lateral support cells, OHC development appears largely normal in the absence of Prox1. Instead, deletion of Prox1 appears to lead to a partial change in the differentiation of Pillar and

Deiter cell identities. This change disrupts trophic interactions between these support cells and OHCs, leading to the death of OHCs as a secondary effect of abnormal support cell function.

Beyond Ciliogenesis: Novel Roles of RFX1/3 in Cochlear Hair Cell Survival and Hearing

12:00 p.m. - 12:15 p.m.

Ningjin Wu^{*1}, Kathleen Gwilliam¹, Reza Amanipour¹, Wei Song¹, Beatrice Milon¹, Ran Elkon², Ronna Hertzano¹

¹*National Institute on Deafness and Other Communication Disorders, National Institutes of Health*, ²*Faculty of Medicine and Sagol School of Neuroscience, Tel Aviv University*

Background: RFX transcription factors are best known for their role in ciliogenesis, yet their broader functions in the auditory system remain poorly understood. We recently reported that deletion of Rfx1/3 at embryonic day (E)16 in cochlear hair cells leads to profound hearing loss and rapid outer hair cell (OHC) degeneration at the onset of hearing. Notably, this occurs despite a normal sensory epithelium appearance, indicating a critical role for RFX1/3 in hair cells beyond ciliogenesis. Here we define the temporal window of Rfx1/3 function in cochlear development and uncover their downstream transcriptional networks required for hair cell survival.

Methods: The spatiotemporal pattern of Rfx1/3 expression was recorded across embryonic and postnatal stages using RNAscope. To define the role of RFX1/3 in cochlear hair cells, we generated multiple conditional knockout models: Rfx1/3;Myo15-Cre (deletion at postnatal day (P)0) and Rfx1/3;Prestin-CreERT2 (inducible deletion at P4 or P8). Auditory function was assessed by auditory brainstem response (ABR) and distortion product otoacoustic emissions (DPOAEs) testing, followed by histological analysis. Single-cell RNA sequencing and single-nuclei RNA sequencing of cochlea from P7 and P10 Rfx1/3;Myo15-Cre mice were performed to identify downstream regulatory pathways. In addition, these datasets will be compared with multi-omics data generated from Rfx1/3;Gfi1-Cre mice (deletion at E16).

Results: Rfx1 and Rfx3 are broadly expressed in the cochlea across embryonic and postnatal stages, with enrichment in hair cells relative to other cell types. Deletion of Rfx1/3 specifically in hair cells, followed by functional analyses, revealed a narrow temporal requirement for hearing and hair cell survival between P0 and P8. Deletion at P0 or P4–5 induced hearing loss and outer hair cell (OHC) degeneration comparable to deletion at E16. In contrast, deletion of Rfx1/3 from OHCs at P8 had no effect on hearing or OHC survival. Transcriptomic analysis revealed that beyond structural ciliogenesis genes, RFX1/3 regulate transcriptional programs central to cell survival, mitochondrial homeostasis, oxidative stress resistance, and synaptic signaling, pointing to novel regulatory networks essential for cochlear hair cell maintenance after the onset of hearing.

Conclusions: These findings establish RFX1/3 as critical regulators of cochlear hair cell survival, acting within a narrow postnatal window to safeguard auditory function at the onset of hearing. By uncovering downstream pathways linked to mitochondrial function and synaptic signaling, this work highlights novel RFX transcriptional programs essential in the inner ear

expanding from their known role in ciliogenesis to survival regulation, offering new mechanistic insight into hair cell vulnerability in sensorineural hearing loss.

Exploring the Role of Nedd4-2 Ubiquitin Ligase in Hearing Function

12:15 p.m. - 12:30 p.m.

Ronald Pouyo¹, Enes Spahic¹, Nicolas Thelen¹, Kateryna Shostak¹, Brigitte Malgrange¹, Laurence Delacroix*¹

¹*University of Liege*

Background: Ubiquitination is an essential post-translational modification in which ubiquitin, a small regulatory protein, is covalently attached to substrate proteins. This dynamic process governs protein stability, turnover, subcellular localization, and activity, thereby exerting broad control over cellular homeostasis and function across all tissues. During development and functional maturation, ubiquitination is particularly critical for proper spatial and temporal control of protein networks. Consistent with its importance, mutations in the human gene encoding the E3 ubiquitin ligase NEDD4-2 (Neural precursor cell Expressed Developmentally Downregulated 4-2) have been linked to neurodevelopmental and sensory disorders, including periventricular nodular heterotopia and hearing impairments. Upon Nedd4-2 depletion, brain malformation has been shown to arise from defective neuronal migration around the cerebral ventricles, however, the mechanisms by which Nedd4-2 contribute to hearing loss remain unknown.

Methods: We investigated the role of Nedd4-2 in inner ear organogenesis and auditory function using conditional knockout mouse models. Genetic depletion from the early otocyst was achieved by crossing Nedd4-2Lox/Lox with Foxg1Cre animals, while targeted deletion in sensory progenitors was induced using a tamoxifen-inducible Sox2Cre driver. Auditory function was assessed by auditory brainstem responses (ABR) and distortion product otoacoustic emissions (DPOAEs). Cochlear morphology and cellular integrity were evaluated by scanning electron microscopy and immunofluorescent staining over developmental time points. A yeast two-hybrid screen with an E16.5 mouse inner ear library was employed to identify Nedd4-2 interacting partners. Nedd4-2 was transfected in HEK293 cells, along with candidate substrates, to confirm protein interaction and outcome.

Results: Early otocyst-specific depletion of Nedd4-2 led to severe auditory deficits at hearing onset (P18), with elevated ABR thresholds and reduced DPOAEs across frequencies. Despite normal cochlear morphology at this stage, progressive degeneration of hair cells, spiral ganglion neurons, and stria vascularis was observed in a basal-to-apical gradient from P30 onwards. Depleting Nedd4-2 from sensory progenitors was sufficient to cause significant auditory impairments at young age, and also resulted in massive cochlear degeneration over time. Our yeast two-hybrid screen identified novel Nedd4-2 interactors, including an actin-binding protein localized at tight junctions around hair cells. This protein was degraded upon Nedd4-2 expression in HEK293 cells, and was found to accumulate in Nedd4-2-deficient cochleae at early postnatal stages.

Conclusions: Our findings demonstrate that Nedd4-2 is essential for auditory function and cochlear integrity in mice. Its loss leads to early-onset hearing deficits followed by progressive cochlear degeneration. Identification of a novel actin-binding junctional protein as a potential

Nedd4-2 substrate provides new insight into molecular mechanisms that may underlie hearing loss, although its role in deafness and cochlear pathology requires further investigation.

Podium 11: Hearing Loss: Consequences and Adaptation

10:30 a.m. - 12:30 p.m.

Meeting Room 209ABC, Floor 2

Moderators: Aravaind Parthasarathy and Jack White

ECHO: A Data Resource for Cancer, Hearing, and Outcomes Research

10:30 a.m. - 10:45 a.m.

Katharine Fernandez*¹, Amanda Bonczkowski¹, Abu Chowdhury², Quentin Price¹, Lisa Cunningham¹

¹NIDCD, ²Georgia State University

Background: Cisplatin is a highly effective chemotherapy agent, but it causes permanent hearing loss in up to half of treated patients. However, ototoxicity monitoring is rarely implemented in practice. This lack of baseline and follow-up audiograms has hindered characterization of cisplatin-induced hearing loss in adults. To address this gap, we established the ECHO (Enhancing Cancer Hearing Outcomes) dataset, a multi-institutional resource designed to capture high-quality audiologic and oncologic data to study cisplatin ototoxicity and protective factors.

Methods: We partnered with eight U.S. cancer centers to harmonize and aggregate de-identified audiograms and treatment records from cisplatin-treated adult patients. Pre- and post-cisplatin audiometric thresholds were collected alongside clinical variables including cumulative cisplatin dose, dosing schedule, cancer type, sex, age, and concurrent medications. The harmonized dataset currently includes 1,053 unique patients (74% male; median age 58 years, IQR 49–65) contributing 2,452 audiograms. NCI CTCAE and ASHA criteria were applied where applicable. Cumulative cisplatin exposure ranges 50–750 mg/m². Cancer types were predominantly head and neck (81%), with additional cases from lung, bladder, liver, kidney, and gynecologic cancers. Further harmonization and standardized integration of audiological and oncologic variables is underway for two additional centers, improving and expanding the utility of ECHO for future analyses. We used the ECHO resource to examine the relationship between cisplatin dosing regimen and ototoxicity in patients with head and neck cancer.

Results: This large real-world dataset enables detailed analysis of cisplatin ototoxicity. Dosing protocol significantly influenced hearing outcomes: patients on tri-weekly cisplatin had more severe high-frequency hearing loss than those on weekly dosing, confirming greater ototoxic risk with higher individual dose administration protocols. Additionally, patients taking statins during chemotherapy experienced markedly less hearing loss: concurrent atorvastatin use was associated with an approximately three-fold lower incidence of significant post-cisplatin hearing loss (~10% of patients affected vs 29% without statin). This retrospective finding directly informed a Phase II clinical trial now underway to evaluate atorvastatin as an otoprotective

intervention. The large sample size permits stratified analyses by age, sex, cumulative dose, and statin type – analyses that were previously underpowered in single-center studies.

Conclusions: The ECHO dataset is a unique multi-center audiometric data resource that fills a critical gap in cisplatin ototoxicity research. This resource has already validated known risk factors and predicted new protective factors for cisplatin-induced hearing loss. It clearly demonstrates the power of data sharing in bridging laboratory findings with clinical practice. These insights have direct implications for oncology and otolaryngology – from guiding safer chemotherapy protocols to informing hearing conservation strategies and novel otoprotective trials. ECHO continues to expand via new partnerships and is available upon request as a community resource to drive discovery and improve quality of life for cancer survivors.

Designing a Discriminative, Time-Efficient Diagnostic Battery for Small Arms Fire-Like Noise Exposure

10:45 a.m. - 11:00 a.m.

Meredith Ziliak^{*1}, Jax Marrone², Edward Bartlett²

¹*Purdue University; PULSe - Interdisciplinary Life Sciences*, ²*Weldon School of Biomedical Engineering, Purdue University*

Background: Developing a streamlined stimulus battery capable of identifying and classifying damage from noise induced hearing loss (NIHL) would advance diagnostic precision and treatment planning. As individual audiological profiles can differ according to hearing pathology, protocols would ideally capture these distinctions with minimal time. Small arms fire (SAF) noise exposure is a common source of NIHL linked to inner hair cell synapse loss, elevated auditory brainstem response (ABR) thresholds, and poorer gap detection. Building on this work, we aim to establish a sensitive and time-efficient stimulus arsenal to reveal discriminative assessment types of SAF NIHL.

Methods: F344 rats were bilaterally exposed to SAF-like noise overexposure (OE) (120-126 dBpSPL; n=31) or sham exposure (60 dBpSPL; n=11) levels. DPOAEs and two-channel AEPs were recorded pre-exposure and post-exposure days 7, 14, 28, and 56. AEPs included standard ABRs, fast ABRs (fABRs; multi-tone pip sequences yielding thresholds and morphology 4x faster than standard ABRs), MLRs (click trains with varying interclick intervals from 100 ms to 3 s), dynamic amplitude-modulated sweeps (dAMs; sinusoidal AM frequency continually swept from 12-1500 Hz with either gaussian noise or 8 kHz tone carrier to rapidly determine a modulation transfer function 5x faster with 30x improved spectrotemporal resolution compared to traditional AM stimuli), and speech tokens (rectified and non-rectified male-voiced “Purdue” envelope with noise/tone carriers). Each response was analyzed to characterize changes between exposure groups and time points before comparing across stimulus types to identify the combination most time-efficient and sensitive to functional changes following SAF OE.

Results: SAF OE reduced DP amplitudes and elevated ABR thresholds, particularly 7-14 days post-exposure. ~45% of subjects exhibited click threshold shifts (≥ 10 dB at day 7), while others showed little to no threshold change despite OE. Preliminary analyses indicate fABRs provide threshold information comparable to ABRs with significantly reduced acquisition time. MLR peak amplitude and latency were sensitive to both group and time point. Noise carrier dAMs

showed reduced power at 750-1500 Hz post-exposure whereas tone carriers did not. Speech tokens revealed reduced power at the “P” consonant onset, with variable effects on other phonetic regions. dAMs and speech tokens showed similar temporal tracking between carrier types. Speech EFRs demonstrated greater sensitivity between groups using noise and rectified stimuli.

Conclusions: SAF OE produced heterogeneous functional outcomes, with almost half of subjects showing threshold shifts accompanied by OHC function reduction and altered temporal processing. fABRs and dAMs are emerging as tools for rapid assessment of SAF, while speech tokens may capture ecologically relevant processing changes. Ongoing analyses will identify which diagnostic features and assessments should be utilized in a streamlined stimulus battery tailored for SAF noise overexposure, with the potential to be sensitive enough to distinguish between other types of NIHL.

When Animal Models Don’t Speak Human: Reassessing EFRs as Biomarkers of Cochlear Synaptopathy

11:00 a.m. - 11:15 a.m.

Srikanta Mishra*¹

¹*The University of Texas at Austin*

Background: Experimental noise exposure in animal models has established cochlear synaptopathy as the loss of ribbon synapses between inner hair cells and auditory nerve terminals, despite full recovery of outer hair cell function. However, translation to human populations has been fraught with inconsistency, fueling debate over the validity of proposed biomarkers and contributing to a broader replication crisis in auditory science. Among candidate measures, envelope following responses (EFRs) have been widely promoted as objective indicators of synaptopathy, based on the premise that low-spontaneous-rate auditory nerve fibers exhibit robust temporal envelope phase-locking. Yet, evidence from human studies remains equivocal. The aim of this study was to evaluate the reliability of EFRs as biomarkers of cochlear synaptopathy in humans by combining meta-analytic evidence with experimental data.

Methods: To address this, we conducted a systematic review and meta-analysis of 15 studies (n~850) examining EFRs across tinnitus, noise exposure, and aging. As the highest level of evidence for clinical translation, meta-analysis revealed highly variable outcomes, with no consistent evidence that EFRs reliably capture synaptopathic changes in any category—whether noise-induced, age-related, or tinnitus-associated. These findings underscore the limitations of EFRs as standalone biomarkers and highlight the need for mechanistic clarity. Toward this goal, we tested the contribution of cochlear compressive nonlinearities to EFRs in young adults with normal audiograms (n=39). Distortion product otoacoustic emission input/output functions were used to estimate compression threshold and slope, which were then related to suprathreshold EFR phase-locking.

Results: Meta-analysis showed no significant effects across studies for any categories of synaptopathy. Preliminary results suggest that individual differences in cochlear compression may shape EFR sensitivity to amplitude modulation, complicating their interpretation as direct indices of synaptopathy.

Conclusions: Together, the meta-analytic synthesis and experimental findings converge to show that EFRs lack diagnostic reliability as markers of human cochlear synaptopathy—across noise-induced, age-related, and tinnitus-associated etiologies. This calls into question the possibility that synaptopathy, as demonstrated in animal models, translates directly to humans—a result that is not surprising given the broader observation that more than 90% of behavioral neuroscience findings fail to generalize to human populations.

The Role of Microglia in Sex Differences of Noise-Induced Hearing Loss

11:15 a.m. - 11:30 a.m.

Amelia Schaefer¹, Lucille Papile², Alice Burghard*²

¹*University of Illinois Urbana-Champaign*, ²*University of Connecticut School of Medicine*

Background: Noise exposure is the second leading cause for hearing loss. Recent studies have shown that biological sex plays a role in hearing loss after sound exposure with a greater susceptibility in male subjects. However, the cause for this sex-difference in noise susceptibility remains unknown.

A possible explanation for sex-differences in hearing outcomes after noise exposure is the neuroimmune response, which differs between males and females. Inflammatory responses after noise exposure have been reported from the cochlea up to the auditory cortex and it has been proposed that inflammation contributes to synaptopathy in the cochlea.

Microglia, the resident immune cells in the brain, play an important role in the observed neuroinflammation in the central auditory. Several studies have shown that microglia contribute to sex-differences in neuroinflammation and in responses to injury in the adult brain. To elucidate if sex-differences in microglia activation contribute to sex-differences in noise susceptibility we sound exposed microglia depleted mice of either sex and compared their hearing function to control mice of either sex.

Methods: Mice of both sexes were fed PLX5622 medicated chow for two weeks before the start of the experiments and throughout the rest of the study. This compound is a colony stimulating factor-1 antagonist that leads to the abolishment of microglia after 7 days of consumption. Hearing assessments before and after noise exposure were performed via auditory brainstem response (ABR) and amplitude modulation following response (AMFR) measurements. Animals were awake during the 1 h, 113 dB SPL, narrow-band noise (2 kHz wide, centered at 16 kHz) sound exposure. Animals were sacrificed after the last recording for histological assessments.

Results: We found that microglia depletion has no effects on baseline hearing thresholds in either sex. Four days after noise exposure male mice had worse hearing thresholds than female mice in controls. In microglia depleted animals this sex difference was reduced with microglia depleted female mice showing worse hearing threshold than female control mice. Male mice showed similar hearing thresholds in microglia depleted and control conditions. Two weeks after sound exposure hearing thresholds improved in all animals. However, microglia depleted animals showed no sex-difference in hearing loss, while control animals showed a clear sex difference, with the female having less hearing loss.

Conclusions: Microglia depletion reduced sex differences in noise susceptibility in mice. This was due to a greater noise-susceptibility in microglia depleted female mice compared to controls.

This indicates that female microglia serve a protective role in the auditory system after noise exposure.

Kainic-Acid Induced Cochlear Synaptopathy Alters Neural Adaptation in Budgerigars

11:30 a.m. - 11:45 a.m.

Yingxuan Wang^{*1}, Leslie Gonzales², Kenneth S. Henry²

¹*University of Rochester*, ²*University of Rochester Medical Center*

Background: Neural adaptation is the dynamic adjustment of neural responses to the statistics of the preceding acoustic context. This adjustment enables auditory neurons to operate across a wide range of environmental conditions and may be altered by intrinsic changes like sensory impairments, reflecting either a compensatory mechanism or a form of dysfunction. Cochlear synaptopathy is the loss of synapses between the inner hair cells and auditory-nerve fibers, a common health problem associated with aging and overexposure to loud sound. Recent studies in animal models suggest cochlear synaptopathy may alter temporal dynamics of single-unit neural responses, for example amplifying the onset of the peristimulus-time histogram (PSTH).

Methods: To investigate the temporal effects from a systems-level perspective, we developed a novel paradigm using Poisson click train for fast and reliable measurement of neural adaptation. The random nature of the stimulus timing allows us to measure the relationship between ICI and the amplitude of responses adapted to the prior stimulation. ABRs to Poisson click trains were measured in anesthetized budgerigars before and after induction of cochlear synaptopathy with kainic acid, with 50-70% loss of auditory-nerve synapses. The stimuli consisted of 5-second Poisson click trains with an average presentation rate of 40 clicks/s, presented at 50, 65, and 80 dB peak equivalent SPL. Each click was 0.1 ms in duration, and a total of 6000 clicks were presented with alternating polarities at each sound level.

Results: ABRs to Poisson click trains allowed efficient characterization of the neural adaptation. The adaptation functions of ABR wave I, II and V in budgerigars represent the neural temporal dynamic of auditory nerve (AN), midbrain and cortical processing stages along the auditory pathway. Despite the reduction of the overall amplitude, ABR wave I showed 7% more reduction on short ICIs (< 2 ms) compared to long (> 50 ms) ICIs, specifically at 65 dB SPL. Simulations using a computational model of the AN (Zilany et al., 2014) indicate this finding cooccurs with amplified PSTH onset. ABR wave II exhibited both delayed latency, and altered adaptation function shapes at lower (50, 65 dB) but not higher (80 dB) sound levels, which may be a cascade effect from the AN-level effects.

Conclusions: Our novel paradigm efficiently measures neural adaptation by utilizing the random timing of stimulus presentation. Our ABR measurements show that cochlear synaptopathy strengthens AN adaptation, particularly at moderate, conversational levels, which may lead to delayed temporal processing in the midbrain. These findings of altered neural adaptation along the ascending pathway provide insight into neural mechanisms that potentially underlie hearing difficulties in noisy listening environments caused by cochlear synaptopathy.

Neuromodulatory Mechanisms Underlying Cortical Neuroplasticity and Perceptual Recovery After Noise-Induced Hearing Loss

11:45 a.m. - 12:00 p.m.

Manoj Kumar^{*1}, Thanos Tzounoupoulos¹

¹*Pittsburgh Hearing Research Center, University of Pittsburgh*

Background: Noise-induced hearing loss (NIHL) induces cell-type-specific plasticity in the primary auditory cortex (A1), which supports perceptual recovery. This plasticity involves coordinated changes among key interneuron populations: recovered sound-evoked activity of parvalbumin-expressing (PV) interneurons contributes to the stability of principal neurons (PNs); the reduced activity of somatostatin-expressing (SOM) interneurons permits recovery of both PN and PV activity; and the recovery of vasoactive intestinal peptide-expressing (VIP) interneurons facilitates PN and PV recovery by inhibiting SOMs. While A1 plasticity after NIHL is generally beneficial for restoring perceptual hearing, it fails to fully compensate for auditory features encoded by precise spike timing, such as temporally modulated noise and speech. Moreover, maladaptive forms of this plasticity may contribute to the emergence of tinnitus and hyperacusis. Despite its importance, the neuromodulatory mechanisms that orchestrate this cell-type-specific, system-level plasticity remain poorly understood. To investigate these mechanisms, we focused on synaptic zinc signaling, a major modulator of synaptic transmission and cortical sensory processing. Understanding the role of synaptic zinc in A1 plasticity has the potential to uncover novel therapeutic targets for enhancing cortical and perceptual recovery, while also mitigating the development of tinnitus and hyperacusis following NIHL.

Methods: We combined cell-type-specific acute and longitudinal two-photon Ca^{2+} imaging in awake mice with a genetically encoded synaptic zinc sensor, operant behavioral assays, and pharmacological manipulations in both wild-type and conditional ZnT3 knockout (cKO) mice lacking synaptic zinc.

Results: Using in vivo wide-field and 2-photon Ca^{2+} imaging in awake mice, we found that pharmacological and conditional deletion of AC synaptic zinc reduced A1 PN sound-evoked responses and impaired perceptual recovery after NIHL, suggesting that cortical synaptic zinc contributes to A1 plasticity and perceptual recovery. Next, we tested whether plasticity in A1 synaptic zinc levels is associated with A1 and perceptual plasticity after NIHL. We performed in vivo wide-field Zn^{2+} imaging in awake mice expressing FRISZ-TM, a genetically encoded far-red transmembrane fluorescent zinc sensor that detects extracellular zinc in response to sound stimuli. One day after NIHL, we observed reduced sound-evoked FRISZ-TM (zinc) responses, suggesting decreased synaptic zinc signaling in A1. Ten days after NIHL, we found significantly increased sound-evoked zinc responses, indicating enhanced synaptic zinc signaling. These findings demonstrate that NIHL induces dynamic, time-dependent plasticity in A1 synaptic zinc levels. To further investigate the mechanistic role of zinc plasticity in neural adaptation after NIHL, we examined its effects on specific neuronal populations over time. Using in vivo Ca^{2+} imaging in awake mice, we found that synaptic zinc plasticity contributes to increased PN sound-evoked responses after NIHL, likely through enhanced SOM inhibition.

Conclusions: Our results establish synaptic zinc as a key neuromodulator of cell-type-specific neuroplasticity in A1 and demonstrate that synaptic zinc signaling is essential for perceptual recovery following NIHL.

Area-Specific Homeostatic Regulation of Cortical Sensitivity of Congenitally Deaf Cats

12:00 p.m. - 12:15 p.m.

Prasandhya A. Yusuf¹, Gideon H.P. Sinaga¹, Stella Clarissa¹, Laurentia Yamin¹, Peter Hubka², Jochen Tillein³, Rüdiger Land⁴, Andrej Kral*⁵

¹*Faulty of Medicine, University of Indonesia*, ²*Medical University Hannover*, ³*MED-EL*,

⁴*Institute of Audioneurotechnology, Hannover Medical School*, ⁵*Hannover Medical School*

Background: Homeostatic regulation stabilizes brain activity, preventing excessive excitation and the cessation of activity in divergent neuronal networks with. It involves synaptic rescaling, resetting of spiking thresholds, and adjustments in excitatory-inhibitory balance. These play a crucial role in the impact of sensory deprivation, such as deafness, on the brain.

Methods: To investigate the impact of prolonged deprivation on such regulation, three animal groups were compared: adult hearing cats stimulated acoustically (HA, n=6), hearing cats stimulated electrically with cochlear implants (CIs) (HE, n=6), and adult congenitally deaf cats (CDCs) stimulated acutely with CIs (CDCs, n=5). Stimuli were presented at the contralateral ear and varied in intensity (10 dB steps for acoustic and 1 dB steps for electric stimulation). The auditory brainstem response (ABR) from the acoustic stimulus and the electric eABR were determined. Subsequently, cortical responses were recorded simultaneously using two Neuronexus multielectrode arrays inserted in the primary auditory cortex (A1) and posterior auditory field (PAF). These encompassed numerous penetrations and several hundred recording sites in each cortical area. Local field potential (LFP) and multi-unit (MU) responses were measured for varying stimulation levels. The ABR and LFP thresholds were determined using statistically significant inter-trial phase coherence. The MU thresholds were determined by a significant increase in activity above the prestimulus interval. Comparisons were non-parametric (paired Wilcoxon rank sum or Wilcoxon-Mann-Whitney test).

Results: Cortical thresholds in PAF were consistently higher than in A1. All animals showed lower mean LFP thresholds compared to MU thresholds, and minimal cortical thresholds were consistently lower than the ABR thresholds. HAs had LFP thresholds 6-12 dB below mean ABR thresholds. In HE, electrical thresholds were lower in eABR (1-2 dB). In CDCs, the opposite was found: significantly higher thresholds for the eABRs (1-2 dB difference). In pairwise comparison, the MU thresholds were in all animal groups nominally higher than LFP thresholds. There was no significant difference in the mean thresholds between A1 and PAF in HA ($p=0.381$). In HE there was a smaller difference of LFP and MU thresholds in PAF compared to A1 ($p=0.039$). In A1 of CDCs, a more similar MU and LFP thresholds than HE was found ($p=1.47 \cdot 10^{-12}$), with a pronounced difference to HE ($p=1.014 \cdot 10^{-7}$). However, in PAF of CDCs, the threshold of units was much higher relative to LFP compared to HE ($p=0.0033$).

Conclusions: While in A1 the neurons became more sensitive to CI stimulation in CDCs, in PAF the neurons became less sensitive. This documents an upregulation of the sensitivity to auditory stimuli in A1, and a downregulation in PAF. This demonstrates a dissociation of the homeostatic regulation between A1 and PAF, supporting their differential role in crossmodal processes.

The Impact of Neonatal Intensive Care Unit Sensory Experience on Rodent Auditory Development

12:15 p.m. - 12:30 p.m.

Todd Mowery*¹, Eran Peci¹, Faith Chukwudinma¹, Noor Zaman¹, Shrinidhi Ramachandran¹

¹*Rutgers University*

Background: According to the World Health Organization, ~15 million children are born prematurely each year. Many of these infants end up spending days to weeks in a neonatal intensive care unit (NICU). Infants who are born prematurely are often exposed to noise and light levels that affect their auditory and visual development. Children often have long-term impairments in cognition, visuospatial processing, hearing, and language. OSHA regulations consider noise levels under 85 dB SPL safe for indefinite exposure; however, the infant may be sensitive to noise below this level especially during the critical periods of auditory development.

Methods: To test this, we have developed a rodent model of NICU exposure to light and sound using the Mongolian gerbil (*Meriones unguiculatus*), which has a low-frequency human-like audiogram and is altricial. Postnatal day 11 animals housed with their breeding parents had their eyes and ears opened prematurely or sham opened, after which they were exposed to the NICU-like sensory environment (24 hour light cycle (400 lumen), and 75 (day)/45 (night) dB SPL broadband noise) throughout the gerbil's cortical critical period of auditory development (P11 to P18). Control animals were reared in the same box, with no manipulation and the normal colony environment (12/12 light dark cycle, ambient room noise). Auditory status was assessed in neonates (P19), juveniles (P35), and adults (P86) with ABR and DPOAE recordings. Once adults, all animals were trained on a two-tone auditory discrimination task to determine the presence of any learning or performance impairments. A noise masker was then introduced (50, 75, 100, and 125%). Behavioral performance on noise masker trials were correlated with ABR Wave 1 amplitudes and latencies and DPOAE thresholds to identify animals with possible synaptopathy.

Results: NICU reared animals showed behavioral impairments and changes to auditory status (increased thresholds) compared to control animals.

Conclusions: Our preliminary results suggest that this animal model could provide researchers with an ethical way to explore the long-term effects of NICU exposure on the preterm infant's brain development.

Special Session: Auditory Periphery to Cortex: Research Advances and Career Journeys

10:30 a.m. - 12:30 p.m.

Meeting Room 208ABC, Floor 2

Auditory Periphery to Cortex: Research Advances and Career Journeys

Elinette Albino

Celebrating Hispanic and Latin Scientists: Research Advances and Career Journeys

Michele Insanally*¹

¹*University of Pittsburgh School of Medicine*

Individual Abstract: This session aims to increase the visibility of underrepresented Hispanic and Latinx scientists in the field of Otolaryngology and will include participants both locally from Puerto Rico and from the United States. Hispanics and Latinos are largely underrepresented in the field of Otolaryngology at all career stages from students to postdocs to faculty with only 4.1% Latino full professors in Otolaryngology (Watkins et al., 2024; Solis and Valdez et al 2023). This session will highlight the scientific achievements and career trajectories of Hispanic and Latinx researchers in Otolaryngology, with a focus on increasing visibility and fostering community among underrepresented groups. The panelists will highlight both their research contributions to the field of Otolaryngology as well as career trajectories. Panelists will include seven scientists from different career stages spanning postdoc to senior faculty. The panelists research topics will span a broad range from the auditory periphery to cortex as will their career stage. Topics will include auditory hair cell biology, genetics of hearing loss, head and neck cancer, auditory neuroscience, and health disparities in Hispanic and Latinx populations. Each speaker will present their research, and reflect on their unique career paths, challenges, and opportunities as Hispanic and Latinx scientists. The session will conclude with a moderated discussion and networking opportunity, designed to inspire trainees and facilitate collaborations across geographic boundaries and career-stages.

Impact of Resting Mechanotransduction Current on Stereocilia Actin Dynamics in Mammalian Auditory Hair Cells

A. Catalina Velez-Ortega*¹, Manuela Gomez-Giraldo², Juliana Castro Jimenez²

¹*University of Kentucky*, ²*University of Kentucky, College of Medicine*

Individual Abstract: Background: The mechanosensitivity of inner ear hair cells depends on microvilli-like projections – termed stereocilia – supported by parallel actin filaments. In mammalian hair cells, actin filaments are remarkably stable along the length of a stereocilium, except at a small tip region that exhibits continuous actin turnover. We previously discovered that stereocilia harboring mechano-electrical transduction (MET) channels retract after blockage of the calcium influx through these channels – which are partially open at rest – while the neighboring tallest non-transducing stereocilia in the same hair bundle are not affected. Once the resting MET current is restored, transducing stereocilia regrow. Our preliminary data indicate that the MET-dependent shortening of stereocilia exceeds the tip region of active actin turnover. Lastly, stereocilia of cochlear hair cells are supported by two different actin isoforms (β and γ), which exhibit different polymerization and depolymerization dynamics in the presence of calcium. Here, we are evaluating the extent to which changes in the resting MET current alter the active turnover and composition of the actin cytoskeleton in auditory stereocilia.

Methods: We used tubocurarine to block MET channel currents in isolated neonate cochlear explants from mice. We visualized changes to (a) the incorporation of β -actin via fluorescence recovery after photobleaching using hair cells expressing β -actin-eGFP and (b) the β/γ actin ratio in C57Bl/6 wild-type hair cells using isoform-specific antibodies. Changes were evaluated along the length of individual stereocilia using confocal microscopy.

Results: Our results show that, in inner hair cells, the zone of active actin incorporation in stereocilia progressively becomes smaller as cells mature during the first postnatal week. In addition, the blockage of MET channels decreases both the size of this zone and the rate of actin incorporation in stereocilia from transducing (shorter) as well as non-transducing (tallest) rows. Our preliminary results with immunolabeling against β - and γ -actin indicate that the blockage of MET channels leads to a decrease in the β/γ actin ratio at the tips of transducing stereocilia.

Conclusions: Altogether, our results indicate that the resting MET current in cochlear hair cells is essential to maintain the appropriate size, rate, and composition of the zone of active actin remodeling at the tips of stereocilia. In the presence of MET deficits, it is plausible that actin dynamics shift towards a scenario that is unfavorable for the lifelong maintenance of stereocilia.

Targeted Cell Interconversions Reveal Inner Hair Cell Control of Organ of Corti Cytoarchitecture

Ignacio Garcia-Gomez¹, Jemma L. Webber¹, Berta Soria Izquierdo¹, John C. Clancy¹, Anne Duggan¹, Yingjie Zhou¹, Charles P. Murphey¹, Trevor D.M. Harriman¹, Jianghong Wang¹, Mary Ann Cheatham¹, Jaime Garcia-Anoveros^{*2}

¹*Northwestern University*, ²*Northwestern University Institute for Neurosciences*

Individual Abstract: The mammalian organ of Corti is a precisely intercalated mosaic of two types of mechanosensory hair cells and six types of supporting cells (SCs) arranged in eleven parallel rows. Differentially specialized SCs surround inner (IHC) and outer (OHC) hair cells. To elucidate the developmental roles of IHCs and OHCs in the formation, differentiation, and assembly of the various SCs, we genetically switched HC identities at several developmental stages. In addition, we generated mice lacking IHCs. We find that IHCs promote or induce the: (1) differentiation of one type of outer compartment supporting cell (Outer Pillar or OPC) at the expense of another (Dieters' 1 and 2, but not 3), so that each completely and exclusively populates separate rows; (2) high packing density, but not identity, of Inner Pillar Cells (IPCs), so that they form a continuous wall that lines the medial side of the tunnel of Corti; (3) embryonic formation and (4) cytoplasmic attraction of adjacent Inner Phalangeal Cells (IPhCs), so that they tightly envelop IHCs. The longer-range effects of IHCs on outer and inner pillar cells are caused by their transient developmental production of FGF8 ligands, but the effects of IHCs on the immediately adjacent IPhCs are not FGF8-dependent and must involve another signaling mechanism. Hence, developing IHCs dictate major aspects of SC identity and distribution to assemble the complex organ of Corti.

GPSM2-Dependent Regulation of Actin Dynamics and Stereocilia Integrity in Mature Hair Cells

Lubriel Sambolin-Escobales*¹, Elli Hartig¹, Ana I. López-Porras², A. Catalina Vélez-Ortega², Basile Tarchini¹

¹*The Jackson Laboratory*, ²*University of Kentucky*

Individual Abstract: GPSM2 is a critical component of the elongation complex (EC), a group of proteins that drive hair bundle growth and patterning during development. Recent work showed that all EC proteins persist at row 1 stereocilia tips in mature hair cells (Hartig et al., 2024). In adult hair cells, GPSM2 depletion reduces accumulation of other EC proteins at tips and causes a progressive collapse in stereocilia height (~0.5-0.6 μm) matching the tip compartment defined as the actin turnover region. This suggests EC proteins may regulate actin dynamics to maintain dimensions of the tip compartment and preserve hair bundle architecture in mature hair cells under mechanical strain.

We used Gfi1CreERT and tamoxifen delivery to temporally control Gpsm2 inactivation in hair cells. Cochleae were harvested 6 months after inactivation at 6 weeks of age, doubling the chase period from our previous study (3 months). We also inactivated Gpsm2 at 6 months and analyzed hair cells 3 months later. Confocal microscopy was used to quantify hair cell survival, row 1 stereocilia height in inner hair cells, and EC protein enrichment. To track actin dynamics in vivo, we generated a new mouse model expressing HaloTag-ACTG1 upon Cre activation. Crossing this model with Gfi1CreERT; Gpsm2 mutants enabled labeling of newly incorporated actin at tips post inactivation. Stereocilia tip remodeling was further examined using FIB-SEM.

Six months after Gpsm2 inactivation, stereocilia height and EC protein levels were reduced, but not significantly more than after 3 months (Hartig et al., 2024). This suggests that the tip compartment depending on EC proteins is largely depleted by ~3 months already while shafts remain stable. Inactivation at 6 months led to slightly milder height reduction but ongoing analyses suggest hair cell loss and occasional bundle degeneration at the cochlear apex, phenotypes absent in earlier inactivation schemes. Loss of GPSM2 at 6 weeks progressively reduced the amount of new actin (HaloTag-ACTG1) incorporated at tips 4, 6, and 12 weeks later, formally linking EC protein loss to impaired actin turnover. FIB-SEM analysis confirmed a disrupted row 1 stereocilia morphology, including abnormally rounded tips and a reduced electron-dense tip compartment.

Loss of EC proteins in young adult hair cells impairs actin turnover at row 1 stereocilia tips, leading to a progressive remodeling and collapse in size of the tip compartment complete by ~3-4 months. Mild auditory dysfunction observed 3 months post inactivation (Hartig et al., 2024) is thus not expected to worsen. At later stages, GPSM2 loss might further impact stereocilia and occasionally compromise the core as well. We propose that EC proteins not only drive stereocilia elongation during development but also fine-tune actin dynamics at row 1 stereocilia tips to maintain hair bundle integrity throughout life.

Genetic and Audiological Profiles of Hearing Loss in Puerto Rico

Elinette Albino*¹

¹*University of Puerto Rico*

Individual Abstract: Understanding the genetic causes of hearing loss (HL) in Puerto Rico is essential given that approximately 7% of the population experiences significant HL—exceeding mainland U.S. averages. However, the underrepresentation of Puerto Rican individuals in genetic research limits accurate diagnoses and equitable care. This study aims to investigate the genetic and audiological landscape of childhood-onset HL in Puerto Rican families by integrating genomic sequencing, detailed phenotyping, and functional analyses. Through exome and genome sequencing of affected individuals and their parents, we seek to identify population-specific variants that contribute to HL onset and progression. Comprehensive audiological and vestibular assessments are conducted using standardized protocols to correlate genetic findings with clinical presentation. Functional validation in cellular and animal models further elucidates the biological impact of prioritized variants. This approach will help establish a foundational variant database for this population, improve diagnostic precision, and inform personalized treatment strategies. Ultimately, this work aims to reduce health disparities, enhance early detection, and contribute to global efforts to understand HL in diverse and underrepresented populations.

Mechanisms of Serotonergic Signaling in the Auditory Midbrain

Marina Silveira^{*1}, Wenicios Chaves¹, Maria Carrasco¹

¹*University of Texas at San Antonio*

Individual Abstract: The inferior colliculus (IC) is the midbrain hub of the central auditory pathway that processes and integrates many auditory and non-auditory inputs. The IC receives a major serotonergic input from the dorsal raphe nuclei. Serotonin differentially modulate how IC neurons respond to sound. However, because of the diversity of neuron types and complex circuitry in the IC, the mechanisms by which serotonin leads to changes in auditory responses are unclear. We previously identified that neuropeptide Y (NPY) expression is a marker for a class of IC GABAergic neurons while the majority of glutamatergic neurons express the NPY Y1 receptor (Y1R neurons). We hypothesized that serotonin differentially modulates the excitability of NPY and Y1R neurons. To determine the subtypes of serotonergic receptors expressed by NPY and Y1R neurons, we performed fluorescent in situ hybridization in IC brain slices of mice. We used probes against *Npy*, *Vglut2*, and *Htr1a*, *Htr1b*, *Htr2a*, and *Htr2c*. Next, to determine how serotonin modulates the excitability of NPY and Y1R neurons, we performed whole-cell patch clamp recordings combined with serotonin puff application targeted to either NPY (identified in the NPY-hrGFP mouse) or Y1R (identified in the Y1RxAi14 mouse) neurons. Selective antagonists were bath applied to determine the receptors mediating the serotonergic effect. Since many regions that project to the IC express serotonergic receptors, we next used optogenetics to determine how serotonin modulates defined presynaptic inputs to IC neurons. Our data show that 32% of *Vglut2* neurons express *Htr1a*, and 38.2% of *Vglut2* neurons express *Htr1b*. Fewer *Vglut2* neurons express the excitatory serotonergic receptors *Htr2a* (1.1%) and *Htr2c* (14%). *Npy* neurons express either *Htr2a* (45.3%) and/or *Htr2c* (39.2%) receptors. Few *Npy* neurons expressed the *Htr1a* (2%) and *Htr1b* (1%). In agreement, our electrophysiology data show that NPY neurons are depolarized by serotonin by activation of 5-HT_{2A/C} receptors, while Y1R neurons are hyperpolarized by activation of the 5-HT_{1A} receptor. Optogenetics experiments suggest that serotonin decreases the strength of local IC circuits but enhances the strength of contralateral IC circuits. In addition, we find that serotonin can either enhance or diminish the strength of descending cortical projections. Our results suggest that serotonin

signaling favors inhibition in the IC by inhibiting the Y1R and exciting NPY neurons. Future studies will determine whether the effects of serotonin are changed in auditory processing disorders such as tinnitus and age-related hearing loss.

Dynamics of Auditory Cortical Neural Activity in Response to Natural Sounds

Santiago Jaramillo*¹

¹*University of Oregon*

Individual Abstract: Research in the Jaramillo laboratory focuses on the neural circuits responsible for auditory cognition. Our goal is to understand how the brain assigns meaning to sounds, how it attends to or ignores auditory stimuli, and how expectation influences sound perception. In this talk, I will present work characterizing the dynamics and geometrical structure of population activity in the auditory cortex during the presentation of natural sounds. We collected datasets containing hundreds of simultaneously recorded neurons from distinct regions of the mouse auditory cortex. Analyses of these datasets have revealed potential mechanisms that explain a counterintuitive perceptual phenomenon where discrimination accuracy between sound samples decreases for longer-duration samples if the sounds are distinct instances of the same acoustic category.

Poster Session III with Coffee

1:30 p.m. - 3:00 p.m.

Ballroom A, Floor 3

Due to the policies of the Puerto Rico Convention Center, the Poster Hall will be available to attendees between the hours of 7AM – 11PM (local time), with a 1- hour break every day between 11AM and 12 PM (Noon) to facilitate setup for the next poster session. This is an appreciated extension of their normal permitted hours. ePosters are available on the conference website and the ARO MWM mobile app.

M1. Interareal and Interlaminar Differences in Sound Envelope Encoding in Core and Parabelt Auditory Cortex

Chase Mackey*¹, Monica O'Connell¹, Yoshinao Kajikawa¹

¹*Nathan S. Kline Institute*

Background: Sound envelope fluctuations are a key sound feature that drives the perception of complex stimuli such as species-specific vocalizations and music. Many previous studies have gained insight into how sound envelope encoding differs across the auditory pathway by recording neuronal responses to click trains and sinusoidally amplitude modulated (AM) tones and noise in nonhuman animals. These studies document a hierarchical progression across the pathway, generally characterized by a decrease in the temporal precision of AM encoding as the pathway is ascended. In primary auditory cortex, there are also parallel differences in AM

encoding across cortical layers, with the extragranular layers preferring slower AM relative to the thalamorecipient granular layer. In human and nonhuman primates, additional interhemispheric differences have been observed; namely, the left hemisphere exhibits enhanced temporal encoding relative to the right hemisphere. The NHP model provides an opportunity to understand what circuit mechanisms generate these transformations in encoding by characterizing AM encoding in different cortical circuits within area, and across the cortical hierarchy.

Methods: To address this, here we report the encoding of AM signals as a function of cortical layer and hemisphere in NHP core and parabelt auditory cortex. We recorded concurrent synaptic and multiunit spiking activity using linear array multielectrodes positioned across cortical layers. AM noise and click trains (1.6-200 Hz) were presented while NHPs passively listened. We derived measures of AM frequency classification from the neuronal responses using linear discriminant analysis.

Results: Core AC exhibited enhanced AM classification relative to the parabelt, across all layers. Sites in core AC typically encoded all AM frequencies (1.6-200 Hz) with high (> 90%) accuracy, while sites in the parabelt typically encoded a subset of lower (~1.6-25 Hz) frequencies; often via rapid, synchronized fluctuations in the local neuronal population. Across both areas, the granular and infragranular layers displayed enhanced AM encoding relative to the supragranular layers. Both areas displayed enhanced AM encoding in the left hemisphere, restricted to the supragranular layers.

Conclusions: These results suggest a complex interplay of area, cortical layer, and hemisphere is at work in the NHP auditory cortical hierarchy, and a potential supragranular layer origin of previously documented left-hemisphere dominance in temporal encoding.

M2. Cingulate Cortex Activity is Modulated During an Effortful Task in Gerbils

Kelsey Anbuhl^{*1}, Ayden M. Chavez¹, Alyssa B. Price¹, Dan H. Sanes²

¹Creighton University School of Medicine, ²New York University

Background: When sensory perception occurs under challenging acoustic conditions (e.g., noisy background), our stimulus sensitivity can remain surprisingly unaffected. One plausible neural mechanism involves the recruitment of a top-down neural pathway, from the cingulate-to-auditory cortex, that selectively facilitates auditory processing (Anbuhl et al., 2025). Here, we asked how gerbil cingulate cortex (Cg) neuron activity is modulated when animals engage in an effortful listening paradigm.

Methods: To assess auditory effort, an amplitude modulation (AM) rate discrimination task was used and stimulus parameters (AM rate, sound duration) were varied to adjust the difficulty of listening conditions. Using an appetitive Go-Nogo paradigm, adult gerbils (n=6) were trained to discriminate between “Go” stimuli (range of AM rates: 4.5-12 Hz; broadband noise carrier, 100% depth) and a “Nogo” AM stimulus (4 Hz). Trials were clustered into ‘Easy’ or ‘Hard’ blocks, where the sound duration was 1s or 0.25s, respectively. AM rate discrimination thresholds were determined from psychometric functions. To determine whether Cg neural activity is modulated during effortful listening, chronic electrode arrays were implanted into the Cg1 of behaviorally-trained animals, and wireless recordings from Cg1 neurons were obtained

during task performance. Neural firing rates were computed across stimulus block type (Easy, Hard) and within trials to assess whether Cg activity is selectively modulated with task difficulty. Behavior sessions were video recorded and tracking of animal movements was quantified using SLEAP, a framework for pose tracking via deep learning. Animal tracking data were aligned to behavior trials to extract movement-related metrics (e.g., position, velocity) within each trial. We then examined the relationship between psychometric performance, neural activity, and pose tracking metrics.

Results: Cg1 neurons (n=600) were recorded from gerbils (n=6) across 36 awake-behaving psychometric sessions during which stimuli were delivered in a block design (i.e., 40 easy trials, 40 hard trials). To test whether Cg1 activity was selectively modulated during specific time windows, a block-level analysis of firing rate was conducted within discrete trial epochs (trial initiation, unmodulated stimulus, modulated stimulus, and post-stimulus period). The first two epochs, trial initiation and unmodulated stimulus, yielded average firing rates that were greater for Easy trials across all stimulus types (Go, Nogo). The remaining epochs, modulated stimulus and post-stimulus period, yielded greater firing rates for Hard trials especially for 4 Hz AM (Nogo) and 4.5 Hz AM (the most difficult Go stimulus often associated with a Miss). Analysis of video recordings are currently underway to determine whether pose metrics can be correlated with task difficulty and with elevated Cg activity observed during the AM and post-stimulus period.

Conclusions: Taken together, the results suggest Cg1 neurons are recruited during hard stimulus conditions and are selectively modulated during trial epochs that may be associated with elevated auditory effort (i.e., stimulus, post-stimulus).

M3. Chemogenetic Modulation of Prefrontal Cortex Influences Auditory Cortex Responses and Event-Related Potentials in a Schizophrenia Rat Model

Laura H. Bohórquez^{*1}, Adam Hockley¹, David Pérez-González², Manuel S. Malmierca¹

¹*Cognitive and Auditory Neuroscience Laboratory, Institute of Neuroscience of Castilla y León (INCYL), Institute for Biomedical Research of Salamanca, Auditory Neuroscience, University of Salamanca, Faculty of Medicine,* ²*Cognitive and Auditory Neuroscience Laboratory, Institute of Neuroscience of Castilla y León (INCYL), Institute for Biomedical Research (IBSAL), Faculty of Psychology, University of Salamanca*

Background: Research on schizophrenia (SCZ) has shown that cognitive deficits stem partly from an impaired excitatory-inhibitory balance in the prefrontal (PFC) and auditory cortex (AC). Mismatch negativity (MMN), altered in SCZ, arises from AC and PFC where sound patterns, and contextual changes are processed sequentially. Predictive coding theory posit that AC sends bottom-up, ascending sensory signals to the PFC which in turn sends top-down, descending predictions to AC. Thus, top-down predictions modulate responses to expected stimuli, while unanticipated stimuli generate error signals that update the internal model. Pharmacological studies in humans and animal models have shown that MMN reduction in SCZ likely reflects NMDAR hypofunction. Using the chemogenetics technique, we manipulate the mPFC-AC pathway to study how top-down predictions control auditory processing in an animal model of SCZ.

Methods: We implanted Long-Evans female rats with ECoG arrays placed over AC-L, AC-R and PFC-R. We injected a retrograde inhibitory virus (AAVrg-hSyn-hM4D(Gi)-mCherry) into AC-L, and we implanted cannula guides above PFC-L. After recovery, we recorded from awake animals, either without any infusion or an infusion of C21 (5 mg/mL for mPFC-AC inhibition) or saline (sham; 0.8 μ L). We first carried out the recordings in a control condition, then alternated one week with 8 days of MK-801 (0.1 mg/Kg, IP), followed by one week of washout, and the same for MK-801 (0.2 mg/Kg). Auditory stimuli consisted of a classical oddball paradigm using a frequency pair of 11.313 and 16 KHz.

Results: In the control condition, deviant response amplitude increased in the AC-L during mPFC-AC inhibition, but not in the sham infusion. The deviant responses of the AC-L decreased with lower MK-801 dose and increased with the higher dose, but resulting in an abnormal response. We also studied how event-related potential components behaved as a function of MK-801 dosage. Thus, the 0.2 mg/kg dose resulted in a distinct increase of the N1 amplitude while the 0.1 mg/kg dose increased only a marginally compared to the control recording, although these did not reach statistical significance. By contrast, P1 remains unchanged.

Conclusions: Our results show that NMDAR dysfunction induces an alteration of the AC LFP and on the event-related potential components. The C21 infusion into PFC-L increased the amplitude of the AC-L deviant response, an effect that was not present during saline infusion. This suggests that the absence of a top-down PFC predictions, the prediction error increases in AC.

M4. Layer 6 Corticothalamic Neurons Show Attentional-Gain Responses During a Tone-In-Noise Detection Task

Marina Cardoso de Oliveira*¹, Patrick O. Kanold¹

¹*Johns Hopkins University*

Background: Neuronal activity adapts to behavioral context, optimizing performance. Although previous studies have shown that layers (L) 2/3 in the auditory cortex show attentional gain when mice are engaged in a detection task, how this modulation is achieved is unknown. Previous studies have reported the presence of noise-invariant neurons in upper cortical layers, and that the amplitude of responses and bandwidth decrease as SNR decreases. Since L6 corticothalamic (CT) neurons play an important role in modulating cortico-thalamo-cortical activity, we hypothesize that this modulation could sharpen the tuning curves and increase the gain of neurons in L2/3 and thalamic nuclei, thereby improving the perception of sound in environments with high background noise, for example. However, it remains unclear whether L6 CT neurons contribute to the mechanisms that improve performance in such conditions. Here, we aim to investigate how L6 CT neurons respond during behavior and whether L6 CT neurons could enhance the perception of target tones embedded in a noisy background.

Methods: We trained adult mice of the Ntsr1-Cre (B6.FVB(Cg)-Tg(Ntsr1-cre)GN220Gsat/Mmucd) line on a fixed hearing background (B6.CAST-Cdh23Ahl+/Kjn) crossed with a reporter line expressing (B6.Cg-Igs7tm162.1(tetO-GCaMP6s,CAG-tTA2)Hze/J) on a tone-in-noise detection task. Constant broadband white noise (50 dB SPL) was presented together with a one-second duration tone of 11.5 kHz (30 to 70 dB SPL), to obtain signal-to-noise ratios (SNRs) of -20 to +20 dB SPL. The mouse had to turn a wheel 25° degrees in either direction to receive a water reward. Mice were then imaged under 2-photon microscopy while performing the task. The pupil diameter was also recorded to assess the animal's attentional state during the task. Passive imaging sessions were conducted after the behavioral sessions to obtain frequency response areas for each neuron.

Results: Our preliminary findings indicate that pure-tone-responsive L6 CT neurons increase their response gain when mice successfully detect a tone embedded in a noisy background, compared to when they do not. This enhancement in response gain appears to become stronger as the SNR decreases.

Conclusions: Our preliminary results are consistent with our hypothesis for a role of L6 CT neurons in hearing in noisy environments. The observed increase in gain of L6 CT neurons at lower SNRs for hit trials in comparison to miss trials suggests that task difficulty and possibly the state of attention may be driving their responses when hearing target tones becomes more challenging.

M5. Morphometry and Nav 1.6 Expression Changes in Cochlear Ranvier Nodes of Ageing C57BL/6N and CBA/J Mice

Maria Luque¹, Niklas Hammerstein¹, Sree Jeevitha Parameswaran¹, Rudolf Glueckert*¹

¹*Medical University Innsbruck*

Background: Age-related hearing loss (ARHL) is not only caused by hair cell degeneration, but also changes in the auditory nerve, including synaptic loss and impaired neural conduction. Spiral ganglion neurons (SGNs) depend on efficient action potential generation at the hemi node and propagation via Ranvier nodes (RVN), mainly triggered by the sodium channel Nav 1.6. Alterations in node morphometry or Nav 1.6 expression may disrupt this signalling. As SGNs comprise diverse subpopulations with distinct functional and molecular properties, their vulnerability to ageing may differ among humans and mouse strains. Investigating these changes offers insight into the mechanisms underlying ARHL.

Methods: The present work investigates age-related changes in morphometry and Nav 1.6 immunoreactivity of RVN in the auditory system of the mouse to detect temporal changes across the lifespan of the two mouse strains, CBA/J and C57BL/6N. Immunostaining of Nav 1.6 was performed in 1 to 19 months old animals with an automatic immunostainer and quantified with Image J. RVN morphometrics as well as semiquantification of RVN immunoreactivity were done taking into account tonotopic position and auditory path in the cochlea.

Results: A clear tonotopic gradient of Nav 1.6 intensity was evident in both strains, with higher levels in the basal turn, indicating functional specialization along the cochlear axis. Results further show strain-specific age-related changes in RVN morphometry and Nav 1.6 expression. While CBA mice lose small calibre fibers and median RVN length increases, B6 mice show a degradation of big myelinated axons with a reduction in median node diameter. A decrease in

Nav 1.6 immunostaining in middle-aged B6 mice with a subsequent compensation to young mice level in older animals may be explained by an upregulation of Nav 1.6 production after early loss. This Nav 1.6 expression profile perfectly fits to the early hearing deficits in these mice. In CBA mice we do not see such a pattern that matches with ABR data, so hearing deficits in the apical turn do not correspond to changes in Nav 1.6 expression levels.

Conclusions: While B6 mice lose more big calibre nerve fibres with high spontaneous firing rates, CBA mice show the opposite with a pronounced loss of small calibre axons with a low spontaneous firing rate with increasing age. Both results in a loss of the dynamic range of hearing sensation. Nav 1.6 changes affect mainly B6 mice that may contribute to ARHL in this mouse strain.

M6. Auditory Function During the Menopausal Transition in the Accelerated Ovarian Failure (AOF) Mouse Model: Evidence From Young Adult Female CBA/CaJ Mice

Xiao Xia Zhu*¹, Bo Ding¹, Claire Messerschmidt¹, Collin Park¹, Parveen Bazard², Marina Eliass¹, Robert D. Frisina¹

¹*Global Center for Hearing and Speech Research, University of South Florida*, ²*Global Center for Hearing and Speech Research, University of South Florida and Linda and Bipin Doshi Dept. of Chemical and Bioengineering, Missouri S and T*

Background: Menopause-related declines in estrogen are believed to contribute to age-related hearing loss (presbycusis). While estrogen and other female sex hormones are known to play important roles in maintaining auditory function, the specific mechanisms by which hormonal loss—independent of aging—affects hearing remain poorly understood. To isolate the effects of ovarian hormone depletion from those of aging, this study evaluated auditory function in young adult female CBA/CaJ mice using the 4-vinylcyclohexene diepoxide (VCD)-induced Accelerated Ovarian Failure (AOF) model. Peripheral and central auditory function was assessed throughout progressive ovarian hormone loss using auditory brainstem responses (ABRs) and distortion product otoacoustic emissions (DPOAEs)

Methods: Female CBA/CaJ mice (n = 14; 2 months old) received daily intraperitoneal injections of VCD; 160 mg/kg/day for 15 consecutive days to induce ovarian failure. Age-matched control mice received equivalent volumes of vehicle. An additional group of ovariectomized (OVX) mice was included to validate the postmenopausal phenotype induced by VCD. Ovarian failure was confirmed through histological follicle counts and serum hormone analyses. Auditory function was evaluated by measuring ABR thresholds and DPOAE amplitudes and thresholds at baseline (pre-treatment) and across three defined stages of menopause: pre-menopause (< 25 days post-treatment), peri-menopause (50–75 days), and post-menopause (> 129 days post-treatment). Cochlear cryosections from post-menopausal VCD-treated mice and controls were stained with a mitochondrial dye and imaged using confocal microscopy for immunohistochemistry (IHC) analysis.

Results: By 129 days post-treatment, visual assessment of VCD-treated mice demonstrated persistent acyclic diestrus, consistent with ovarian failure. Histological analysis of H and E-stained ovarian sections revealed a progressive decline in primordial and primary follicles over

time, while corpora lutea remained preserved. Serum estradiol (E2) levels significantly decreased by day 24, reaching their nadir by day 129. In parallel, follicle-stimulating hormone (FSH) levels began to rise from day 52 onward. ABR testing showed significantly elevated thresholds in VCD-treated mice at days 52 and 129, especially at high frequencies. No threshold changes were observed at day 24. OVX mice similarly developed elevated ABR thresholds four months post-surgery. DPOAE data revealed reduced amplitudes and threshold shifts at low and high frequencies on days 52 and 129 in VCD-treated mice; mid-frequency responses remained stable. Control mice maintained consistent auditory function throughout. Mitochondrial dye was detected in the spiral ganglion, stria vascularis, and organ of corti in both VCD and control cochleae; however, mitochondrial signal was reduced in the postmenopausal VCD group vs. control non-treatment group.

Conclusions: VCD treatment effectively induced accelerated ovarian failure in young CBA/CaJ mice, mimicking key hormonal changes of the menopausal transition. Declining estrogen levels were associated with progressive auditory deficits, potentially influenced by mitochondrial function. These findings support the anticipated effects of the VCD-induced AOF on female hormonal levels which are associated with auditory function and strengthen the evidence linking estrogen deficiency to presbycusis.

M7. Auditory Novelty Detection Deficits in an Alzheimer's Disease Rat Model: Behavioral and Electrophysiological Evidence

Laura Quintela Vega*¹, Ana Belen Lao-Rodríguez¹, David Perez-González¹, Manuel S. Malmierca¹

¹*Institute of Neuroscience of Castilla y León, Cognitive and Auditory Neuroscience, Faculty of Medicine, University of Salamanca*

Background: Age-related hearing loss is a widespread disability that impairs communication and social participation in the elderly. Recent studies highlight hearing loss as a significant risk factor for dementia, including Alzheimer's disease (AD; Griffiths et al., 2020). Deviance detection is a fundamental element of the predictive coding framework. This theory posits that the brain compares incoming sounds with expected patterns and identifies deviations from predictions. Peripheral accuracy declines with aging, increasing reliance on predictions. Dementia further impairs prediction reliability, as temporo-parietal dysfunction reduces auditory adaptation. Thus, aging and dementia alter predictive processes cognitively and behaviorally. We investigated how AD pathology affects deviance detection using TgF344-AD rats, a transgenic model with hallmark AD lesions.

Methods: We trained 40 rats, aged 16 to 20 months (TgF344-AD and controls, both sexes) to discriminate deviant tones in an oddball paradigm. Animals learned to nosepoke when a deviant sound occurred and were rewarded with food pellets. We used two frequency sets (4.8–6.7 and 8.0–11.3 kHz). We tested discrimination across interstimulus intervals (1.5–4.0 s), frequency contrasts (0.5, 1.00, 1.25 octaves), and deviant probabilities (10–30%). We also applied a many-deviant paradigm. We quantified behavioral performance using d' . After training, we recorded neuronal activity in the auditory cortex with 64-channel probes, using paradigms adapted to neuronal response ranges (250 ms ISI). We included predictive coding controls: oddball

ascending/descending, cascade ascending/descending, and many-standards. We analyzed firing rates and predictive coding indices (iMM, iPE, iRS).

Results: TgF344-AD rats required more sessions than controls to learn the task and achieve stable performance. They showed lower d' , slower latencies, and reduced sensitivity to small frequency contrasts in the many-deviant paradigm. Males generally outperformed females. Longer ISIs improved performance in all groups. Control animals detected higher frequency contrasts better, whereas TgF344-AD animals performed relatively better at lower contrasts in the many-deviant task. Electrophysiological recordings in auditory cortex revealed attenuated responses to deviant sounds in TgF344-AD rats. Predictive coding indices were also altered: iMM was reduced, reflecting weaker deviance encoding, while iPE and iRS showed disrupted balance between prediction and adaptation.

Conclusions: AD pathology in TgF344-AD rats impairs auditory novelty detection at behavioral and neuronal levels. Animals needed more training, showed poorer discrimination and slower latencies, and recordings revealed reduced deviant responses and mismatch indices. These results demonstrate disrupted predictive processing and validate the TgF344-AD rat as a model for deviance detection deficits.

M8. Evaluating Auditory Reflex Measurements: Interactions Between MEMR, MOCR, and Methodological Considerations for Research

Pauline Devolder^{*1}, Francois Deloche¹, Hannah Keppler², Sarah Verhulst¹

¹*Hearing Technology at WAVES, Ghent University*, ²*Ghent University*

Background: The middle-ear muscle reflex (MEMR) and the medial olivocochlear reflex (MOCR) are emerging tools for assessing peripheral auditory function, including hidden hearing loss. However, as with other auditory measurements, the reliability of these tools may be affected by interactions between hidden auditory deficits and outer hair cell (OHC) integrity. Also the influence of MEMR on MOCR measurements remains unclear, since both reflexes are evoked and measured in a similar way. This study evaluates MEMR and MOCR measurements in participants with audiometrically normal-hearing ears, focusing on age-related effects and subtle auditory deficits. In addition, we address methodological considerations relevant for implementing these reflex measures in research.

Methods: This project combines two complementary parts:

- Part 1 assessed age-related effects and MEMR-MOCR interactions. Twenty young (18-35 y/o), normal-hearing participants (≤ 20 dB HL) and twenty older (45-65 y/o), normal-hearing participants were tested using wideband click-evoked MEMR and MOCR in ipsilateral and contralateral configurations. MOCR was measured both with an elicitor noise of 60 (standard) and 75 dB SPL to evaluate potential MEMR contamination.

- Part 2 piloted the effects of subtle auditory deficits on reflex measurements. Ten young normal-hearing controls, five participants with unilateral mild hearing loss (≤ 50 dB HL), and five normal-hearing participants with unilateral tinnitus underwent MEMR and MOCR testing in ipsilateral, contralateral, and bilateral configurations.

Results: Both MEMR and MOCR were decreased in the older test-group, consistent with prior reports. The data of part 1 also reveals that MEMR can affect MOCR estimates, but only at higher stimulus levels, since MEMR typically evokes at higher intensities than the MOCR. Further analyses will be conducted to evaluate whether the effects of MEMR can be reduced in MOCR analyses.

Preliminary results of part 2 suggest that contralateral and bilateral reflex responses are sensitive to subtle hearing deficits. The effects of OHC damage on ipsi- and contralateral MEMR and MOCR measurements will be further evaluated and discussed at the conference. These pilot findings highlight the methodological factors that influence measurement reliability and interpretation.

Conclusions: Wideband click-evoked MEMR and MOCR measurements can be used to study peripheral afferent and efferent function, but interpretation requires careful consideration of age, OHC status, and pathway interactions. By evaluating the effects of age and peripheral deficits within the same framework, this study provides guidance for optimizing reflex protocols in future studies of hidden hearing loss, tinnitus, and other central gain-related conditions.

M9. A Dual-Pathway Model of Fall Risk: The Mediating Role of Balance

Somayeh Shahsavarani^{*1}, Yihsin Tai²

¹San Jose State University, ²Ball State University

Background: Falls represent a major public health crisis for older adults and are a leading cause of morbidity and mortality. Postural stability is a complex process that relies on the interaction among auditory, cognitive, and vascular systems. Deficits across these upstream systems are identified as fall risk factors. These factors are often studied in isolation and the mechanistic pathways that link the collective influence to falls remain poorly understood. In this study, we propose that upstream deficits, such as hearing problems, reduced cognitive performance, or poor vascular health, do not cause falls directly but rather converge to impair balance. This study tests the hypothesis that balance acts as the critical mediator, translating these diverse upstream deficits into functional fall risk.

Methods: We analyzed cross-sectional data from 4,805 community-dwelling adults aged 65 or older in the National Health and Aging Trends Study (NHATS) Round 13. The outcome variable was a summated fall-risk score. Predictors included self-reported hearing ability, cognitive function, mental health, and chronic vascular conditions. The mediators were two complementary measures of balance: a subjective self-report of a balance problem and an objective score from the balance subset of the Short Physical Performance Battery (SPPB). We used survey-weighted multiple regression to identify direct predictors and mediation analyses to test for indirect effects through balance.

Results: The analysis revealed two distinct pathways to fall risk. First, a direct pathway was observed where greater self-report balance problems were the strongest predictor of fall risk ($\beta = 0.53$, $p < .001$). Additional direct predictors included lower objective balance scores ($\beta = -0.08$, $p < .001$), symptoms of depression ($\beta = 0.05$, $p < .001$) and anxiety ($\beta = 0.04$, $p = .001$), as well as a history of heart disease ($\beta = 0.07$, $p = .02$). Second, an indirect pathway was identified where poorer hearing ability, lower cognitive scores, and the presence of hypertension each independently predicted worse balance (both subjective and objective). These balance deficits, in turn, strongly mediated the relationship with fall risk, converging on balance impairment as the key mechanism linking these factors to increased fall risk.

Conclusions: Our findings identify the pivotal role of balance in linking deficits in hearing, cognition, and vascular health to fall risk. For the science and practice of otolaryngology, this reframes hearing and vestibular disorders not merely as sensory deficits prevalent in older adults, but as critical contributors to postural instability. The key takeaway message is that hearing and vestibular functions play a central role in multidisciplinary fall-prevention management, as balance represents the common pathway where the upstream diverse risks can manifest. Future research should employ prospective designs to investigate how multi-modal interventions can target this pathway and reduce falls.

M10. Delayed Synaptic Aging in the Cochlea of Long-Lived Naked Mole Rats (Heterocephalus Glaber)

Karen Castaño González^{*1}, Luis Antonio Buendía Sánchez², Gary R. Lewin³, Sonja Pyott⁴

¹*University Medical Center Groningen; University of Groningen*, ²*División de Neurociencias, Instituto de Fisiología Celular, Universidad Nacional Autónoma de México*, ³*Molecular Physiology of Somatic Sensation Laboratory, Max Delbrück Center for Molecular Medicine in the Helmholtz Association (MDC)*, ⁴*School of Medicine and Health Science, Carl von Ossietzky Universität Oldenburg*

Background: Age-related hearing loss (ARHL) is one of the most common sensory impairments in humans, often associated with progressive loss of cochlear ribbon synapses. These synaptic changes can precede hair cell and neuronal loss and have been described in several mammalian models, including rodents and humans. The naked mole rat (*Heterocephalus glaber*) is a unique model for studying cochlear aging. Despite its elevated auditory thresholds at young ages—likely reflecting their subterranean lifestyle—naked mole rats (NMR) rely heavily on vocal communication within their social groups. Given their lifespan (up to 31 years) and resistance to cancer and age-associated diseases, NMR provide an opportunity to explore how cochlear synaptic integrity is preserved across aging.

Methods: Cochleae were obtained from naked mole rats aged 4–15 years. Temporal bones were isolated and fixed in 4% paraformaldehyde, decalcified, and immunostained for Prestin (hair cell marker) and CtBP2 (presynaptic ribbons). Confocal microscopy was used to image the cochlea, and IMARIS software was used for quantification of inner and outer hair cells as well as ribbon synapses along the cochlear length. Counts were normalized to cochlear region and age group for comparison.

Results: Hair cell integrity remained stable across the lifespan examined. Confocal imaging revealed no major structural changes from 4 to 12 years of age, and both inner and outer hair cell counts were preserved even in 15-year-old animals. Ribbon synapse counts showed a gradual decline with age, but the reduction did not reach statistical significance. Compared to other rodent models, where substantial synapse loss occurs early in life, naked mole rats displayed a markedly delayed onset of synaptic decline.

Conclusions: Our results show that inner and outer hair cell and ribbon density are remarkably stable with age in naked mole rats. These results indicate that cochlear aging is markedly delayed in naked mole rats, providing new avenues to uncover protective mechanisms that may inform strategies to prevent or slow age-related hearing loss in humans.

M11. Frequency-Specific Mapping of Auditory Nerve Fibers: Investigating G-Ratio in Serial Sections

Sree Jeevitha Parameswaran*¹, Rudolf Glueckert¹

¹*Medical University of Innsbruck*

Background: The cochlea encodes sound via a precise tonotopic organization, where specific frequencies map to distinct locations along its length, ranging from 1kHz to 100kHz in mice. To achieve frequency-specific analysis on thin plastic sections, we generated a three-dimensional frequency map using high resolution microCT datasets and Greenwood function. Given the minimal anatomical variation in inbred mouse strains, this serves as a universal reference for a precise frequency localization. Age-related auditory nerve degeneration impacts cochlear implant outcomes, with frequency-specific patterns varying across strains, leading to selective loss and preservation of nerve fiber populations that influence hearing function.

Methods: By integrating frequency-specific auditory brainstem response (ABR) audiometry with precise frequency mapping, we correlate physiological data with nerve fiber morphometry. Manual segmentation of the basilar membrane at the inner hair cells (IHCs) level enabled spatial mapping of nerve fibers into an “atlas” dataset, allowing the registration of the thin sections within the microCT dataset for an exact frequency correlated morphological analysis. The software-based segmentation and automated evaluation of the g-ratio using deep learning algorithms will provide an objective assessment of nerve fiber integrity across different frequency regions.

Results: By correlating ABR parameters, including hearing thresholds and latencies between young vs aged mice, we aim to refine our understanding of frequency-specific neural degeneration.

Conclusions: This insights into cochlear pathology will inform strategies for optimizing cochlear implant electrode placement and stimulation paradigms, ultimately improving clinical outcomes by tailoring interventions to preserve and enhance neural function at critical frequency regions, ensuring better auditory performance for cochlear implant users.

M12. Effects of Aging and Hearing Loss on Neural Tracking of Linguistic Features in Rapid Speech

Lucia Z-Rivera^{*1}, Ciaran Stone¹, Ebtesam Sajjadi¹, Samira Anderson¹

¹*University of Maryland - College Park*

Background: Aging and hearing loss can greatly impact the ability to understand speech, especially in difficult listening conditions. While age-related changes in the brain's temporal dynamics are known to affect speech processing, the specific impact on linguistic representations, beyond acoustic sensory processing, is not fully understood. This study investigates how aging and hearing loss influence the neural encoding of both sensory and linguistic information in time-compressed speech, an ecologically valid signal that mimics challenging listening environments.

Methods: A total of 94 participants from three distinct groups were recruited: young adults with normal hearing (YNH), older adults with normal hearing (ONH), and older adults with hearing impairment (OHI). All participants completed behavioral testing to determine time-compression thresholds for 50% keyword recognition of rapid speech. Also collected were electroencephalography (EEG) recordings to measure cortical envelope tracking of continuous speech in both time-compressed and unprocessed conditions. The data will be analyzed using a Temporal Response Function (TRF) framework, which will allow us to model hierarchical neural responses from early acoustic features up to higher-order linguistic units like phonemes, words, and phrases.

Results: Behavioral results showed a significant difference in performance between age groups, with YNH participants demonstrating higher overall keyword recognition compared to both ONH and OHI groups. This finding suggests a decline in rapid speech processing with age and hearing loss. We hypothesize that this behavioral deficit will be reflected in altered neural encoding patterns. The EEG analysis will reveal if the previously reported exaggerated cortical tracking responses in older adults are present across all representational levels, from acoustic to linguistic, and how time-compressed speech specifically affects this phenomenon. An acoustic signal that is uninformative due to its presentation rate should disrupt cortical tracking to the greatest extent at the highest levels in linguistic representation: linguistic TRFs for the ONH group will begin to resemble the OHI group in the time-compressed condition.

Conclusions: Our findings will provide new insights into how aging affects the neural encoding of speech at various hierarchical levels, from early sensory processing to complex linguistic representations. The results will highlight the specific challenges older adults face in processing rapid speech and may reveal compensatory neural mechanisms that do not fully restore speech perception. These findings may inform rehabilitative strategies for age-related hearing loss. Key takeaways will include evidence for a cascade of processing deficits in older adults, emphasizing that a listener's ability to understand speech goes beyond simply processing the auditory signal.

M13. SPI-1005 Improves High Frequency Hearing in Meniere's Disease Patients in a Multi-Center, Phase 3, Randomized, Placebo-Controlled Trial

Emily Harruff¹, Jonathan Kil^{*1}

¹*Sound Pharmaceuticals, Inc.*

Background: Meniere's disease (MD) is characterized by episodic vertigo or dizziness, fluctuating low-frequency hearing loss, and intermittent or constant tinnitus. Adults are typically

40-65 years of age at diagnosis and can progress to severe-to-profound hearing loss and intractable tinnitus in the affected ear. MD is typically unilateral but can become bilateral in 25-33% of patients as they age. Age-related hearing loss (ARHL) is characterized by progressive bilateral loss of high-frequency hearing and speech discrimination in older adults (> 50 yo) and may be accelerated by prior noise and ototoxin exposure. SPI-1005, an oral capsule containing ebselen, an investigational new drug with unique anti-inflammatory properties (GPx1 mimic and inducer), was tested in a Phase 3 Randomized Controlled Trial (RCT) with Open-Label Extension (OLE) in MD patients with active symptoms (NCT04677972). SPI-1005 treatment showed clinically relevant improvements in two pre-specified efficacy endpoints involving low-frequency hearing and speech discrimination over placebo. Here, we present post-hoc analyses involving high-frequency hearing and speech discrimination characteristic of ARHL.

Methods: Adults (18-75 yo) with definite MD were enrolled at 11 US sites and were randomized to 28-days of SPI-1005 400 mg or placebo BID. Pure-tone audiometry (PTA) and Words-in-Noise (WIN) were assessed at baseline, 28, 56, and 84-days. Compliant participants entered OLE and received up to 12-months SPI-1005 400 mg BID and were reassessed every 3-months. Improvements in high-frequency PTA (HFPTA) and WIN scores in either ear from baseline were: ≥ 10 dB at two adjacent high-frequencies (4-kHz and 6-kHz, or 6-kHz and 8-kHz) and ≥ 4 -words in WIN score. Subjects were also stratified by age (≥ 50 yo) and sex.

Results: 191 Per-Protocol subjects (mean age 55.5; 103 males/88 females) were analyzed; 141 were ≥ 50 yo (mean age 60.8; 71 males/70 females). During RCT, HFPTA improvements were 18/95 SPI-1005-treated (18.9%) vs 7/96 placebo-treated (7.3%), $p=0.0190$. WIN improvements were 40/95 SPI-1005-treated (42.1%) vs 26/96 placebo-treated (27.1%), $p=0.0336$. In ≥ 50 yo, HFPTA improvements were 14/65 SPI-1005-treated (21.5%) vs 4/76 placebo-treated (5.3%), $p=0.0049$. WIN improvements were 27/65 SPI-1005-treated (41.5%) vs 19/76 placebo-treated (25.0%), $p=0.0475$. In males ≥ 50 yo, HFPTA improvements were 7/31 SPI-1005-treated (22.6%) vs 2/40 placebo-treated (5.0%), $p=0.0357$. WIN improvements were 16/31 SPI-1005-treated (51.6%) vs 9/40 placebo-treated (22.5%), $p=0.0136$. In females ≥ 50 yo, PTA improvements were 7/34 SPI-1005-treated (20.6%) vs 2/36 placebo-treated (5.6%), $p=0.0802$. WIN improvements were 11/34 SPI-1005-treated (32.4%) vs 10/36 placebo-treated (27.8%), $p=0.7956$. During OLE, SPI-1005-treated subjects continued to show HFPTA (11-13%) and WIN (33-38%) improvements at 3- to 12-months.

Conclusions: MD patients treated with SPI-1005 demonstrated significant improvements in bilateral high-frequency hearing and speech discrimination characteristic of ARHL during RCT and OLE. These disease-modifying observations in an aged population > 50 yo support the future testing of SPI-1005 for the treatment of ARHL.

M14. Trajectory of Metabolic and Sensory Components of Age-Related Hearing Loss in 1.7 Million US Workers From the NIOSH Occupational Hearing Loss Surveillance Project

Kenneth Vaden^{*1}, Lauren Dillard¹, Judy Dubno¹

¹*Medical University of South Carolina*

Background: The current study investigated the longitudinal trajectory of age-related hearing loss (ARHL) across the adult lifespan and occupational noise effects. ARHL is theorized to

involve distinct cochlear pathologies that result from combined genetic and environmental risk factors with effects accumulated over the lifespan. Our theoretical framework is based on evidence that healthy outer hair cell function is critical for hearing sensitivity to low level sounds. Cochlear amplification can be reduced by a combination of outer hair cell losses (sensory) and declines in stria function that weaken outer hair cell motility (stria/metabolic). Sensory losses are associated with steep reductions in sensitivity to high-frequency sounds, while stria/metabolic declines affect sensitivity across lower- and higher-frequencies. Previously, self-reported noise exposure histories have provided support for noise-related sensory hearing losses. Our current goal was to further examine the role of occupational noise in ARHL with a population-scale, longitudinal audiogram collection that could be linked to noise exposure information.

Methods: Retrospective analyses were performed with a large audiogram dataset from US workers in 302 industry groups and 6 geographical regions (1.73 million participants, 77% men, 23% women; 18-75 years of age, average ~35 years; 1-6 audiograms collected at five-year intervals), originally collected as part of the NIOSH Occupational Hearing Loss Surveillance Project (1981-2010). Our previously developed model-fitting approach was used to estimate metabolic and sensory components of ARHL (in dB) per ear and audiogram, in addition to 4-frequency pure tone averages (0.5-4 kHz). Occupational noise measurements from the Job Exposure Matrix 2 were used to estimate noise levels for each worker's industry group. Regression-based analyses were then used to evaluate associations between metabolic or sensory estimates and each worker's baseline age, time across consecutive visits, sex, and noise exposure, while adjusting for US regions.

Results: Metabolic and sensory estimates both significantly increased with older age and across serial visits, with metabolic losses accelerating for older workers while sensory losses slowed. Men showed significantly higher sensory and metabolic estimates than women, and the sex differences significantly widened over time. Increasing occupational noise levels were significantly associated with higher sensory and metabolic estimates, and those noise exposure effects were significantly smaller for older than younger workers.

Conclusions: Our findings, based on up to 30 years of serial audiograms from nearly two million participants in the NIOSH dataset, expanded on earlier observations in the MUSC Longitudinal Cohort Study of ARHL and other cohorts. Consistent with previous observations, both components of ARHL increased with age, and men showed much higher sensory estimates than women. Interestingly, our results also suggest that noise exposure may worsen both components of ARHL, which reinforces the importance of hearing protection procedures and compliance with policies.

M15. Spectral Influences on Silent Gap Perception in the Aging Auditory Cortex

Victoria Duda*¹, Sayeed Devraj-Kizuk¹, Erica Ogier¹

¹*Université de Montréal*

Background: This study examined how older adults process silent gaps in auditory stimuli by recording cortical evoked potentials using a multi-deviant paradigm that is compared to a psychophysical gap-detection task.

Methods: Seventeen older adults (mean age = 63 years) with normal hearing or minimal hearing loss participated. Participants passively listened to pairs of noise markers separated by silent intervals. Markers were either spectrally identical (within-channel) or spectrally distinct (between-channel) and comprised both broadband and narrowband noise. Seven gap durations served as deviants in a multi-deviant sequence. The deviance-related negativity (DRN) and the P2/P3a complex were recorded from fronto-central electrodes.

Results: Broadband within-channel gaps significantly enhanced DRN amplitude. In narrowband conditions (within- and between-channel), only DRN was modulated; P2/P3a responses remained absent. Behavioral gap-detection thresholds did not differ across narrowband configurations, mirroring the ERP findings. For supra-threshold gaps, between-channel presentations produced reduced peak-to-peak amplitudes compared to broadband within-channel.

Conclusions: Older adults maintain robust neural sensitivity to silent gaps, reflected in DRN modulations that depend on the markers' spectral relationship. The absence of P2/P3a for spectrally narrow and distinct stimuli suggests limited pre-attentive engagement and may indicate age-related declines in temporal resolution or neural synchrony.

M16. Factors Influencing the Discontinuation of Cochlear Implants in Children With Autism Spectrum Disorder

Anna-Gabriela Ramirez¹, Lucie Morin², Marie-Ève Carrier³, Jenny Laperriere², Boutheina Jemel¹, Victoria Duda*¹, Stefano Rezzonico¹

¹*Université de Montréal*, ²*CISSS de la Montérégie-Ouest*, ³*CIUSSS du Centre-Sud-de-l'Île-de-Montréal*

Background: To address significant hearing impairment, cochlear implants (CI) are often recommended as early as possible (Sharma et al., 2020), at an age when it is not always possible to identify other disorders (Cruz et al., 2012; Young et al., 2016). In recent years, the number of children with a CI who are later diagnosed with a co-occurring condition has increased (Edwards, 2007; Young et al., 2016); this includes children with autism spectrum disorder (ASD) (Edwards, 2007). There is considerable variability in CI outcomes among children with ASD (Robertson, 2013; Tavares et al., 2021), and 31% of children in this population use their CI only intermittently or not at all (Mathew et al., 2022). This study aims to identify factors that may explain the discontinuation or continued use of CIs among children with ASD. A better understanding of these factors could help clinicians optimize follow-up care for this population, especially given the current lack of research-based resources.

Methods: This retrospective and exploratory study includes children with or suspected of ASD (n = 11), aged 5 to 14 years, who received a CI as early as 2012. Participants' rehabilitation records were reviewed, and a telephone interview with a parent was conducted.

Results: Children were divided into two groups: the intermittent-use group (n = 6) and the consistent-use group (n = 5). The intermittent group included children who wore their CI for < 8 hours per day. On average, participants in this group wore their CI for 3.33 hours per day (SD = 2.94 h). Most had not acquired spoken language, had below-average cognition or suspected cognitive delays, and half exhibited behavioral issues. All had previously shown negative reactions to the CI, such as crying, refusal, or intentional damage. The consistent group included

children who wore their CI for at least 8 hours per day. On average, participants in this group wore their CI for 11.84 hours per day (SD = 2.06 h). Most had acquired spoken language, had average cognition, and no behavioral issues were noted.

Conclusions: This study provides a better understanding of CI use among autistic children and offers intervention strategies for clinicians, while also encouraging reflection on new clinical assessment techniques for children with neurodevelopmental disorders in future research.

M17. Delta-Band Cortical Speech Tracking Predicts Audiovisual Speech-In-Noise Benefit From Natural and Simplified Visual Cues

Michael Thornton^{*1}, Enrico Varano², Dorothea Kolossa³, Steffen Zeiler³, Tobias Reichenbach¹
¹*Friedrich-Alexander Universität Erlangen-Nürnberg*, ²*Imperial College London*, ³*Technische Universität Berlin*

Background: Visual speech cues improve speech-in-noise comprehension but it remains unclear which visual features are necessary and how they shape neural audiovisual (AV) integration. Prior work has tested both naturalistic faces and highly abstract envelope-driven visualisations, with the latter yielding mixed results. We aimed to determine how structural detail in visual signals modulates behavioural AV benefit and its neural correlates.

Methods: Two experiments were conducted. In a behavioural study (N = 19), participants performed a speech-in-noise comprehension task across conditions varying in visual detail: fully natural videos, edge-only faces, landmark-based cartoons, and abstract envelope-driven disks. In an EEG experiment, the same participants viewed longer audiovisual narratives from a single speaker, and neural tracking of the speech envelope was quantified using temporal response functions (TRFs) in the delta (1–4 Hz) and theta (4–8 Hz) bands.

Results: Behaviourally, AV benefit scaled with visual fidelity: natural faces produced the strongest improvements, edge and cartoon faces yielded weaker but reliable benefits, while disk stimuli produced none. Neurally, natural AV speech elicited a delta-band enhancement of auditory envelope tracking at ~180 ms, with similar trends for degraded faces. This delta-band AV–A difference correlated strongly with individual behavioural AV gains ($r = 0.52$, $p < 0.001$). By contrast, disk stimuli elicited no neural integration effects, instead producing SSVEP-like visual responses.

Conclusions: Facial structural detail is critical for AV speech benefit: even simplified faces provide measurable gains, whereas abstract envelope-driven signals do not. At the neural level, AV integration manifested not as a super-additive enhancement over summed uni-sensory responses, but as an increase in auditory envelope tracking and a reduction in visual envelope tracking. Overall, the results suggest a role of AV speech integration in enhancing auditory cortical encoding of word-rate dynamics. The findings could provide direction for the design of visual hearing aids or expressive virtual avatars.

M18. Hearing Aid Effectiveness and Probable Dementia Risk Across 33 Countries: A Pooled Analysis of Seven Cohorts

Fan Jiang¹, Qiuyue Dong², Dona Jayakody³, Xi Chen⁴, Christoph Mueller⁵, Bei Wu⁶, Benjamin Underwood⁷, Lijing Yan⁸, Xinyu Li², Chiara Bruck⁹, Gordon G Liu¹⁰, Wai-Kit Ming¹¹, Sha Feng¹², Chenkai Wu⁸, Lianping Yang¹³, Alimu Dayimu¹⁴, Haibo Wang², Shanquan Chen¹⁵, Lei Xu^{*16}

¹Shandong Provincial ENT Hospital, ²Shandong Provincial ENT Hospital, Shandong University, ³Ear Science Institute Australia, Ear Sciences Centre, Medical School, University of Western Australia, ⁴Yale School of Public Health, ⁵Psychological Medicine, Institute of Psychiatry, Psychology and Neuroscience, King's College London, ⁶NYU Aging Incubator and Hartford Institute for Geriatric Nursing, ⁷University of Cambridge, ⁸Global Heath Research Center, Duke Kunshan University, ⁹Erasmus MC University Medical Center, ¹⁰Institute for Global Health and Development, Peking University, ¹¹Jockey Club College of Veterinary Medicine and Life Sciences, City University of Hong Kong, ¹²Shenzhen Institute of Advanced Technology, Chinese Academy of Sciences, ¹³School of Public Health, Sun Yat-sen University, ¹⁴Cambridge Clinical Trials Unit Cancer Theme, University of Cambridge, ¹⁵School of Public Health, University of Hong Kong, ¹⁶Shandong Second Provincial General Hospital

Background: Hearing loss is recognized as a major modifiable risk factor for dementia, yet evidence linking hearing aid use to a lower risk of dementia is limited and inconsistent. This study aimed to evaluate whether the use of hearing aid—particularly effective use that improves hearing—is associated with a reduced risk of dementia in older adults with hearing loss and whether this association varies by level of economic development.

Methods: We used longitudinal data from seven international cohort studies (CHARLS, KLOSA, SHARE, ELSA, TILDA, HRS, MHAS). Hearing loss and hearing aid use were self-reported. Probable dementia was defined by cognitive impairment with functional decline or a physician diagnosis. We employed inverse probability of treatment weighting (IPTW)-corrected Cox proportional hazards models to address confounding. We estimated hazard ratios (HRs) for probable dementia by hearing aid use and hearing aid effectiveness in the harmonized cohort, and further conducted stratified analyses by country income level (High-income vs. Middle-income).

Results: The analysis included 61,089 hearing-impaired participants aged 55 and older from 33 countries. Over an average follow-up of 6.5 years, 8,911 participants (14.6%) developed probable dementia. In the IPTW-weighted analysis, hearing aid use was associated with a significantly lower risk of probable dementia risk (pooled HR 0.91, 95% CI 0.88-0.94). This association varied significantly, appearing stronger in settings with lower baseline hearing aid adoption, notably the middle-income countries (HR 0.76). Crucially, only participants who reported effective hearing improvement with their hearing aid showed a significant reduction in probable dementia risk (HR 0.86, 95% CI 0.80-0.93); those with poor hearing improvement had no significant benefit (HR 0.98, 95% CI 0.90-1.07). Subgroup analyses indicated a stronger association with a lower risk of probable dementia among participants aged ≥ 70 , women, those with lower education, lower family income, and unmarried individuals. Sensitivity analyses confirmed the robustness of findings.

Conclusions: Effective use of hearing aids was associated with substantially reduced probable dementia incidence, particularly among vulnerable populations. These findings highlight that

improving global access to high-quality hearing rehabilitation warrants consideration as a public health priority in efforts to address the global burden of dementia.

M19. The Pulse Polarity and Inter-Phase Gap Offset Effect in Patients With Low Frequency Residual Hearing After Cochlear Implantation

Lei Xu^{*1}, Ruijie Wang¹, Jianfen Luo¹, Xiuhua Chao¹, Haibo Wang¹

¹*Shandong Second Provincial General Hospital*

Background: The auditory nerve (AN) status is important for the rehabilitation of patients with cochlear implant (CI), especially for patients with residual hearing (RH).

Methods: A total of 29 ears from patients with sensorineural hearing loss (SNHL) and LFPTA who underwent CI at our hospital were enrolled. All ears met the preoperative criteria, with hearing thresholds of ≤ 85 dB HL at 125–500 Hz, and > 85 dB HL at 1k–8 kHz. All ears were implanted with a CochlearTM Nucleus[®] device. The pulse polarity effect, including cathodic and anodic leading, as well as the inter-phase gap 35 (IPG35), were evaluated at electrodes 22, 12, and 3 after implantation. Parameters including slope of the input/output (I/O) function, maximum eCAP amplitude, eCAP threshold, and N1 latency were simultaneously analyzed.

Results: The mean acoustic hearings of all 29 ears were 55.0 dB, 65.7 dB, 91.1 dB, 102.3 dB, 105.7 dB, and 89.8 dB HL at 250, 500, 1K, 2K, 4K, and 8K Hz pre-CI. For cathodic results, the amplitude at C level of e22 was higher than e12, and e3 was higher than e12 ($p=0.0076$, $p=0.0378$); the threshold of e22 was lower than e12 and e3 was lower than e12 ($p < 0.0001$, $p=0.0005$); and the N1 latency at C level of e22 was shorter than e3 ($p=0.0454$). For e22, both the threshold and the N1 latency of cathodic were the same to anodic ($p < 0.05$). For e3, the threshold of cathodic was higher than anodic ($p=0.0039$), and the N1 latency for cathodic was longer than anodic ($p=0.0116$). The IPG35 offset compared to cathodic was the same for e22 and e3. For straight and pre-modiolar electrodes, the results differed in some parameters.

Conclusions: The apical electrode, which retains more residual hearing, exhibited a smaller pulse polarity effect compared to the basal electrode. This difference was particularly evident in the threshold and N1 latency parameters. Compared to IPG35, the pulse polarity proved to be more sensitive in distinguishing auditory neural function alongside different hearings.

M20. Extreme Neural Phase-Locking Across the Barn Owl's Lifespan

Christine Koeppl^{*1}

¹*Carl Von Ossietzky University*

Background: Barn owls are famous for the unique ability of their auditory-nerve fibres to represent temporal fine structure into the 10 kHz-range, which requires extremely low jitter in spike timing, of the order of 20 μ s. The mechanisms that enable this remain unknown, but likely involve specializations of the hair cells, their ribbon synapses with afferent neurones, and afferent axons. Here we report two series of experiments: first at various posthatching ages, documenting the emergence and maturation of auditory-nerve responses, and phase-locking in particular, and second, in aged barn owls, probing for age-related changes in temporal fine-structure representation.

Methods: Single-unit recordings were carried out with glass microelectrodes, under general anesthesia, either 1-1.5% isoflurane or ketamine/xylazine. Sound stimulation was through closed, individually calibrated earphones, situated at the entrance of the ipsilateral ear canal. Young barn owls were aged post-hatching day 11 to 130. Older individuals were classified either as adult (up to 4.5 years) or aged (8.8 – 11.8 years). Our definition of “aged” corresponds to about 50% of the species’ maximum lifespan potential and is approximately comparable to a 3-year-old gerbil, a 1.5-2-year-old mouse, or a 60-year-old human.

Results: Phase-locked responses were observed in all auditory-nerve fibres that were acoustically responsive, and from the earliest age tested. Following the typical avian developmental progression, only lower-frequency responses were found at the earliest ages, and progressively higher-frequency responses with advancing age. As in adult owls, phase-locking was typically observed from sound levels below rate threshold and vector strengths saturated at levels around 10dB above rate threshold. Maximal vector strengths were close to adult values from the earliest ages, but at high frequencies, > 5 -6 kHz, did not reach adult values until > 3 months of age. Phase-locking in aged barn owls was unchanged, i.e. no age-related decline was apparent. This was also true for additional metrics of fine-structure representation tested with broadband stimuli, derived from Wiener kernel and autocorrelogram analyses.

Conclusions: Compared to cat (Kettner et al., 1985, J Neurosci 5:275-283), maturation of neural phase locking in the barn owl is disproportionally prolonged in the specialized, highest-frequency regions of its hearing range. This is consistent with prolonged maturation also of CAP threshold sensitivity and amplitudes (Köppl and Nickel, 2007, J Comp Physiol A193:613-624), suggesting a generally delayed maturation of the very specialized, foveal regions of the barn owl cochlea. At the other end of the lifespan, our findings support the notion that birds have truly ageless ears; that is, they are able to preserve cochlear function to an advanced age – even in the barn owl, a species with extremely sensitive hearing and a specialized cochlea. It should be informative to probe the morphology of hair cells, ribbon synapses, and myelination across the lifespan for correlates.

M21. A Novel Mouse Model of Auditory Neurodegeneration via Ouabain Delivery Into the Posterior Semicircular Canal

Yoshihiro Nitta^{*1}, Takaomi Kurioka¹, Sachiyo Mogi¹, Hajime Sano², Taku Yamashita¹

¹*Kitasato University School of Medicine*, ²*School of Allied Health Sciences, Kitasato University*

Background: Cochlear nerve damage has been reported to involve reactive oxygen species and glutamate; however, the detailed mechanisms remain unclear. In addition, because hair cell (HC) death can secondarily cause cochlear nerve damage, it is necessary to develop a selective model of cochlear nerve damage to elucidate the underlying mechanisms. Ouabain, a Na,K-ATPase inhibitor, has been reported to selectively eliminate spiral ganglion neurons (SGNs) when administered to the round window membrane (RWM) in mice (Yuan et al., J Assoc Res Otolaryngol. 2014). However, in practice, the strong pharmacological action of ouabain, the complexity of RWM administration, and individual variability among mice make it difficult to reliably establish a cochlear pathology model. Therefore, to enable more stable and selective inner ear delivery of ouabain, we investigated whether local ouabain administration to the posterior semicircular canal could generate a model of selective cochlear nerve injury.

Methods: The left retroauricular area of 8-week-old male CBA/J mice was incised. Under microscopic guidance, a small hole was created in the left posterior semicircular canal using a 32G needle. A micro-glass capillary was inserted into the opening, and either 1 mM or 5 mM ouabain or saline (control) was infused at 1 μ L/min using a microsyringe. Auditory brainstem response (ABR) was measured before and one week after administration, and threshold shifts and wave I amplitudes were compared between the groups. The inner ear was harvested one week after drug administration for histological evaluation.

Results: One week after 5 mM ouabain administration, a significant ABR threshold shift was observed compared to that in the controls ($p < 0.05$). Wave I amplitudes were reduced in the 1 mM and 5 mM ouabain-treated groups compared to those in the control group. A significant loss of SGNs was observed in both the apical and basal turns of the cochlea in the 5 mM ouabain group. In addition, 1 mM ouabain-treated groups showed a significant reduction in the number of cochlear synapses compared to the control group ($p < 0.05$). No loss of HCs was observed in any of the groups.

Conclusions: The results demonstrate that 5 mM ouabain administration induces significant threshold elevation and SGNs loss, successfully reproducing severe cochlear nerve damage. In contrast, although 1 mM ouabain did not cause marked SGN loss, it resulted in synaptic loss and a reduction in wave I amplitude, suggesting that it reproduces the pathophysiology of cochlear synaptopathy. This presentation also includes a literature-based discussion on the pathophysiological mechanisms of ouabain-induced auditory neurodegeneration via posterior semicircular canal administration.

M22. Intra-Operative Neural Health Measures: Relation to Etiology and Cochlear Implant Outcome

Dyan Ramekers^{*1}, Tinne Vandenbroeke¹, Vincent Van Rompaey¹, Marc J.W. Lammers¹

¹*Antwerp University Hospital*

Background: The electrically evoked compound action potential (eCAP) reflects the combined responsiveness to electrical stimulation of the spiral ganglion neurons (SGNs) that form the auditory nerve. In animal studies eCAP measures correlate strongly with numerical survival of SGNs, and with the health of the remaining SGNs. These correlations suggest that the eCAP is a potent predictor of hearing performance in human cochlear implant (CI) users, since it reflects the condition of the electrode-neural interface. However, correlations between eCAP measures and measures of hearing outcome are typically weak. Complicating factors in studies with human CI users include heterogeneity of the population (etiology, age, cognitive ability, duration of implantation), low patient numbers, and processing of clinically obtained data.

Methods: In the present study we examine the potential of the eCAP as a neural health measure in a population of > 150 MED-EL CI users. In this relatively large population the influence of etiology on eCAP measures can be studied. eCAPs were recorded with a short (2.1 μ s) and a long (30 μ s) inter-phase gap (IPG) using autoART in MED-EL's MAESTRO software. Both the absolute eCAP measures (e.g., amplitude, slope, dynamic range, latency) as well as their IPG effects were evaluated. Electrocochleography (ECoChG) was recorded in a subset (~40%) of patients.

Results: Preliminary results show moderate correlations between several eCAP measures and patient characteristics, such as age or duration of hearing loss. Etiology seemed to influence overall appearance of eCAP recordings.

Conclusions: Further analysis will reveal whether patient characteristics such as the extent of residual hearing, or etiology and duration of hearing loss play a significant role in the predictive value of the eCAP for CI performance.

M23. Potential Causes and Implications of Multi-Response Electrocochleography Electrode Sweep

Sidharta Gupta¹, Dyan Ramekers^{*2}, Tinne Vandenbroeke¹, Griet Mertens², Vincent Van Rompaey², Marc J.W. Lammers²

¹*University of Antwerp*, ²*Antwerp University Hospital*

Background: During cochlear implant (CI) surgery, it is desirable to perform intraoperative, intracochlear recordings during electrode insertion to monitor the inner ear function to support the preservation of any residual hearing and to investigate cases of implantation-related residual hearing loss. One such method is intracochlear electrocochleography (ECoChG) which is the response of the inner and outer hair cells and the auditory nerve to acoustic stimuli. Although intracochlear ECoChG responses provide higher amplitudes as compared to round window recordings, significant challenges arise as the recording location of intracochlear ECoChG via the CI electrode changes during electrode insertion. Additionally, the acoustic stimulus is usually of a single frequency and not a compound of multiple frequencies where the subject might have residual hearing. This work aims to investigate the relationship between intracochlear ECoChG recordings during insertion and immediately after insertion, to understand the implications from patient audiogram and electrode location.

Methods: ECoChG responses were recorded in more than 35 CI subjects undergoing manual and robot-assisted CI surgery by two experienced surgeons in the same center. The acoustic stimulation to elicit this response was presented via Etymotic ER-3C insert earphones which were calibrated for Hearing Level (dB HL). The earphones were connected to an external acoustic stimulator which was programmed and triggered by the Maestro 9.0.4 based Research software (MED-EL GmbH, Innsbruck, Austria). The recordings were performed during and immediately after electrode insertion. During electrode insertion, alternating ECoChG measurements were made continuously as a response to a 12 ms long Chirp at 40 dB HL above the subject's pre-operative hearing threshold at 500 Hz. Immediately after the insertion, an electrode sweep was performed. Electrode sweep is a set of alternating ECoChG measurements from all 12 channels of the CI in response to the same acoustic stimuli. An 8 ms long burst at 500 Hz and at 40 dBHL above the subject's hearing threshold was used to perform the electrode sweep.

Results: We will present two categories of responses during insertion – first with multiple similar and large amplitude responses during insertion at different time points and second with only a single large amplitude response. Then the 500 Hz electrode sweep of these two categories will be compared. Finally, an estimate of the “final” tonotopic location of the channels along the electrode after full insertion will be made from CT images to investigate origins of responses in both categories.

Conclusions: This study hypothesizes that both thresholds and morphology of the preoperative audiogram influence the intracochlear ECochG. It is hypothesized to correlate with measurements made immediately after insertion, reflecting the tonotopic location during the electrode insertion, at least in interventions with residual hearing preservation.

M24. Temporal Processing Deficits in Cochlear Implant Users Assessed via Forward Masking With Direct Stimulation of Multiple Electrodes

Chengjie Huang¹, Natalie A. Field¹, Gianna I. DeLucca¹, Rebecca Scheerer¹, Matthew J. Goupell¹, Samira Anderson¹, Samira Anderson*²

¹*University of Maryland College Park*, ²*University of Maryland*

Background: As people age, one of the main contributors to poor speech perception is auditory temporal processing deficits. Although this has been extensively studied in acoustic listeners, the mechanisms underlying these deficits and how they occur in cochlear-implant (CI) users are not well understood. Furthermore, it is unknown whether these temporal processing deficits arise at the level of the inner hair cells and the auditory nerve (peripheral) or further up in the brain (central). CI users offer the advantage of studying these questions as the device completely bypasses the peripheral auditory system, aiding to understand differences in speech perception performance in CI listeners, especially as they age.

Methods: We recruited 12 CI users across the adult lifespan with Cochlear Ltd. devices. We evaluated their electrode-to-neural interface (ENI) by measuring electrically-evoked compound action potential amplitude growth functions (ECAP AGFs) to determine their “best” (steepest slope) and “worst” (shallowest slope) electrodes. We used the NIC4 system to generate an electrical broadband masker followed by a target electrical “chirp” while varying the masker-to-target interval (MTI) between 5-200 ms. We then stimulated multiple electrodes across the electrode array centered around their “best” electrode. While presenting the stimulus, we measured electrically evoked auditory brainstem responses (eABRs) and evaluated averaged eABR Wave V amplitudes and latencies. Separately, we performed a behavioral three-interval two-alternative forced-choice task using the same stimuli to evaluate detection thresholds for release from masking at each MTI.

Results: We initially hypothesized that with increasing age, the overall amplitudes of wave eV would decrease while latencies would increase, and that release from forward masking would be at an earlier time for younger than older CI users. In contrast, we found that increased duration of severe-to-profound hearing loss (DoSPL), and not age contributed significantly to decreased eV amplitudes and increased latencies. Furthermore, we found that with increasing MTI, the eV amplitudes increased and latencies decreased only in those participants with long DoSPL and poor ENI and did not significantly change in participants with shorter DoSPL and good ENI. These results demonstrate that central measures are correlated with peripheral physiological measures of ENI. Finally, these neural measures are correlated with behavioral release from forward masking regardless of age.

Conclusions: These findings suggest that ENI (peripheral) due to DoSPL at the time of implantation is the most important factor in the temporal processing deficits CI users may experience and that these are reflected downstream in the brain (central). By understanding the deficits at each neural locus, we can aim to treat these issues more effectively at the stages before

CI implantation as well as post-implantation through improving CI processing. Thus, the findings here can potentially influence future design of CI devices to better individualize treatment for patients in the clinic.

M25. Short-Term Improvements of Speech Perception Testing With Experimental Processing Strategies in Cochlear Implant Users

Caylin McCallick*¹, Charles Hem², Julie G. Arenberg³

¹*Mass. Eye and Ear*, ²*Harvard University*, ³*Massachusetts Eye and Ear, Harvard Medical School*

Background: Capturing speech recognition abilities of cochlear implant users is difficult given the high variability of performance. A significant amount of this variability can be captured with peripheral estimates of the quality of the electrode-neuron interface. Estimates are based on detection thresholds obtained with focused electrical fields. To reduce negative effects of poor ENI quality, programming can be optimized for individuals using selective channel deactivation of high threshold channels and/or use of focused electrical fields. This study assessed three experimental maps that had high threshold channels deactivated and employed either monopolar, dynamic tripolar (DT) or a combination to remaining active channels, compared to subjects' clinical programs that served as a control. This study compared the difference in performance scores for IEEE sentences between the first (Run #1) and second (Run #2) sentence list in quiet and two conditions of background noise, an easy and hard condition. We hypothesized there would be a greater learning or improvements with experimental programs most different from the control, the conditions with focused electrical fields.

Methods: This study included 7 participants, aged 51-75 years (average age 64.7 years) with Advanced Bionics cochlear implants. One of the participants is bilaterally implanted and completed testing on both ears individually, for a total number of 8 ears tested. To identify high threshold channels for deactivation, participants first completed a fast sweep procedure to obtain thresholds across all channels using a highly focused electrical field (σ 0.9). Listener-tailored programs were then created using the Harmony research processor for each participant wherein high threshold channels were deactivated, and remaining channels were either MP, DT, or a combination of the two, mixed focused (MF). DT stimulation applies more focusing (σ 0.8) for low-intensity input sounds and less focusing (σ 0.5) for high-intensity sounds. A MF program uses DT on high threshold channels and MP for low threshold channels. For testing participants' clinical strategies, they were downloaded onto a Marvel and noise reduction was deactivated to best match processing in the Harmony. Speech perception testing was completed on a tablet in a sound booth across multiple sessions. Testing conditions were pseudo-randomized. Testing was completed in quiet and in noise with varying signal-to-noise ratios (SNRs) to assess a range of performance for easy and difficult conditions. For each SNR tested in each condition, two lists of 20 sentences each were administered. Audio responses were recorded on the tablet and scored later.

Results: Focused conditions—DT and MF—demonstrated the largest improvement in median percentages from Run 1 to Run 2, suggesting learning or acclimatization is occurring.

Conclusions: These preliminary findings suggest participants need more time with strategies involving focusing before they reach performance plateau and more than two runs may be necessary in future experiments.

M26. Auditory Spatiotemporal Interactions in Single-Sided Deaf Patients With Unilateral Cochlear Implants

Carolyn Kroger*¹, Deborah Fu¹, Renee Banakis Hartl¹, Ruth Litovsky², Anahita Mehta¹

¹University of Michigan, ²University of Wisconsin

Background: There is growing use of unilateral cochlear implants (CIs) as a promising intervention for patients with single-sided deafness (SSD), especially to improve speech perception in noisy environments and sound localization performance. However, the effectiveness of CIs in improving spatial hearing for this population remains uncertain. Traditional sound localization tasks are often lengthy and cognitively taxing for individuals who struggle to identify sound source locations. This study introduces a new task for evaluating the restoration of auditory spatial cues in SSD-CI users by examining the biasing effects of spatial location on timing judgments for sequential sounds. The auditory spatial kappa (ASK) effect manifests as a bias in perceived relative onset timing between subsequent sounds as a function of the spatial distance between them. Sounds that are farther in space are judged as farther apart in time compared to sounds presented closer in space. We tested the degree of spatial bias on temporal judgments in SSD individuals with and without their CI as well as normal hearing controls to evaluate the restoration of spatial cues with CI in different frequency ranges. Crucially, participants are instructed to ignore the location of sounds, making this task a label-free measure of spatial cue restoration.

Methods: Participants heard sequences of three sounds played from loudspeakers, where the spatial distance between the first and third sound was fixed at 90 degrees apart (azimuth). The second sound changed location from trial-to-trial to be closer to the first or third sound. Participants made timing judgments by responding “short-long” to indicate that the second sound was closer in time to the first or “long-short” to indicate that the second sound was closer to the third. Stimuli were 200 ms narrowband noise bursts with low (500 Hz) or high (4kHz) center frequency to compare effects of predominant interaural timing or level cues, respectively. Sound sequences were presented within three sound fields: in front, on the right, or left side. Psychometric curves were fit to participant data to assess timing perception and response bias for each experimental condition.

Results: We found robust auditory spatial kappa (ASK) effects across all frequency and sound field conditions in normal hearing controls. Participants reported that the two sounds closer in space were closer in time. Preliminary results with SSD-CI participants show ASK effects for high but not low-frequency sounds without CI, indicating that monaural level cues for spatial location are sufficient to induce a temporal biasing effect. ASK effects were larger with CI in both frequencies, with effects moderated by sound field condition.

Conclusions: This study provides evidence that the novel ASK task may be a useful tool for implicitly assessing spatial hearing in clinical populations who perform poorly on traditional sound localization tasks.

M27. Improved Neural Adaptation by Integrating Voltage-Gated Ion Channels Into a Hybrid Phenomenological-Biophysical Model of Electrical Stimulation of the Auditory Nerve

Anil Nagathil*¹, Ian Bruce²

¹*Ruhr-Universität Bochum*, ²*McMaster University*

Background: Computational models of electrical stimulation of auditory nerve fibers (ANFs) contribute to the understanding of physiological and perceptual phenomena of electric hearing, thereby helping to improve the development of novel cochlear implant coding strategies. The hybrid phenomenological-biophysical model of Joshi et al. (2017) aims to balance computational simplicity with sufficient physiological detail and achieves accurate predictions of a wide range of physiological phenomena. However, the model also demonstrates weaknesses in terms of limited neural adaptation for high-rate stimulation pulse trains and prediction of abnormally high spontaneous firing in ANFs. Additionally, its ability to explain the dependence of the dynamic range of firing efficiency (i.e., relative spread) on the pulse phase durations (PPDs) is an artifact of how the model code is initialized. An improved parameterization of the model (Bruce, ARO 2024) reduced the dependence on pulse onset timing and the spontaneous firing behavior, however leading to a loss of the monotonically growing relative spread (RS) vs. PPD relationship observed in physiological data. This is likely caused by a missing mechanism in the model accounting for the RS vs. PPD relationship and spike-rate adaptation.

Methods: In this study we replaced the phenomenological supra- and subthreshold adaptation mechanisms in the Joshi et al. model by voltage-gated KLT and HCN ion channels from a biophysical model (Negm and Bruce, 2014), which have shown to predict a strong adaptation behavior in ANFs for high-rate pulse trains and can explain the growing RS vs. PPD relationship (Negm and Bruce, 2008). After calibrating the adaptation currents of the voltage-gated ion channels with respect to the membrane noise sources and the exponential integrate-and-fire mechanism of the Joshi et al. model, the RS was measured as a function of the PPD for different pulse onset times. In addition, the adaptation behavior was quantified for low- and high-rate pulse trains via post-stimulus time histograms.

Results: The simulation results demonstrate a considerably reduced dependence of pulse onset times on the RS while predicting the monotonically growing RS vs. PPD relationship observed in physiological measurements. Moreover, after including the voltage-gated ion channels in the model a strong spike-rate adaptation behavior can be observed for high-rate stimulation pulse trains.

Conclusions: Replacing the phenomenological supra- and subthreshold mechanisms of the Joshi et al. model by biophysically inspired voltage-gated ion channels improves the spike-rate adaptation behavior of the model, reduces the dependence of the pulse onset time on the RS, and predicts the growing RS vs. PPD relationship observed in physiological data. Additional refinements such as modeling a more biophysically realistic spike waveform may yield further improvements in terms of the adaptation behavior.

M28. Cochlear Microphonic, Compound Action Potential and Pure Tone Audiometry in the First Year After Cochlear Implantation

Imogen van Beurden*¹, Ilse Haan¹, Dyan Ramekers², Robert J. Stokroos¹, Hans G.X.M. Thomeer¹, Huib Versnel¹

¹University Medical Center Utrecht, ²Antwerp University Hospital

Background: Electrocochleography (ECoChG) has become increasingly valuable in cochlear implant (CI) surgery as it allows intraoperative monitoring of effects of electrode array insertion on residual hair cell function. Additionally, ECoChG has the potential to portray postoperative cochlear function. Here we examine the postoperative time course of residual hair cell function by recording ECoChG in CI recipients intraoperatively and at several time points up to one year postoperatively.

Methods: Twenty-four patients with severe sensorineural hearing loss receiving a CI participated in a trial comparing electrode arrays (SlimJ and Mid-Scala of Advanced Bionics) and surgical approaches (Jwair et al., Trials, 2021). Here, the data was analyzed by investigators blinded to the randomization. ECoChG recordings were performed at 5 time points using the active insertion monitoring (AIM) system of Advanced Bionics: intraoperatively, at 6 weeks, 3 months, 6 months and 12 months postoperatively. Intraoperative recordings and recordings at 6 weeks and 3 months postoperative were obtained from 23/24 participants. Postoperative recordings at 6 months were obtained from all 24 participants. Postoperative recordings at 12 months were obtained from 22/24 participants. Responses to pure-tone stimuli with frequencies varying from 125 to 4000 Hz, at sound levels 100-115 dB HL, were recorded at each of the 16 available electrodes, in two opposite phases. The difference and sum of the recordings to the opposite phases were computed as estimates of cochlear microphonics (CM, reflecting hair cell potentials) and compound action potentials (CAP, reflecting auditory nerve responses), respectively. Mean CM and CAP amplitudes of responses will be compared to hearing thresholds from pure tone audiometry.

Results: Significant CM responses were found in 14 out of 23 participants intraoperatively, and postoperatively in 21/23 participants at 6 weeks, 22/23 at 3 months, 23/24 at 6 months, and 23/23 at 12 months. Substantial CM responses ($> 1.5 \mu\text{V}$) were found in 13 out of 23 participants intraoperatively, and postoperatively in 3/23 participants at 6 weeks, 3/23 at 3 months, 5/24 at 6 months, and 4/23 at 12 months. Notably, 3 intraoperative non-responders showed significant responses in the first postoperative session. Averaged across frequencies 125, 250 and 500 Hz, the largest responses were observed recorded at the apical electrodes 1 – 5 during the intraoperative session. The responses were smallest at 4-6 weeks postoperatively, then recovered after 3 to 7 months, and decreased again up to one year after implantation.

Conclusions: Residual hair cell function gradually declines over the course of one year. Three months after cochlear implantation a short period of recovery is seen, which may be attributed to natural reduction of the acute local inflammatory response to the electrode array.

M29. Co-Registered 3D X-Ray Microscopy and Cubic-Shield Cleared Whole-Cochlea Imaging Demonstrate Co-Localization of Post-Implantation Neo-Angiogenesis and Neo-Ossification Foci in Mice

Md Fahad Hossain*¹, Bryce Hunger¹, Brian Mostaert¹, Muhammad Rahman¹, Shakila Mahmuda Fatima¹, Ya Lang Enke², Robert D Gay², Marlan Hansen¹, Alexander Claussen¹

¹The University of Iowa, ²Cochlear Ltd, Sydney

Background: Cochlear implants (CIs) are a well-established neuroprosthetic intervention for hearing loss, yet outcomes remain variable, particularly in speech perception and hearing preservation. This variability is multifactorial, but cochlear neo-ossification, part of the foreign body response to implantation, has been linked to poorer neural health and speech understanding. The relatively hypoxic milieu of the scala tympani suggests a role for hypoxia-driven angiogenesis in post-CI neo-ossification. We employed complementary 3D X-ray Microscopy (3DXRM) and whole-cochlea CUBIC-SHIELD clearing to examine temporospatial relationships between post-CI angiogenesis and ossification.

Methods: Ten- to twelve-week-old PECAM+/GFP C57Bl6 mice with normal hearing underwent unilateral cochlear implantation. Cochleae were harvested at 10 (n=6) or 28 (n=6) days post-implantation and fixed. Mineralized bone was detected via 3DXRM, while PECAM+/GFP reporters labeled new vasculature. Whole cochleae underwent 3DXRM prior to CUBIC-SHIELD clearing, DAPI counterstaining, and immunolabeling with anti-GFP and anti- α -SMA. Cleared specimens were imaged by confocal microscopy, and reconstructed z-stacks were co-registered with 3DXRM datasets to assess ossification and angiogenesis adjacent to the implant tract.

Results: CUBIC-SHIELD clearing preserved PECAM-GFP reporter signals and revealed marked vascular proliferation and α -SMA-positive fibrosis in the basal scala tympani encircling the implant, with prominent vascular arcades near the round window. Anti-GFP staining corroborated reporter expression. At 10 days post-implantation, preliminary analyses demonstrated spatial co-localization of early ossification foci with areas of angiogenesis, particularly in the basal turn adjacent to the round window.

Conclusions: CUBIC-SHIELD clearing enables whole-cochlea imaging with preservation of reporter signals and compatibility with immunolabeling. Integration of 3DXRM and CUBIC-SHIELD yields complementary datasets that can be co-registered to characterize both mineralized (neo-ossification) and soft-tissue (fibrosis, angiogenesis) components of the post-CI foreign body response. These findings suggest that robust neo-angiogenesis may support inflammatory cell infiltration and foreign body reactions within the normally hypoxic, acellular scala tympani, however further studies are needed to investigate this hypothesis. Angiogenesis may represent a modifiable therapeutic target to mitigate deleterious post-CI tissue responses.

M30. Outcomes for Revision Cochlear Implant Surgery - Perimodiolar to Straight Electrodes

Sophie Jabban*¹, Emily Spitzer¹, Maya Hatley¹, Michael Bartellas¹, Mario A. Svirsky¹, J. Thomas Roland¹

¹New York University Grossman School of Medicine

Background: It is common practice to replace perimodiolar electrodes with straight electrodes during revision cochlear implant (CI) surgery. The electrode spacing and contact positions differ between these electrode types. In particular, the most basal contact of the Slim Straight electrode sits approximately 4 mm deeper than the Slim Perimodiolar or Contour Advance electrodes, which may alter pitch perception. This type of revision surgery may also result in different modiolar proximity due to electrode location and fibrous tissue growth around the

original electrode, potentially further altering pitch perception and hearing outcomes. This study aims to investigate how reimplantation with the Slim Straight electrode after original implantation with the Slim Perimodiolar or Contour Advance electrodes affects patient outcomes, basal contact modiolar proximity, and stimulation levels.

Methods: This was a single-institution retrospective cohort study of patients who received revision CI with a Slim Straight electrode following implantation with a Slim Perimodiolar or Contour Advance electrode from 2020-2025. Patients were included if they underwent revision surgery at our institution for any cause. Etiology of hearing loss, cochlear anatomy, surgery dates, reasons for revision, and documentation on sound quality were abstracted from patient records. Speech perception scores, X-rays, and mapping parameters, including frequency allocation tables (FATs) and lower and upper stimulation levels before and after revision, were analyzed.

Results: 17 implanted ears from 16 patients were included in this study. Ages at time of revision ranged from 1.3 to 86.4 years (mean 20.1, SD 30.7). All included patients had normal ear anatomy. Reasons for revision included device infection (76.5%), failure (17.6%), and migration (5.9%). The high frequency edge of the filter associated with the most basal electrode was 7938 Hz for all patients before and after revision. The low frequency edge of the filter was typically 6938 Hz, with two exceptions (Patient X, pre-revision, 7793 Hz; Patient Y, post-revision, 6563 Hz). Comparison of threshold levels demonstrated significantly higher thresholds in the most basal electrode before versus after revision (140.5 vs 121.3, $p < 0.05$). Speech perception was evaluated in 5 patients, with no difference in mean scores before versus after revision (CNC: pre-revision 47.8%; post-revision 43.4%, $p=0.79$. AZ-Bio: pre-revision 42%; post revision 59.4%, $p=0.39$). Review of qualitative data demonstrated lack of documentation on pitch perception. X-ray data will be further explored.

Conclusions: Speech perception data suggests reimplantation with an electrode of different design and spacing does not alter frequency allocation or overall speech perception. We anticipate analysis of X-rays to confirm deeper location of the Slim Straight electrode and explore whether straight electrodes adopt modiolar proximity due to fibrous tracts from prior implantation with perimodiolar electrodes. A prospective study evaluating pitch perception among this population is warranted to assess impacts of changing electrode contact location on overall hearing quality.

M31. DeepFS4: An End-To-End Deep Learning Based Cochlear Implant Sound Coding Strategy

Robert Hart*¹, Tom Gajecski¹, Waldo Nogueira¹

¹*Hannover Medical School*

Background: Cochlear implant (CI) users typically achieve good speech understanding in quiet environments. However, intelligibility declines significantly in the presence of background noise. Conventional front-end speech enhancement techniques can mitigate this effect, yet often introduce latency, work primarily with stationary noise, and do not fully exploit the CI sound coding chain. Recently, DeepACE, an end-to-end neural network fully replacing the Advanced Combination Encoder (ACE), demonstrated that tightly integrated, learnable CI strategies can improve intelligibility without added latency. However, no such approach has yet been

developed for sound coding strategies that encode temporal fine structure (FS), such as the FS4 strategy, which determines low-frequency channel pulse timings from zero-crossings in the audio signal to represent neural phase locking in the auditory nerve.

Methods: We developed DeepFS4, a temporal convolutional network designed to replicate FS4 outputs while simultaneously embedding speech enhancement. The architecture is compact, with fewer parameters than comparable models, making it feasible for real-time, low-power CI devices. To assess the impact of FS encoding on speech intelligibility, two variants were tested, one with ideal FS locations and the other with noisy ones. Objective evaluations included the signal-to-noise ratio improvement (SNRi), while the speech intelligibility was evaluated with ten CI recipients in stationary and non-stationary noise. These tests consisted of the German HSM sentence test (Word Recognition Score), a MUSHRA quality rating, and a 3-AFC test to examine FS location effects.

Results: DeepFS4 achieved a mean SNRi of 8 dB across input SNRs from −5 to 10 dB for stationary and 6 dB SNRi for non-stationary noise. In listening tests, it yielded significantly higher word recognition scores and higher subjective quality ratings than both the commercial FS4 strategy and state-of-the-art front-end enhancement algorithms. The comparison between the DeepFS4 variants of the FS encoding revealed negligible differences in speech intelligibility and user detectability.

Conclusions: DeepFS4 demonstrates that integrating speech enhancement directly into the sound coding strategy via a low-latency deep learning architecture can substantially improve CI speech perception in noise. The results demonstrate that robust performance improvements are possible even without FS location enhancements, encouraging simpler and more streamlined designs in future research. The approach introduces a pathway towards the first AI-powered, clinically viable sound coding strategy for CIs, with direct relevance for improving real-world listening outcomes.

M32. Contralateral Sound Attenuation Can Help Hearing-Aid Users Understand Speech in Realistic, Dynamic “Cocktail Party” Listening Situations

Paula García-Zaballos^{*1}, Almudena Eustaquio-Martín¹, Milagros J. Fumero¹, Enrique Lopez-Poveda¹

¹*University of Salamanca*

Background: Hearing aids (HAs) can restore audibility and loudness perception, but users often complain that they struggle to understand speech in noisy, “cocktail-party”-like listening situations. We have shown elsewhere that contralateral sound attenuation (CSA) (Lopez-Poveda et al., 2022, Hear Res 409:108469) can help HA users in these situations by improving the signal-to-noise ratio in the acoustically better ear (San-Victoriano et al., 2023, Hear Res 432:108743). The evidence, however, was restricted to free-field simulations where the better ear was known to the listener and fixed across trials, which is far from realistic. Here, the aim was to assess the potential benefits of CSA in more realistic conditions with reverberation and changing the masker location dynamically from trial to trial to make the better ear uncertain to the listener.

Methods: 15 users of bilateral HAs were asked to recognize the key words of sentences presented in competition with five simultaneous masking sounds. Stimuli were delivered via loudspeakers mounted on a ring located in a room with low reverberation ($t_{60}=20$ ms). The target (a female speaker, 65 dB SPL) was in front of the listener (0-degree azimuth). Four of the maskers (international female fluctuating maskers, 60 dB SPL) were symmetrically placed around the listener (at ± 45 -degree and ± 135 -degree azimuth). The fifth masker was speech-shaped noise (SSN) and its level was previously determined to avoid ceiling and floor effects on recognition. Importantly, the location of the SSN source varied randomly within the arc between ± 120 -degree for each sentence presentation. Participants performed the task while listening with the left ear alone, the right ear alone, or the two ears. To make this possible with life sounds, stimuli at either or both ears were picked up with an acoustic mannikin placed in the center of ring and sent to the listener, who was seated in a separate room. Sounds were either unprocessed or processed through the CSA algorithm before they were processed through a software HA that applied individualized nonlinear, frequency-specific amplification.

Results: CSA significantly improved speech recognition in bilateral listening [$F(1,14) = 19.0$, $p < 0.001$], and in unilateral listening with the left ear [$F(1,14) = 40.4$, $p < 0.001$] or the right ear [$F(1,14) = 67.5$, $p < 0.001$]. The benefit of CSA was significantly greater for SSN source locations further away from the target

Conclusions: Contralateral sound attenuation can improve speech intelligibility for HA users in realistic (reverberant and dynamic) multitalker listening situations. (Work supported by a predoctoral contract of Junta de Castilla y León to PGZ, and by MED-EL GmbH).

M33. Experimental Programming for Cochlear Implants: Dynamically Focused Stimulation Combined With Monopolar Edge Electrodes

Charles Hem^{*1}, Julie Arenberg²

¹Harvard University, ²Massachusetts Eye and Ear Infirmary, Eaton Peabody Laboratory

Background: Channel interaction, or activation of overlapping neural populations, is one likely contributing factor to cochlear implant (CI) users' difficulties in understanding speech in noise and music. Clinical strategies in CIs use monopolar (MP) stimulation, which results in broad current spread that contributes to channel interaction. Current focusing with adjacent electrodes is one potential solution to reduce spread. Experimental programs using current focusing to reduce channel interaction have shown potential benefit; however, these programs have only been tested using 14 of 16 electrodes, as the electrodes at the edge of the array have no flanking electrodes to use for focusing and are therefore deactivated. Using these edge electrodes with monopolar stimulation may provide better spectral resolution by reducing channel filter size and fuller sound quality by stimulating spiral ganglion neurons at the edges of the electrode array that were previously un-stimulated in focused programs. In this study, participants were tested on speech in noise and timbre instrument recognition using three programs: a 14-channel monopolar program (MP14), a 14-channel dynamic tripolar program (DT14), and a 16-channel dynamic tripolar program with electrodes 1 and 16 active as monopolar electrodes (DT16).

Methods: At this point, data have been collected from 11 ears in 9 adult participants (mean age = 50.9 years, SD = 19.4 years). All participants used Advanced Bionics devices and were tested across two sessions. In session one, three experimental programs were created: auditory

detection thresholds and max comfort levels were first measured across all electrodes to be used as the programming levels, which were further fine-tuned using live speech. Participants finished session one by completing the test battery using their clinical device as training. The test battery consisted of the instrument timbre recognition task from the UW CAMP test, closed-set /hVd/ vowel identification in noise, and the closed-set American English Matrix Test (AMT) in adaptive noise. In session two, participants completed the test battery for each program, with program order block-randomized across participants. Data was analyzed using linear-mixed effects models to determine the effect of program.

Results: Planned comparisons showed no significant mean difference between MP14 and DT14 (testing the effect of focusing) and DT14 and DT16 (testing the effect of MP edge electrodes), with high variability across subjects. Despite incorporating additional training during session one and increased practice trials for each program during session two, the timbre task shows significant learning with test order ($\beta = 5.81\%$ /test block, $p = .028$). AMT and vowels were stable across test order.

Conclusions: Reincorporating electrodes 1 and 16 as monopolar electrodes in a dynamically focusing program show no clear benefit in this interim analysis, but data collection is still underway. It is possible that the added interaction from these electrodes contributed to this lack of benefit.

M34. Musical Context Influences the Impact of Vocal Boost Manipulations for Cochlear Implant Users

Stephanie Younan¹, Arjun Kurup¹, Patpong Jiradejvong¹, Jonathan Mo², Charles J. Limb¹, Nicole Jiam¹, Stephanie Younan*³

¹UCSF, ²University of California, Davis School of Medicine, ³University of California - San Francisco

Background: Music perception and enjoyment remain a persistent challenge for post-lingually deafened adults with cochlear implants (CIs), largely due to the degraded spectral cues essential for melodic processing. Vocal boosting - enhancing the levels of vocals relative to background - has been proposed as a means of improving sound quality and enjoyment in this population. Yet, whether the benefit of vocal boosting derives from greater access to lyrical content within a coherent musical scene, as opposed to increased audibility over a non-musical masker, remains unclear. This study investigates how the perceptual gains from vocal boosting depend on the acoustic nature of the background.

Methods: Fourteen CI users rated the sound quality of stimuli on a 100-point scale. Vocals from ten popular songs were extracted and paired with three types of backgrounds: original instrumentals, off-key instrumentals (+4 semitones), and multi-talker babble. Each vocal-background pair was normalized to have an equal signal-to-noise ratio (SNR), forming the +0 dB SNR condition. Stimuli were then manipulated to create +9 dB (boosted) and -9 dB (attenuated) SNR conditions. An anchor stimulus (1,000 Hz low-pass filter with white noise) was included. Participants rated stimuli relative to the +0 dB SNR condition for each background. A subsequent forced-choice test assessed recognition of the original song from the three background types.

Results: Background type had a dominant impact on sound quality ratings ($\eta^2=0.68$), exceeding the vocal level effect ($\eta^2=0.35$). Vocals over both original and off-key instrumental backgrounds were rated similarly (58.2 vs. 56.9; $p=0.774$) and significantly higher than vocals over babble noise (22.9-point difference, $p < 0.001$). Thus, CI users reliably differentiated musical from non-musical backgrounds, but were insensitive to large pitch distortions. Vocal boost (+9 dB) increased ratings modestly (+ 7.2 points; $p < 0.05$), while attenuation (-9 dB) produced a more pronounced decline (-14.7 points; $p < 0.001$). Results revealed a significant interaction between background type and vocal level ($F(2,39)=11.31$, $p < 0.01$), with vocal boost effects varying by background type: babble showed the largest improvement (+16.6 points, $p < 0.001$), followed by original instrumental (+7.2 points, $p=0.001$) and off-key instrumental (+4.1 points, $p=0.122$). Overall song recognition accuracy was 68%. Participants with a history of musical training showed a significant advantage in recognition (75% vs. 61%, Cohen's $d=0.31$) and derived greater benefit from vocal manipulations.

Conclusions: While vocal boosting provides benefit across all background types, the highest absolute sound quality ratings emerge when vocals are embedded within a coherent musical structure, highlighting the importance of preserving contextual cues rather than simply amplifying speech. The ability to distinguish musical from non-musical content, coupled with insensitivity to pitch inaccuracy, underscores a reliance on structural over spectral fidelity. These findings suggest that future CI musical processing strategies should retain musical scaffolding, while selectively boosting vocal prominence to meaningfully improve musical enjoyment.

M35. Impact of Percussive Rhythmic Cues With Different Timbres on Music Sound Quality Ratings in Cochlear Implant Users

Stephanie Younan^{*1}, Arjun Kurup¹, Patpong Jiradejvong¹, Karen C. Barrett¹, Nicole T. Jiam¹

¹*University of California - San Francisco*

Background: Music perception is a significant challenge for cochlear implant (CI) users due to device limitations that degrade the spectral cues necessary for pitch and timbre perception. In contrast, the perception of rhythm, which is conveyed by temporal envelope cues, is largely preserved. Consequently, CI users often rely on temporal and rhythmic information to parse complex auditory scenes. However, it remains unknown whether the deliberate enhancement of music with salient rhythmic textures can improve subjective sound quality. This study investigated how CI users' and normal hearing (NH) listeners' ratings of musical sound quality are affected by overlaying piano music with percussive textures that differ in timbre and frequency ranges.

Methods: An online sound quality rating task was completed by 13 experienced CI users and 14 NH controls. Participants rated ten instrumental piano excerpts under six conditions: an unaltered Reference, a degraded Anchor (1,000 Hz low-pass filter with noise), and four conditions where a distinct percussive texture was overlaid. The textures, equated for rhythmic complexity and RMS-normalized, were: a low-frequency Membrane (300-500 Hz), a mid-frequency Woods (500-4,000 Hz), a high-frequency Metallics (4,000-8,500 Hz), and a full-spectrum Mixed (300-8,500 Hz). A mixed-effects ANOVA was used to analyze differences in ratings between groups and conditions.

Results: A significant interaction between condition and hearing group was found ($F(5,1595)=31.2$, $p < 0.001$, $\eta^2=0.089$), revealing opposing patterns of preference. Compared to the Reference condition, CI users provided significantly higher ratings for the mid-frequency Woods ($p < 0.001$), higher-frequency Metallics ($p=0.012$), and full-spectrum Mixed ($p=0.045$) overlays. Conversely, NH listeners rated the mid-frequency Woods ($p < 0.001$) and full-spectrum Mixed ($p=0.003$) overlays significantly worse than the Reference. For the CI group, the largest enhancement was observed for the Woods condition (+27.3 points; Cohen's $d=1.35$). No significant group differences were found for the Reference ($p=0.76$), Anchor ($p=0.69$), or Membrane ($p=0.80$) conditions.

Conclusions: Cochlear implant users experience a significant enhancement in musical sound quality when complex piano music is augmented with salient, rhythmically congruent percussive textures. This effect, which is opposite to that observed in NH listeners, is most pronounced for textures with substantial mid-frequency energy. These findings suggest that leveraging CI users' preserved temporal processing abilities via textural enhancement may be a useful tool to improve musical enjoyment. This work has implications for the development of front-end, user-centric music mixing strategies for CI music perception.

M36. A Machine Learning Framework for Predicting Vowel Confusion in Cochlear Implant Users

Stephanie Younan*¹, Brooke Barry¹, Patpong Jiradejvong¹, Julie G. Arenberg², Nicole T. Jiam¹

¹*University of California - San Francisco*, ²*Massachusetts Eye and Ear Infirmary, Eaton-Peabody Laboratories, Harvard Medical School*

Background: Vowel perception, in part, reflects the auditory system's ability to extract and utilize spectral peaks (formant frequencies). Therefore, identifying vowel confusion patterns may highlight frequency regions where formant cues are degraded and guide targeted cochlear implant (CI) programming. Current approaches rely on time-intensive, reactive testing to identify problematic vowel contrasts. This study aimed to develop and validate a machine learning framework that predicts vowel confusion patterns from clinical and psychophysical data, enabling rapid, clinically feasible, data-driven insights into the electrode-neural interface (ENI).

Methods: We analyzed 1,319 vowel identification trials from six adult CI users tested in noise with a 9-vowel corpus (/u/, /ʊ/, /oʊ/, /ɑ/, /ʌ/, /æ/, /ɛ/, /ɪ/, /i/) presented in a nonsense syllable context. Multi-modal data were flattened through feature engineering, aggregating electrode measurements and psychophysical data into subject-level summary statistics while converting temporal sequences and acoustic properties into scalar features. Input features were multi-modal, including: (1) acoustic parameters (formant frequencies, electrode-frequency mapping); (2) Psychophysical measures of the ENI, such as focused stimulation thresholds and psychophysical tuning curve slopes; and (3) performance metrics (historical confusion matrices, within-session trial effects). The predictive framework combined five heterogeneous base learners (random forest, gradient boosting, neural networks, support vector machines, k-nearest neighbors) in an ensemble model. Feature selection was optimized using mutual information analysis to capture non-linear dependencies. Model performance was validated with leave-one-subject-out cross-validation and assessed for stability via bootstrap resampling. The primary outcome was prediction accuracy for the 9-class vowel classification task.

Results: The ensemble model achieved 92.4% cross-validated accuracy (95% CI: 91.0%–93.8%) and a macro F1-score of 0.924 in predicting the specific vowel response on a per-trial basis. Model performance was strongly dependent on ENI integrity, with accuracy ranging from 96%–99% for subjects with robust ENI to 48% for those with poor ENI. The model demonstrated robust performance across cochlear regions (89.5%–94.8%) while identifying clinically relevant confusion patterns, including systematic front vowel substitutions (/eɪ/→/ɛ/: 9.8%). Feature ranking via mutual information analysis confirmed that ENI measures (normalized MI: 0.41) and historical confusion matrix (0.35) were the strongest predictors, outweighing the vowel's acoustic formant structure (0.18). This ranking establishes that individual neural response characteristics exert greater influence on vowel perception than acoustic parameters alone.

Conclusions: This study introduces a validated machine learning framework capable of predicting specific vowel confusion patterns in CI users. These preliminary results establish that the fidelity of ENI as an important determinant of vowel perception outcomes. Potential applications include leveraging vowel identification tasks to infer ENI integrity without relying on time-intensive psychophysical testing. Future translation will require integration into existing audiology workflows, and prospective validation in larger, more diverse patient cohorts.

M37. Open Board

M38. The Role of Electrode-Neural Interface Viability on Timbre Perception and Reorganization Following Electrode Deactivation in Cochlear Implant Users

Nicole Jiam*¹, Brooke Barry¹, Stephanie Younan¹, Caylin McCallick², Charles Hem³, Dietmar Wohlbauer⁴, Patpong Jiradejvong¹, Julie Arenberg⁵

¹University of California - San Francisco, ²Mass. Eye and Ear, ³Harvard University, Massachusetts Eye and Ear, ⁴Harvard Medical School, Massachusetts Eye and Ear, ⁵Massachusetts Eye and Ear Infirmary, Eaton Peabody Laboratory

Background: Music perception remains a major challenge for cochlear implant (CI) users. While the integrity of the electrode-neural interface (ENI) has a known effect on speech-in-noise outcomes, its role in perceiving musical features such as timbre is less clear. This study aimed to (1) identify psychophysical correlates of timbre perception and (2) assess whether a targeted programming intervention—deactivating electrodes with high stimulation thresholds—modifies timbre performance.

Methods: Thirteen adult CI users participated. Forward and reverse sweep-focused thresholds were obtained for electrodes 2 through 15. The stimulus levels were averaged across all trials. ENI uniformity, a measure of the consistency of the interface between the electrodes and auditory neurons, was assessed using the standard deviation of the differences in thresholds between neighboring electrodes. Frequency selectivity, which reflects the sharpness of neural activation patterns, was measured using the slopes of psychophysical tuning curves (PTCs). In the first phase, we performed a Pearson correlation analysis to relate ENI uniformity and PTC slopes to timbre identification on the CAMP test. In the second, interventional phase, we compared user performance on the timbre task with their everyday clinical program and an

experimental program where two to five electrodes with the highest stimulation thresholds were acutely deactivated. Changes in accuracy and perceptual confusion patterns were analyzed using paired t-tests and Chi-square analysis, respectively.

Results: PTC slope, rather than ENI uniformity, was a significant predictor of timbre perception. The PTC slope at high-threshold electrodes was a strong negative predictor of overall timbre perception ($r=-0.66$) and specifically for the strings/percussion category ($r=-0.70$). In the interventional phase, deactivating high-threshold electrodes did not significantly alter overall timbre identification accuracy (42.6% vs 43.9%). However, this stable accuracy masked a profound underlying perceptual reorganization, confirmed by a shift in the pattern of instrument confusion errors ($\chi^2(112)=698.19$, $p < 0.001$). The total perceptual distance between the programs was 16.1%, indicating a moderate but meaningful change in error patterns. This reorganization was systematically linked to acoustic features; instruments with a low spectral centroid showed moderate stability (15.8% distance), whereas those with a medium spectral centroid were the most affected (17.3% distance). Among the eight instruments, piano showed the greatest stability (12.8% distance), while guitar demonstrated the largest reorganization (20.5% distance).

Conclusions: The sharpness of PTCs is a key predictor of CI-mediated timbre perception. Targeted electrode deactivation acutely modifies spectral cue processing without altering global accuracy, demonstrating neural plasticity and reweighting of acoustic information. The paradoxical improvement in identifying some instruments alongside the decline of others highlights the importance of analyzing perceptual confusions, not just accuracy scores, to understand how CI users adapt to their signal. Future tonotopic analyses are needed to link these perceptual shifts to the spectral properties of the deactivated electrodes.

M39. Patient Preferences for Hearing Aid Features and Service Delivery Models

Preeti Pandey¹, Anu Sharma², Kerry Walker¹, Kayla Cormier², Carly Schimmel², Sung-Joon Min¹, De Wet Swanepoel³, Elaine Hoi Ning Ng⁴, Vinaya Manchaiah*¹

¹University of Colorado School of Medicine, ²University of Colorado Boulder, ³University of Pretoria, ⁴Oticon A/S

Background: Patient preferences play a critical role in hearing aid adoption and sustained use. As new hearing device features evolve and new service delivery pathways emerge, including over-the-counter (OTC) devices, it is increasingly important to understand how adults with hearing loss value device features and professional services. Financial considerations and convenience may draw some patients toward OTC options, yet many individuals may continue to prioritize advanced device features and professional involvement in their care. The current study explored the patient preferences for hearing aid features and service delivery models.

Methods: This study is nested in a four-arm randomized clinical trial and used a cross-sectional survey design. A total of 114 adults with self-reported hearing disability completed the participant profile questionnaire. The questionnaire collected demographic information along with preferences for hearing device features and service delivery models. Responses were analyzed descriptively.

Results: The average age of participants was 66 years; 73% were female. Most held at least a university degree (77%), and more than half were retired (53%), with 28% employed full time. Thirty-nine percent reported annual household incomes between \$50,000 and \$99,999, and 28% lived alone. Regarding device features, participants rated the ability to hear friends and family in noisy environments, physical comfort, and device reliability as highly important. For service delivery, prescription hearing aids with in-person support from a hearing healthcare professional were rated most favorably, whereas OTC devices with online technician support were least preferred. Cost was considered an important factor, but the role of healthcare professionals in the decision-making process was rated as more important. Most participants reported feeling moderately to extremely uncomfortable with purchasing a hearing aid without a prior hearing test.

Conclusions: Adults with self-reported hearing disability placed a high value on interpersonal communication in noise, comfort, and reliability when considering hearing aid features. The strong preference for professional guidance highlights the continued importance of hearing healthcare professionals in facilitating hearing aid journey. This highlights the importance of professional support despite the availability of OTC devices and virtual models.

M40. Relation Between Financial Toxicity and Hearing Aid Preferences

Preeti Pandey¹, Anu Sharma², Kerry Walker¹, Kayla Cormier², Carly Schimmel², Sung-Joon Min¹, De Wet Swanepoel³, Elaine Hoi Ning Ng⁴, Vinaya Manchaiah*¹

¹University of Colorado School of Medicine, ²University of Colorado Boulder, ³University of Pretoria, ⁴Oticon A/S

Background: Financial toxicity, defined as the financial distress or hardship associated with healthcare costs, may influence decision-making among individuals with hearing loss. Patients experiencing higher financial burden are likely to consider low-cost hearing devices, even if they express preferences for professionally fitted devices or advanced features. Understanding how financial strain shapes hearing aid feature and service delivery preferences can provide valuable insights for tailoring patient-centered care and informing policy decisions. The purpose of this study is to examine the relationship between financial toxicity, demographic and audiologic factors, and preferences for hearing aid features and service delivery models among adults with self-reported hearing disability.

Methods: This study is nested in a four-arm randomized clinical trial and used a cross-sectional survey design. Data were collected from 114 adults with self-reported hearing disability who completed a patient profile and financial toxicity questionnaires. The questionnaire assessed demographics, hearing aid features, and preferences for service delivery models. Associations between financial toxicity, demographic variables, and preferences for hearing aids were examined using Spearman correlation coefficients. For preferences with nominal responses (> 2 categories), standardized mean differences were calculated to evaluate differences in demographic variables and financial toxicity across preferences.

Results: Eighty-two (76%) had Comprehensive Score for Financial Toxicity (COST) Grade 0 (No impact, score $\geq$ 26) for financial toxicity. Higher financial toxicity was moderately correlated with having Medicaid insurance and with cost being an important factor in choosing hearing aid service delivery models. Participants who rated affordability as the most important factor

influencing their decision to purchase a over-the-counter (OTC) hearing aids were more likely to be working at least part time and younger than those who prioritized initial fitting by a healthcare professional or ability to adjust the sound (medium-to-large effect). Preference for advanced OTC hearing aid features was more common among individuals with six-figure incomes compared to those preferring moderate features (large effect). Participants with a stronger preference for online support and assistance with OTC devices compared to in-person support were more likely to be Medicaid-insured (large effect). Similarly, individuals who preferred online support over combined online and in-store support options were more likely to be living alone (large effect).

Conclusions: Financial toxicity appears to meaningfully shape hearing aid preferences, with cost-related concerns influencing willingness to adopt OTC devices and the type of support services desired. While affordability was an important factor, participants continued to value professional involvement and advanced features, suggesting a tension between financial constraints and preferred models of care. These findings underscore the need to consider financial burden when developing and promoting OTC hearing aid service delivery pathways to ensure equitable access without compromising patient preferences.

M41. Electrically Evoked Compound Action Potentials and Electrocochleography as Complementary Measures of Cochlear Health

Huib Versnel^{*1}, Dyan Ramekers², Ralf Boerboom¹, Alexander Hoetink¹, Hans Thomeer¹, Robert Stokroos¹

¹University Medical Center Utrecht, ²Antwerp University Hospital

Background: Hearing performance of cochlear implant (CI) users relies on the condition of the auditory nerve. Animal studies have shown that electrically evoked compound action potentials (eCAPs) can be applied to assess this condition. Relative measures, obtained by comparing eCAPs to different stimuli, are strongly correlated with neural survival (Ramekers et al., J. Neurosci. 2015). Studies in humans demonstrated the value of such relative measures in their correlations with hearing performance (Zamaninezhad et al., Front Integr Neurosci, 2023). The presence of residual hair cells, which we assume is beneficial for neural survival, can be assessed with intracochlear electrocochleography (Giardina et al., Ear Hear, 2019). In an ongoing trial, we record eCAPs and ECoChG in CI recipients to examine the predictive value for hearing performance. Here we consider the relation between eCAPs and ECoChG.

Methods: Twenty subjects with severe sensorineural hearing loss, aged 34 to 82 years, received a CI (Flex28, MED-EL). Intraoperatively and four months postoperatively, eCAPs were recorded at each electrode to biphasic current pulses with varying interphase gaps (IPGs; 2.1 to 30 μ s) and current levels varying up to saturation (AutoART, MED-EL). Outcome measures include latency at maximum current levels, and several measures derived from sigmoid fitting of the amplitude growth function (AGF) such as maximum amplitude and the current level halfway the AGF, level50%. Relative measures were obtained by the difference between measures at IPG of 30 and 2.1 μ s. ECoChG was postoperatively performed to tones at 115 dB SPL at frequencies from 250 to 4000 Hz. Hearing performance was assessed by CVC in noise perception and the spectral-temporally modulated ripple test (Aronoff and Landsberger, JASA, 2013).

Results: Generally, maximum eCAP amplitudes varied between 200 and 1000 μV , typically with the higher values at apical electrodes. Cochlear microphonic (CM) could be recorded for most participants not only at low frequencies but occasionally also for 4000 Hz. Correlations between eCAP amplitude (averaged across electrodes) and CM amplitudes were not significant; neither did relative eCAP outcomes significantly vary with CM amplitudes. A within-subject analysis revealed strong correlations ($R > 0.5$) between eCAP and CM amplitude across the electrode array in five subjects, whereas weak or negative correlations were observed in nine subjects.

Conclusions: A lack of consistent correlations between eCAPs reflecting neural health and CM reflecting residual hair cells may be explained as follows. The CM mainly reflects surviving outer hair cells, while inner hair cells are more important for neurotrophic support of the SGCs. Alternatively, it is rather the supporting cells being relevant for neurotrophic support (Zilberstein et al., 2012) and hair cell survival does not mirror supporting cell survival that well. We conclude that ECochG and eCAP provide largely independent measures reflecting the health of different cochlear structures.

M42. The Acoustic Change Complex Compared to Onset Auditory Evoked Potentials in Cochlear Implant Users

Bernard Vonck¹, Jan van Heteren¹, Laura Jacksens², Dominique de Jel³, Robert Stokroos¹, Marc Lammers², Huib Versnel^{*1}

¹University Medical Center Utrecht, ²Antwerp University Hospital, ³University Medical Center Groningen

Background: The acoustic change complex (ACC) is a cortical potential evoked in response to a change within an ongoing sound stimulus. The ACC has been reported to correlate to speech perception in cochlear implant (CI) users and is therefore promising as an objective measure of auditory performance. Since processing of auditory changes is indispensable for speech perception, the ACC might be more predictive of speech perception than auditory potentials evoked in response to an onset stimulus. The aim of this study is to compare the ACC to onset potentials of the auditory cortex and brainstem, as objective measures of auditory performance in CI.

Methods: Thirteen bilaterally deaf and six single-sided deaf CI users aged between 18 and 63 years were included, all with unilateral CI (Cochlear Ltd) experience for at least one year (Van Heteren et al., 2022, Ear Hear 43:1783-1799). ACCs were evoked in response to frequency increases within pure tones. ACCs were compared to cortical auditory evoked potentials (CAEP) in response to onsets of pure tones, and to auditory brainstem responses (ABR) in response to biphasic pulses. ACC reference tones and CAEP tone stimuli had frequencies of about 500 and 2000 Hz corresponding to an apical and middle electrode respectively. The ABRs were evoked by biphasic pulses at the same apical and middle electrodes. Auditory performance tests included speech perception in quiet and in noise.

Results: Averaged across the two frequencies, both ACC amplitudes ($R = 0.51$ - 0.53 , $p = 0.019$ - 0.026) and latencies ($R = 0.51$ - 0.68 , $p = 0.003$ - 0.04) had strong correlations to speech perception in quiet and in noise. Onset CAEP amplitudes ($R = 0.51$ - 0.66 , $p = 0.002$ - 0.02) correlated to speech perception in quiet and in noise. ABR wave V amplitudes were only correlated to speech

perception in noise ($R = 0.55$, $p = 0.01$). Latencies of onset CAEP and ABR did not show such correlations.

Conclusions: The ACC has a stronger and more consistent relation to speech perception compared to onset CAEP and ABR. This can be contributed to the fact that the ACC reflects cortical processing of spectral modulations which are more important than sound onsets for perception of dynamic sounds as speech. The correlations found between speech perception tests and ACC amplitudes and latencies underlines the promising value of this test as an objective measurement of auditory performance in CI users.

M43. Auditory Processing of the Fast Noise Burst Sequences – An Electrophysiologic Perspective

Ivan Sleziak¹, Ema Cicelova¹, Kristina Kostrubanicova¹, Peter Hubka*²

¹*Comenius University*, ²*Faculty of Medicine, Comenius University*

Background: The fast sequence of a short and a long noise burst (NB) separated by a short gap has been shown to evoke nonlinear transition of subcortical electrophysiological responses depending on their parameters (Burkhard et al. 2019). However, it was not clear whether, and how, this phenomenon is related to the perception of the discontinuity of such sound sequence. The present study focused on an analysis of electrophysiological responses and auditory perception of these NB sequences.

Methods: Electroencephalographic signals (EEG) were recorded from a selected skull positions using Ag-AgCl electrodes in a group of adult probands ($n=13$, age: range of 23-42 years) with normal hearing. Auditory responses were evoked by a sequence of two NBs separated by a short gap. Durations of the leading NB varies (5, 10, 30 ms), whereas durations of the trailing NB and gap are fixed (50 ms and 10 ms, respectively). Each NB has a 1 ms rising/falling phase. The stimuli were presented by Tucker-Davis Technology system RZ6 (TDT, Alachua, USA). Auditory perception of NB sequences with different parameters (durations of the first noise burst and following gap) were detected by answering a question, if probands hear one or two sounds after each presentation (min. 20 presentations). EEG signals were then recorded using TDT SI4 amplifier and RZ2 system (sampling rate of 24.414 kHz) to all three NB sequence conditions and separate NBs of corresponding durations (i.e. 5, 10, 30, and 50 ms) with repetition interval of 1.3 s with 10% jitter 300 trials for each stimulus condition were recorded.

Results: The combination of short leading NBs (5 and 10 ms) combined with the 10 ms long gap were usually perceived as one continuous sound, whereas leading NB of 30 ms duration were consistently perceived as two-sound sequence. The observed discrepancies in perception have been linked to differences in the evoked EEG responses within the early (0-100 ms) and late (150-350 ms) latency windows, corresponding to the auditory and perceptual processing, respectively.

Conclusions: Present results suggest electrophysiological biomarkers of diverse neuronal activations linked to specific auditory perception of fast sound sequences in EEG. Considering the importance of fast sound sequences in speech perception and their nonlinear processing nature, the results can provide insights into the temporal auditory processing underlying categorical speech perception.

M44. Differential Processing of Clear and Spectrally Degraded Sentences in the Human Cortex Revealed by Intracranial Electrophysiology

Kirill Nourski^{*1}, Mitchell Steinschneider², Ariane Rhone¹, Alexander Billig³, Emily Dappen¹, Ingrid Johnsrude⁴, Matthew Howard¹

¹*The University of Iowa*, ²*Albert Einstein College of Medicine, The University of Iowa*, ³*UCL Ear Institute*, ⁴*Western University*

Background: Cochlear implants (CIs) are the treatment of choice for severe to profound hearing loss. Despite progress in CI technology, there is considerable variability in outcomes. The function and plasticity of central auditory pathways contribute to this variability. While assessing cortical processing in CI users is methodologically difficult, spectrally degraded sounds presented to normal-hearing listeners can approximate the CI's input to the central auditory system. A previous intracranial electroencephalography (iEEG) study used spectrally degraded (noise-vocoded) speech tokens in a phonetic behavioral task (Nourski et al., 2024, *Front Hum Neurosci* 17:1334742). Differential responses to clear and vocoded stimuli could present as a “clear-preferred” or a less common “vocoded-preferred” pattern. This study sought to further characterize these differential responses using clear and vocoded sentences.

Methods: Participants were adult neurosurgical epilepsy patients undergoing chronic iEEG monitoring. Speech sentences (1.3-3.7 s duration) were degraded using a 3-band noise vocoder (Billig, Herrmann et al., 2019, *J Neurosci* 39:8679-89). Cortical activity was recorded using depth and subdural electrodes. Electrode coverage included superior temporal plane, superior temporal gyrus, dorsal and ventral auditory-related areas, prefrontal, and sensorimotor cortex. Analysis of iEEG data focused on event-related band power (ERBP) in canonical bands. Differences between responses to clear and vocoded sentences were established by cluster-based permutation tests.

Results: Differential responses (AEP, ERBP augmentation or suppression) to clear and vocoded sentences were broadly distributed in both hemispheres and could persist throughout the sentence duration. The vocoded-preferred pattern was less common than clear-preferred. Vocoded-preferred responses occurred bilaterally in the superior temporal plane, to a lesser extent in posterior regions of the superior and middle temporal gyri and inferior parietal cortex and were virtually absent in prefrontal cortex.

Conclusions: The results emphasize the role of auditory cortex and the dorsal stream in processing degraded speech. Clear-preferred responses are likely driven by spectral complexity and intelligibility. Vocoded-preferred responses may reflect processing demands associated with challenging listening conditions. These responses emerge at relatively early cortical processing stages and can engage the dorsal stream without extending into prefrontal cortex. Cortical regions that are differentially activated by clear and vocoded speech may have diagnostic and prognostic utility and present potential targets for neuromodulation-based CI rehabilitation strategies.

M45. Motor-Auditory Contributions to Speech: Trf Evidence Across Multiple Datasets and Implications for Imagined Speech

Maryam Maghsoudi Shaghghi*¹, Rupesh Chillale², Shihab, A Shamma³

¹*University of Maryland - College Park*, ²*Institute for Systems Research, University of Maryland - College Park*, ³*University of Maryland, École Normale Supérieure*

Background: Producing speech engages interacting motor and auditory processes; During overt speaking, the cortex both issues articulatory/motor commands and receives auditory feedback from one's own voice. In mimed (silent) speech, the motor drive remains while external auditory feedback is absent. In listening, auditory input is present without articulation. Imagined speech engages internal motor and auditory simulations without overt movement or sound. We ask two questions: (i) Does neural activity during vocalized speech approximate an additive mixture of the mimed (motor-dominant) and listening (auditory-dominant) responses? (ii) Can activity across these sensory-motor modes help characterize, and even predict, the content of imagined speech? To test this, we analyze three modes of speech across complementary recordings: invasive sEEG (vocalized, mimed, imagined) and noninvasive EEG (speaking, miming, listening).

Methods: We analyzed two complementary datasets: (1) sEEG during vocalized, mimed, and imagined production (He et al., 2025); (2) dry-EEG during speaking, miming, and listening (dry sensors to reduce movement artifacts during speech/miming). Data were preprocessed and segmented by word and trial. Stimuli were represented with multi-band spectrograms (Chi et al., 2005). We fit forward TRFs (stimulus to neural) (Crosse et al. 2025) to reconstruct evoked responses and backward TRFs (neural to stimulus) to reconstruct the envelope/spectrogram.

Results: EEG (additivity with backward TRFs). Backward TRFs were fit separately for each sensory mode in the EEG data to reconstruct the audio spectrograms. We observed that the reconstruction for Speaking/Vocalized is well approximated by the sum of the reconstructions from Miming and Listening, supporting a superposition of motor and auditory components.

sEEG (transfer to imagination). We tested whether backward TRFs trained on vocalized speech could detect imagined words from sEEG. A backward TRF was fit to the vocalized responses to predict the audio spectrogram from sEEG, and the same model was applied to imagined responses for the same words. We observed a time-localized increase in the reconstructed spectrogram's energy consistent with word onset. Because imagery onset is uncertain, these increases were variably time-shifted across trials; ongoing analyses quantify and compensate for this latency variability.

Conclusions: TRF-based analyses on our EEG dataset provide converging evidence that overt speech responses can be approximated by additive contributions from motor and auditory components. Preliminary results from TRF analysis of the sEEG dataset show that models trained on vocalized speech transfer to imagined modes. This supports shared encoding across overt and covert speech and could offer a principled linear baseline for imagined-speech decoding, an essential step toward practical brain-computer interfaces for communication without articulation.

M46. Divergent Cortical Speech Tracking at the Cocktail Party: Preserved in Hearing Aid Users, Impaired in Cochlear Implant Users

Constantin Jehn^{*1}, Jasmin Riegel¹, Tobias Reichenbach¹, Anja Hahne², Niki Katerina Vavatzanidis²

¹University of Erlangen-Nuernberg, ²University Hospital Carl Gustav Carus, Technische Universitaet Dresden

Background: Although modern hearing aids (HAs) and cochlear implants (CIs) effectively restore speech perception in quiet, understanding speech in complex acoustic environments remains a challenge. Competing talkers and noise demand high listening effort and can severely impede communication. Neuro-steered hearing prostheses, using EEG to decode attentional focus, offer a promising solution by enhancing the attended speech stream. However, developing such devices requires a deeper understanding of neural speech tracking in the hearing impaired population. While prior work investigated HA or CI users in isolation, a direct comparison is lacking. This study provides the first comprehensive, direct comparison of cortical speech tracking in HA and CI users, using a more ecologically valid paradigm with free-field stimulation and participants' clinical devices.

Methods: To this end, we collected EEG data from bilateral CI users (n=25), bilateral HA users (n=29), and age-matched typical hearing (TH) controls (n=29) during a selective attention paradigm. Participants listened to two-minute audiobook trials in both single-speaker and competing-speaker conditions. They were visually cued to attend to a target story. Post-trial comprehension questions and subjective listening effort ratings were used to quantify speech comprehension and perceived difficulty, across conditions and cohorts.

Neural tracking was assessed using a linear forward model to study the Temporal Response Function (TRF) to the speech envelopes. Moreover, a linear backward model served to examine the differences in reconstruction scores of the attended speech envelope and the decoding accuracy across cohorts. Statistical analysis comprised both parametric and non-parametric tests. If applicable p-values were corrected for multiple comparisons, using FDR-correction.

Results: Behaviorally, significant group differences emerged only in the competing-speaker condition. Self-reported listening effort showed a graded increase from controls to HA users to CI users (all $p < 0.01$). In contrast, objective comprehension was significantly impaired only for the CI group ($p < 0.001$), as both HA users and normal-hearing controls performed at ceiling.

The decoding accuracy of the attended speaker was significantly reduced for the CI user, compared to the HA and TH groups (all $p < 0.001$). This could be explained by higher reconstruction scores of the distractor envelope (all $p < 0.001$) that we observed for the CI group. Importantly, we found that the HA group exhibited cortical tracking and attentional modulation that were largely comparable to the TH group. This finding was supported by both forward and backward model analysis.

Conclusions: The first key take-away is that CI users exhibit significantly less neural speech tracking, and smaller attentional modulation of the speech tracking, in line with their behavioral difficulties in speech-in-noise comprehension. The second take-away is that modern HAs largely normalize cortical speech tracking. This suggests that their increased listening effort, as compared to typical hearing people, may have a different neural origin.

M47. Prevalence of Tinnitus According to Audiometric Profiles in a Population of Hearing-Impaired Subjects Who Are Candidates for Hearing Aids (n = 250,000)

Arnaud Norena*¹, Nicolas Detroy², Jean-Luc Blanc¹, Wolfgang Reip¹

¹CNRS, ²Institut Pasteur

Background: We had access to a database collected by hearing aid suppliers from Amplifon retailers in France. We analysed more than 250,000 subjects with and without tinnitus. The main objective of this study was to assess whether the prevalence of tinnitus varied according to audiometric profiles.

Methods: For most subjects, we had audiograms, loudness discomfort levels, speech in silence and noise, and a visual analogue scale for tinnitus intensity and distress. All subjects were also asked whether they were or had been exposed to noise. The data were processed using principal component analysis and hierarchical clustering (PCA-HC) and logistic regression.

Results: Overall, the prevalence of tinnitus in this population is approximately 45%. This prevalence is very high, but it is probably due to the fact that the population is highly biased in that most subjects are hearing impaired. It is interesting to note that the prevalence of tinnitus follows a bell curve with age, peaking around 60 years of age. PCA-HC identified 14 subtypes of audiograms. Tinnitus increased with average hearing loss, but was highest for audiograms with steep slopes. Tinnitus prevalence is higher in the population of subjects who answered positively to the question relative to noise exposure. It is also enhanced in subjects with low loudness discomfort levels.

Conclusions: We discuss the results as a function of the tinnitus mechanisms.

M48. Responses of Inferior Colliculus Neurons to Notched Noises in Awake Mice: Putative Neural Correlates of Auditory Enhancement and Zwicker Tone

Arnaud Norena*¹, Alexander Galazyuk², Chun-Jen Hsiao³

¹CNRS, ²NEOMED, ³Northeast Ohio Medical University

Background: Sensory systems are well adapted to constantly changing statistics of the environment and to process specific spectral features of sounds, such as spectral notch (i.e. low energy frequency band) embedded in broadband stimuli. Spectral notches can be added to the stimulus spectrum due to filtering by the outer ear, and can be used as monaural cues related to head or pinna position for localizing sound sources. In addition, broadband sounds with spectral notch are known to produce auditory enhancement, a perceptual phenomenon in which a target within a spectrally notched masker can become salient if preceded by a copy of the masker. Notched noise can also produce an auditory illusion, called Zwicker Tone (ZT), which is perceived immediately after stimulation and whose pitch corresponds to the spectral notch.

Methods: The present study aimed to further investigate the mechanisms of auditory enhancement, including those of ZT, in the inferior colliculus of awake mice using glass electrode electrophysiology.

Results: We show that neural activity can be strongly suppressed during NN stimulation and enhanced immediately after NN stimulation. These effects depend on notch center frequency relative to the best frequency of neurons, stimulus level and notch width. Our results are consistent with the mechanisms described for post-inhibitory rebound in the central auditory system: NN could hyperpolarize the membrane potential, which can then activate several cationic conductances, leading to a rebound of neural activity.

Conclusions: We discuss auditory enhancement and ZT as collateral effects of an essential neural mechanism aimed at enhancing the central representation of acoustic spectral contrasts.

M49. Characterization of Masker Modulation Frequency Effects on Moc Activity in a Forward-Masking Paradigm

Afagh Farhadi*¹, Arezou Rokhforouz¹, Michael Heinz¹

¹*Purdue University*

Background: Although anatomical studies have established that the inferior colliculus (IC) provides a major projection to the medial olivocochlear (MOC) system, the physiological contribution of this pathway remains unclear. IC cells, sensitive to low-frequency modulation inherited from auditory-nerve (AN) responses, convey spectral information distinct from the level-driven input of the CN. We hypothesize that varying masker modulation frequency alters the IC input to MOC, independent of CN effects, with reduced MOC activity for frequencies outside the IC's modulation transfer function (MTF) range. This approach provides insight into IC contributions to MOC. In our previous work, we varied the modulation frequency of the probe while using the same broadband noise as the masker. Here, we instead vary the masker's modulation frequency while keeping the probe modulation fixed, ensuring the probe engages the same EFR-generating mechanisms across conditions so that differences can be attributed to the masker.

Methods: We recorded envelope following responses (EFRs) and transient evoked otoacoustic emissions (TEOAEs) simultaneously in awake chinchillas using a forward-masking paradigm. The goal was to test how masker modulation frequency influences the modulation enhancement effect, defined as an increase in EFR response in the masked compared to the unmasked condition. This effect has been reported in chinchillas (Farhadi et al., 2023) and humans (Bharadwaj et al., 2015), but here we specifically examine its dependence on masker modulation frequency. TEOAEs were measured before and after stimulation to assess cochlear gain changes (associated with MOC activation), and EFR responses were analyzed using phase-locking value (PLV) to quantify neural changes associated with MOC activation. We also tested whether effects differ between sedated and awake conditions to better link them to MOC mechanisms.

Results: We observed a broad reduction in TEOAE responses in the presence of a broadband noise masker, whereas responses in silence remained unchanged. For SAM tones, a larger decrease at the carrier frequency occurred for 103 Hz modulation (within the IC MTF range) compared to 303 Hz (outside the range). Similarly, EFR PLVs showed an increase in the first PLV peak under forward-masked conditions, with stronger effects at 103 than 303 Hz. Together, these results indicate a frequency-dependent enhancement of EFR responses, consistent with our hypothesis based on IC MTFs and supported by computational modeling.

Conclusions: This study establishes a forward-masking paradigm as a noninvasive approach to probe MOC activity as a function of masker modulation frequency. The design allows us to examine how IC input may shape MOC activity, complementing the better-studied cochlear nucleus pathway, and helps clarify the physiological contribution of IC projections to efferent control of the cochlea. Although developed in an animal model, the paradigm is noninvasive and therefore has potential for translation to humans, where within-subject normalization may be especially valuable.

M50. The Influence of Local Inhibition on Receptive Fields in the Inferior Colliculus

Sarah Wajdi*¹, Michael Roberts¹

¹*University of Michigan*

Background: The inferior colliculus (IC) is the midbrain hub of auditory processing, receiving most of the ascending input from the lower auditory brainstem and providing the main ascending auditory input to the thalamocortical system. Many neurons in the IC exhibit complex receptive fields for sound features. While some of this complexity almost certainly arises from the combinations of ascending input that individual IC neurons integrate, a wealth of anatomical evidence indicates that the IC is rich in local circuits that may also play critical roles in shaping receptive fields. However, how these local circuits shape IC neuron responses to sounds remains unclear. Here, we are using in vivo electrophysiology in awake mice with optogenetic manipulations to examine how local inhibitory circuits shape IC neuron frequency tuning and selectivity for frequency modulated (FM) sweeps. We hypothesize that local inhibitory circuits sharpen IC neuron receptive fields such that disrupting local inhibition leads to broadened frequency tuning and reduced selectivity for FM sweeps.

Methods: To investigate how local inhibitory circuits in the IC impact sound responses, we are using inhibitory opsins to selectively inhibit IC inhibitory neurons while making in vivo recordings in the IC of awake, head-fixed mice. To selectively inhibit IC inhibitory neurons, we are injecting an adeno-associated virus containing a Cre-dependent construct encoding the inhibitory opsin eOPN3 into the IC of Vgat-Cre mice, in which Cre recombinase is expressed in GABAergic neurons. Two to six weeks later, we use 32-channel silicon probes with an integrated optical fiber to record from and deliver optical stimuli to the IC. During recordings, we assess frequency tuning using tone bursts ranging from 4 – 64 kHz at intensities from 0 – 70 dB SPL and assess FM sweep tuning using 70 dB SPL logarithmic FM sweep stimuli with speeds of 10 – 200 octaves/second and varying between the up and down direction. All sound stimuli are pseudorandomly presented under control conditions and in the presence of optical stimulation.

Results: Experiments for this study are ongoing. We expect to find that inhibiting local inhibition broadens frequency tuning and reduces FM sweep selectivity in many IC neurons.

Conclusions: Anatomical studies have repeatedly demonstrated that the IC is rich in local circuits, but due the intermixing of ascending and local inhibitory synapses in the IC, it has been difficult to directly test how local inhibitory circuits contribute to IC computations. We expect the results of this study will show that local inhibitory circuits critically shape the acoustic receptive fields of most IC neurons.

M51. Encoding of Amplitude-Modulated Stimuli in the Inferior Colliculus: Impact of Reduced Temporal Salience and Corticocollicular Projections

Venezia Carmona Barron^{*1}, Benjamin Richardson¹, Rui Cai¹, Lynne Ling¹, Donald Caspary¹

¹*Southern Illinois University School of Medicine*

Background: Subcortical auditory processing is shaped by ascending auditory projections but also descending, top-down influences. Top-down projections may compensate for degraded ascending acoustic information, seen with aging or in cluttered acoustic environments. One way to model temporal ambiguity is by reducing the modulation depth (m) of sinusoidally amplitude-modulated (SAM) stimuli. Prior work in the MGB revealed neurons that exhibited enhanced responses to repeated, temporally degraded signals in both young and aged rats. Building on these findings, we examined whether aging and reduced m alter single-unit responses to SAM stimuli in the rat inferior colliculus (IC), and how Corticocollicular (CC) projections contribute to shaping these responses.

Methods: We recorded IC single-unit activity in awake passively attending young (4–7 months) and aged (28–32 months) Fischer Brown Norway rats. SAM stimuli were delivered at 100% or at reduced m of 50% and 25%. An additional “Noisy SAM” condition was created by jittering the modulation envelope with low-pass (cutoff: 1 kHz) broadband noise (BBN). Modulation frequencies (Fmod) ranged from 2–1024 Hz, with the carrier set to BBN or to a unit’s CF. Stimuli were presented in blocked sequential trials or random across trials. To test whether reduced m increases reliance on CC inputs, we optogenetically suppressed CC terminals in young IC units by injecting an AAV-Arch-GFP construct into deep layers of primary auditory cortex. Following a 3-week period for the virus to express in the IC, simultaneous recording of IC units and light delivery was performed.

rMTF and tMTF were constructed based on discharge rate and synchrony plotted against Fmod for condition

Results: In vivo recordings revealed young IC units that often exhibited enhanced firing rates to sequentially present SAM stimuli at reduced m, while aged rat IC units could show enhanced response to sequentially presented stimuli both at 100% and at reduced m. Increased responses was observed for both age groups, though it was more prevalent in aged animals. In both groups, while some units showed decreased spiking when m was reduced, a substantial proportion displayed increased discharge rates at lower depths or Noisy SAM stimuli. Optogenetic blockade of CC inputs reduced the magnitude of these enhanced responses, often near the unit’s best modulation frequency (BMF). In some cases, CC blockade shifted the BMF. Temporal responses showed complex effects of CC blockade. Some IC units showed increased synchrony or expanded the range of Fmod showing synchrony, while other IC units showed reduced synchrony to CC blockade. This suggested complex modulatory effects of top-down input on temporal coding.

Conclusions: These findings support evidence that processing temporally degraded auditory signals, such as those with reduced m engages resources from Cortex to the IC, may be critical for perception during aging or in complex acoustic environments.

M52. Top-Down Signaling From the Medial Prefrontal Cortex to the Inferior Colliculus During an Auditory Oddball Paradigm

Yannis Pfleger*¹, Franziska M. Decker¹, Franck Fogaing Kamgaing¹, Mesbah Alam¹, Waldo Nogueira², Joachim K. Krauss¹, Kerstin Schwabe¹

¹Hannover Medical School, ²Hannover Medical School, Cluster of Excellence Hearing4All

Background: Detecting behaviorally relevant auditory information is essential for navigating in dynamic environments. Beyond processing of auditory information in the central auditory system, widespread projections from cognitive higher-order frontal regions support integrative, context-dependent control. The medial prefrontal cortex (mPFC) may be a key role, yet the extent of its influence on central auditory activity remains unclear. This study combined a three-class oddball, in which rats are required to differ between a behaviorally relevant target tone while ignoring distractor and standard tones, with simultaneous recordings from mPFC and the central nucleus of the inferior colliculus (ICc), to assess a potential interaction between these regions during auditory information processing in awake rats.

Methods: Following the training of rats (n = 8) and the stereotaxic implantation of chronic electrodes into the mPFC and ICc under anaesthesia, local field potentials (LFPs) were simultaneously recorded from both regions during an auditory three-class oddball paradigm (500 ms stimuli at 70 dB SPL), requiring behavioral response to a rare target tone (20%), while ignoring a frequent standard (60%) and a rare distractor tone (20%). The neural recordings were analyzed using event-related potentials (ERPs) and time-frequency analysis with a complex Morlet wavelet convolution (CMW), which was used to describe the temporal frequency patterns attributed to each tone. To compare the neural signal on a trial-by-trial basis, a Pearson cross-correlation was applied.

Results: ERPs showed an early ICc onset response for all tones (20 - 50ms post stimulus), characterized by enhanced beta (12-30 Hz) and gamma (> 30Hz) activity. In the mPFC, an early (100ms, N1) and late (300-450ms, P3) deflection was most pronounced for target. In the mPFC, for N1 low frequency activation (< 12Hz) appeared after all tones, whereas only targets evoked beta band responses. Interestingly, only after target, a second deviation in the ICc shortly following the mPFC N1 shared frequency patterns similar as the mPFC N1. Cross correlation indicated a switch in information flow from the mPFC towards the IC for target after mPFC N1, which was not observed for standard and distractor tones.

Conclusions: These findings suggest top-down processing from the mPFC to the IC for behaviorally relevant information. The similarity of spectral features of the mPFC N1 and subsequent ICc activation suggests a model in which prefrontal activity selectively amplifies auditory midbrain representations of behavioral relevant stimuli via top down pathways.

M53. Intracochlear Pressure Measurements During Bilateral and Bimodal Bone Conduction Stimulation

Nathaniel Greene*¹, Andrew Brown²

¹Applied Research Associates, ²University of Washington

Background: Clinical bone conduction hearing devices (BCHDs) have long been used for the diagnosis and treatment of hearing loss. Recently, BCHDs have also increased in popularity for personal audio applications, due to their ability to transmit sound to the inner ear without occluding the ear canal. BCHDs vibrate the head, thus both ears are stimulated when applying BC stimulation through even a single transducer. The relative timing and amplitude differences of sound arriving at each ear – known as transcranial delay (TD) and attenuation (TA) – are nonzero given a transducer placed on either side of the head, but are generally small and frequency-dependent. The introduction of a second BC stimulus (as in bilateral clinical BCHD fittings) and/or concurrent air conducted (AC) stimulation therefore leads to a complex superposition of signals, subject to a host of exogenous (e.g., stimulus, transducer, fitting) and endogenous (morphometric, physiologic) variables. Here, we report intracochlear pressure signals from a series of measurements in human cadaveric specimens designed to quantify effects of bimodal AC/BC and binaural BC interactions.

Methods: Whole cadaveric human heads were prepared bilaterally with canal wall up mastoidectomies and an extended facial recess approach, and suspended upside down via a loose fixation apparatus. Intracochlear pressure was measured in the scalae vestibuli and tympani with fiber optic pressure probes, concurrently with velocity of the cochlear promontory via laser Doppler vibrometry. Depending on the experiment, tone, click, or noise stimuli were presented through AC and/or BC modalities: AC stimuli were presented unilaterally via a loudspeaker (TDT FF1) adapted to the ear canal with PVC tubing. BC stimuli were applied to one or both mastoids with either pairs of RadioEar B81 transducers, or Brüel and Kjær mini-shakers (4810) coupled to bone anchored abutments at clinically typical bone-anchored hearing aid locations.

Results: Both bimodal (AC/BC) and bilateral (BC/BC) stimulation revealed complex frequency- and location-dependent interference that impacted the effective stimulation magnitude in each ear. Interference can result in unexpected and ostensibly undesirable consequences, including the genesis of nonmonotonic amplitude fluctuations with changing sound source location, and the introduction of spurious binaural cues, both predicted to disrupt sound localization. Further, the consequences of signal superposition differed between intracochlear (pressure) and extracochlear (promontory vibration) measures.

Conclusions: Results suggest that both bimodal AC/BC and bilateral BC stimulation produce complex, frequency- and location-dependent superposition of multipath signals. Modern signal processing approaches may provide avenues to mitigate the effective transmission of undesirable signals/components, provided that appropriate target signals (e.g., for cross-talk cancellation) can be identified and measured. Prospects for such interventions are considered.

M54. Signal to Noise: Sound Localization and Speech Perception During Bone Conduction Headset and Hearing Protector Use

Aoi Hunsaker¹, Ted Argo², Andrew Brown*¹

¹*University of Washington*, ²*Applied Research Associates, Inc.*

Background: Bone conduction (BC) hearing devices stimulate the cochlea via vibration of surrounding bone and through secondary and tertiary conduction pathways that are also engaged when the head vibrates – a mode of stimulation distinct from, but overlapping with, conventional air conduction (AC) stimulation. In both clinical (e.g., BC hearing aid) and non-clinical (e.g., BC

headset) contexts, intracranial BC signals may be superposed with AC signals at one or both cochleae, leading to complex interactions that may degrade transmitted acoustic information and constrain auditory performance. Here we provide an update on an ongoing series of psychophysical measurements of the impacts of BC headset use on two fundamental auditory tasks: sound source localization and speech perception. In a subset of conditions, subjects also wore earplugs to capture performance in contexts (e.g., military operational settings) in which hearing protection and access to communications signals are both required.

Methods: In a darkened anechoic chamber, human subjects performed two different tasks: In a localization task, subjects were instructed to localize (via head turn) brief noise bursts presented through loudspeakers while listening to a concurrent speech signal presented through a BC headset. The target AC signal was varied in azimuth, elevation, amplitude, and timing relative to the BC stimulus. Subjects completed the task with open ears and with bilateral earplugs. AC-alone (target-only) performance was also assessed. In a speech perception task, subjects completed a BC-adapted version of the Modified Rhyme Test. Brief sentences with embedded keywords were presented through the BC headset while spatially diffuse pink noise of varied amplitude was presented from eight loudspeakers surrounding the subject (i.e., via AC). Subjects again completed the task with and without bilateral earplugs.

Results: Interactions of AC and BC signals at the cochleae are predicted to result in an AC-BC sum with amplitude and phase characteristics that differ from those of either component signal. However, the extent of interaction – and associated impact on performance – depends directly on the effective spectrotemporal overlap of the component signals, which can be limited by attributes of the sound sources themselves (including relative amplitudes) and especially by filtering characteristics of the BC transducers in use. The concurrent use of earplugs degrades the localization of externally presented sounds, but significantly improves the perception of BC-transmitted speech, ostensibly due to both passive attenuation of external noise and occlusion effect-based boosting of the speech signal.

Conclusions: BC headsets are often used to transmit personal audio or communications signals in settings that also require situational awareness for safe navigation and/or tactical decision-making. In such contexts, the definitions of “signals” and “noise” can change unpredictably. Future work will consider strategies to mitigate masking of critical AC spatial cues by BC headset audio.

M55. Bimodal Localization and Lateralization Response Distributions in Some Normal-Hearing Listeners

Matthew Goupell*¹, Mathias Dietz²

¹*University of Maryland-College Park*, ²*University of Oldenburg*

Background: It is assumed that binaural processing is exquisitely sensitive and accurate in normal-hearing individuals, which supports superb horizontal-plane sound-localization abilities and a remarkable ability to perceive speech in noisy cocktail-party-like environments. This includes the ability to perceive space continuously. When a listener has hearing impairment or uses a hearing-assistive device, there can be a breakdown of these abilities. For example, the listener might respond that the sound is in the left or right hemifield, without any fine ability to determine sound location. In other words, the listener produces a bimodal response distribution

where responses are primarily to the left or right, with few responses directly in front of the listener or in the center of the head. Such response patterns appear to typically have subtle effects in typical reporting of results, meaning they are arguably hidden in most reports. The purpose of this study was to make a rough estimate of often adults with assumed normal hearing respond with a bimodal distribution rather than the expected uniform distribution in laboratory psychoacoustic experiments.

Methods: We did a retrospective analysis of data from five localization and intracranial lateralization experiments. Critically, individual responses were visualized. Several summary metrics were compared to determine if they could be used to identify a bimodal response distribution. This included the root-mean-squared error and slope of a functional fit to the data.

Results: In our retrospective analysis, we found multiple cases of normal-hearing listeners with bimodal response distributions that were previously not noted, particularly in intracranial lateralization studies. In some cases, group mean data hid the presence of bimodal localization and lateralization response distributions. Plotting individual responses as well as response distribution histograms best revealed bimodal response patterns in individuals. Individual mean data for each stimulus location (source angle for localization and interaural difference applied for lateralization) obscured those with bimodal response distributions; these responses had larger error bars and steeper slopes as a function of azimuth for conditions that should be perceived from straight ahead or centrally. Root-mean-squared errors were larger for bimodal response distributions, but the values could be similar to other types of error patterns (e.g., a systematic bias to one side).

Conclusions: Bimodal response distributions were surprisingly common. They occurred more often in lateralization experiments, but also happen in localization experiments and were sometimes stimulus specific. It is unclear if these normal-hearing listeners had some unidentified pathology or if bimodal response distributions are typical. Moreover, the prevalence may differ across studies for an unknown reason. These results should be carefully considered when researchers attempt to identify abnormal binaural processing in clinical populations with hearing impairment or other medical conditions.

M56. ITD Sensitivity in Normal Hearing: The Role of Age and Temporal Stimulus Structure

Susan Arndt^{*1}, Celestine Lucas², Konstantin Wiebe³, Jan W Schnupp⁴, Thomas Wesarg³, Nicole Roßkothen-Kuhl²

¹University of Freiburg, ²Neurobiological Research Laboratory, Section for Experimental and Clinical Otology, University Medical Center Freiburg, Faculty of Medicine, University of Freiburg, ³Cochlear Implant Section, University Medical Center Freiburg, Medical Faculty, University of Freiburg, ⁴Gerald Choa Neuroscience Institute, Chinese University Hong Kong, Chinese University of Hong Kong

Background: Sound localization is based on two binaural cues: interaural time difference (ITD) and interaural level difference (ILD). In normally hearing (NH) adults, the ITD sensitivity threshold for 250 Hz is approximately 25-80 μ s. In comparison, little research has been conducted on ITD sensitivity in children. Sensitivity to binaural stimuli can be influenced by

various factors such as listening experience, general and central developmental status, or the type of sound stimulus. This study investigated the development of ITD sensitivity with increasing age and its dependence on stimulus parameters.

Methods: Eleven NH children ($\bar{X}$ 9.05 years old) and 10 NH adults ($\bar{X}$ 34.03 years old) were tested on sound lateralization using a 2-alternative forced choice gamified setup. Acoustic stimuli were 0.5 second long tone bursts at 250 Hz with a rising and falling slope of 4 ms (onset and ongoing ITD information) or 100 ms (ongoing ITD information only) and were presented via headphones. All subjects were tested for different ITDs of $\pm\{25, 50, 100, 200, 400, 800\}$ μ s. The ITD sensitivity thresholds (just-noticeable differences, JNDs) were calculated for the two ramp durations using psychometric functions.

Results: Compared to NH children ($\bar{X}$ 93.61 μ s), NH adults showed significantly better ITD JNDs ($\bar{X}$ 64.79 μ s) for both stimulation conditions. In NH children, ITD sensitivity showed a positive correlation with age under both conditions, indicating an improvement with increasing development of the auditory pathway. Notably, both cohorts showed significantly better ITD JNDs when the acoustic stimuli were presented with a ramp duration of 4 ms (children: $\bar{X}$ 92.07 μ s, adults: $\bar{X}$ 55.78 μ s) rather than 100 ms (children: $\bar{X}$ 113.89 μ s, adults: $\bar{X}$ 73.28 μ s).

Conclusions: In conclusion, auditory networks for ITD-based spatial hearing are still maturing in early childhood, resulting in poorer ITD sensitivity < 9 years compared to mature adult networks. Regardless of developmental stage, better ITD sensitivity was achieved with acoustic stimuli containing onset ITD information (4 ms ramp duration), confirming the importance of onset ITD sensitivity for optimal spatial hearing.

M57. Developmental Plasticity In Barn Owl ITD Circuits

Catherine Carr^{*1}, Waisudin Kamal¹, Nada Abouelseoud¹, Camelia Abshire-Cohen¹, Fabiana Kubke², Paula Kuokkanen³

¹University of Maryland, ²University of Aukland, ³Institute for Theoretical Biology, HU Berlin

Background: Barn owls experience increasing interaural time differences (ITDs) during development, because their head width more than doubles in the month after hatching. We hypothesized that their ITD detection circuit might be modified by experience. To test this, we raised owls with unilateral ear plugs then measured the ITD representation in the brainstem nucleus laminaris (NL) when the birds were adult. The ITD circuit is composed of delay line inputs from the nucleus magnocellularis (NM) to the coincidence detectors in NL, and we predicted that compensatory plastic changes would lead to shorter delays in the axons from the manipulated ear. In owls that received ear plugs starting around P14, the maps of ITD shifted in the predicted direction, but only on the ipsilateral side, and only in those tonotopic regions that had not experienced auditory stimulation prior to insertion. The contralateral maps did not change. We recorded a frequency imbalance of the inputs from NM to NL which could be large enough to affect ITD tuning but was insufficient to account for all measured ITD shifts (Carr et al, 2024). We therefore examined the anatomical consequences on this circuit of reducing afferent auditory activity.

Methods: Experiments were conducted at the University Maryland, where 4 owls were raised with a unilateral earmold plug from P14 to 3 months. For immunohistochemical studies of GABAergic terminals, owls were perfused and sectioned at 30 μ m. Antisera against vesicular

glutamate Transporter (VGAT) were used at 1:1000, and terminals quantified using Neurolucida. Axon diameters were measured in EM perfused material.

Results: We examined the effects of unilateral earplug raising by measuring cell sizes, NM axon diameters and GABAergic innervation in adult birds after plug rearing. GABAergic inputs originate from the superior olive and mature in a low to high best frequency gradient in both NM and NL in the first month post-hatch. In ear plug raised birds, GABAergic terminal density was unchanged in NL both ipsi- and contralateral to the ear insert. In NM, VGAT immunohistochemical label on the earplug side revealed higher densities of GABAergic terminals in the high best frequency tonotopic regions that had not experienced auditory stimulation prior to plug insertion. VGAT label in the contralateral NM was indistinguishable from controls.

Conclusions: Thus, altered auditory input during development is associated with long-lasting changes in the inhibitory elements of the circuit for computation of ITD.

M58. Spatial Release From Speech-On-Speech Masking in Reverberation Evaluated Using the Portable Automated Rapid Test

Udbhav Singhal^{*1}, Marusa Laure², Alyson M. Ditmore³, William J. Bologna³, Aaron Seitz⁴, Frederick Gallun⁵, G. Christopher Stecker⁶, Norbert Kopco¹

¹*P.J. Safarik University in Kosice*, ²*University of Maribor*, ³*Towson University*, ⁴*Center for Cognitive and Brain Health, Northeastern University*, ⁵*Oregon Health and Science University*, ⁶*Boys Town National Research Hospital*

Background: This study used the Portable Automated Rapid Testing (PART) system to examine the effect of reverberation on spatial release from masking (SRM) for speech stimuli in a multi-talker environment. To examine the informational masking aspects of SRM, the experiment used a closed-set corpus (Coordinate Response Measure, CRM) and symmetrically placed maskers, reducing the energetic benefits of target-masker separation

Methods: Ten young adults with normal hearing (ages 20-32) completed a speech-on-speech recognition task in a sound-attenuating booth, using calibrated headphones and a tablet running the PART system. On each trial three different sentences with the structure “Ready [callsign] go to [color] [number] now” were presented simultaneously and the listener’s task was to identify the color and number in the sentence containing the callsign “Charlie”. The three sentences were spoken by three different male voices and differed in the callsigns, colors, and numbers. The target’s position was always simulated directly ahead of the listener, and the maskers could be either co-located with or spatially separated from the target (simulated at +/- 45° azimuth). The simulated environment was either anechoic or reverberant, generated using a modified image source model simulating a 10 × 10 m room with a reverberation time of 0.4 s, with the subject placed slightly off center to enhance realism of the simulation. Testing employed an adaptive scan procedure consisting of five scans (two non-adaptive, three adaptive), each with nine steps and a three-error termination rule. Trial-level data were analyzed with a general linear model to estimate the slope and 50% threshold of the psychometric function in each condition. Errors were categorized as intrusions if the response matched the color and/or numbers from the masker(s).

Results: SRM was 8.5 dB in the anechoic environment, reduced to only 1.1 dB in reverberation. This was driven mainly by an increase in separated reverberant thresholds (8 dB higher on average than separated anechoic thresholds), whereas co-located thresholds only increased by 0.5 dB in reverberation. The slopes of the psychometric curves were comparable in the co-located conditions (anechoic: 13.4 %/dB, reverberant: 13.3 %/dB). In the separated conditions, slope was shallower overall, particularly in the anechoic condition (anechoic: 8 %/dB, reverberant: 12 %/dB). Most errors were categorized as intrusions, accounting for approximately 85-90% of errors in most conditions, while only accounting for approximately 75% of errors in the separated anechoic condition

Conclusions: The study showed that PART can be used to obtain measures of SRM consistent with published approaches. Results suggest, in scenarios with high informational masking, the benefit of spatial separation can be dramatically reduced in reverberant vs anechoic environments, possibly due to increased difficulty segregating the target from maskers in reverberation.

M59. FMRP Regulates Central Projection Assembly and Synaptic Maturation of Auditory Ganglion Neurons

Xiaoyu Wang¹, Anlu Yong¹, Qiwei Fan¹, Yanmei Li¹, Sima Sabbagh², Danah Alquraish², Diego Zorio², Yuan Wang^{*2}

¹Jinan University, ²Florida State University

Background: The molecular mechanisms guiding the maturation and central projection of auditory ganglion (AG) neurons remain poorly defined. Fragile X messenger ribonucleoprotein (FMRP), a conserved RNA-binding protein essential for neural circuit development, is highly expressed in AG neurons across vertebrate species. However, its role in AG neuron maturation and connectivity remains unknown.

Methods: FMRP expression in chicken AG neurons was selectively reduced using drug-inducible, cell group-specific knockdown in live embryos. Effects on AG axon targeting and the structural and functional formation of presynaptic endbulb terminals within the primary cochlear nucleus—nucleus magnocellularis (NM) in birds—were assessed via axon tract tracing, 3D reconstruction, and FM dye imaging. Molecular players and mechanisms were identified using immunocytochemistry and RNAscope. To evaluate evolutionary conservation, wild-type and *Fmr1* knockout mice were analyzed for endbulb terminal phenotypes.

Results: FMRP knockdown in developing AG neurons led to frequent axon targeting failures onto NM neurons, most pronounced during the axon guidance window. During this period, NM-derived *Sema3A* normally induces AG growth cone collapse; this response was blunted when FMRP was deficient. Mechanistically, FMRP loss caused nuclear accumulation of *plexinA1* mRNA, reducing its cytoplasmic and axonal levels and impairing *Sema3A* responsiveness. In axons that successfully targeted NM neurons, structurally intact terminals were formed, but their function was compromised. This deficit was linked to delayed upregulation of synaptotagmin 2 (*Syt2*), a primary calcium sensor on synaptic vesicles. FMRP stabilized *Syt2* mRNA without

affecting its nuclear export, and knockdown reduced Syt2 transcript abundance. Fmr1 knockout mice exhibited similar deficits in Syt2 expression during the circuit assembly window, confirming conservation of FMRP function.

Conclusions: This study identifies two distinct FMRP-mediated mechanisms critical for AG neuron central projection and synaptic maturation. During axon targeting, FMRP facilitates nuclear export of plexinA1 mRNA, enabling proper Sema3A signaling and target recognition. During presynaptic development, FMRP stabilizes Syt2 mRNA, ensuring timely synaptic functionalization. These findings establish FMRP as a cell-autonomous regulator that orchestrates discrete stages of synaptogenesis via differential regulatory mechanisms.

M60. In Vivo Imaging of the Auditory Pathway in Mice Using Bundle Fibers

Ryohei Akiyoshi*¹

¹*Dokkyo University School of Medicine, Koshigaya Hospital*

Background: Physical or chemical stimuli from the environment are converted into electrical signals by peripheral sensory receptors. These signals then ascend through successive synapses in the nuclei of sensory pathways, ultimately reaching the sensory areas of the cerebral cortex. Once in the cerebral cortex, it is known that sensory information is integrated in distinct sensory areas corresponding to different modalities, or is modified by memory and emotion in structures like the hippocampus and amygdala before being recognized. In auditory processing, evoked responses in relay nuclei to sound stimuli have been studied in various vertebrates using electrophysiological technique. Recently, methods using optical imaging techniques—such as flavin fluorescent proteins, endogenous signals, or calcium-sensitive fluorescent proteins—to observe activity in areas like the auditory cortex have become widely employed. However, optical imaging can only observe the brain surface and to a certain depth. Furthermore, electrophysiological methods make it difficult to observe function and behavior in the awake state. Therefore, we attempted to observe deep brain neural activity or morphology in the awake state by implanting extremely fine optical fibers into the central nervous system.

Methods: Thy1-EGFP mice (genetically modified mice expressing GFP under the control of the Thy1 gene promoter in neurons of the hippocampus, amygdala, and cerebral cortex layer 5, used to observe neuronal morphology) and wild-type mice were used as experimental animals. In wild-type mice, to observe neuronal activity, the green calcium-sensitive fluorescent protein GFP-based Calcium Calmodulin probe (hereafter GCaMP: a green fluorescent calcium sensor genetically engineered from GFP, a green fluorescent protein used for fluorescent labeling of cells and biomolecules) was expressed in deep brain nuclei using an adeno-associated virus. A bundle fiber (diameter 0.6 mm) consisting of a bundle of microfibers was used as the optical fiber. Using these mice, the optical fiber was carefully implanted through the dorsal scalp under anesthesia. The objective lens and optical fiber were connected via a rotary joint.

Results: Observation using a high-brightness LED as the excitation light source allowed visualization of fluorescence from deep brain nuclei through the optical fiber. Changing the depth resulted in spatially distinct fluorescence patterns within the nuclei. Furthermore, time-lapse imaging of the deep brain regions of wild-type mice expressing GCaMP in excitatory neurons revealed temporal changes in GCaMP fluorescence intensity.

Conclusions: These results suggest that using bundle fibers may enable in vivo observation of the morphology or activity of deep brain neurons. Furthermore, since the same bundle fiber can transmit light bidirectionally, it is considered applicable to experimental systems using optogenetic techniques such as channelrhodopsin to evoke or suppress neuronal activity.

M61. Noise-Induced Reduction and Early Recovery of SPN OFF Responses

Mihai Stancu¹, Ezhilarasan Rajaram¹, Joseph Kroeger¹, Benedikt Grothe¹, Conny Kopp-Scheinpflug*¹

¹*LMU Munich*

Background: Neuronal circuits exhibit a remarkable capacity for plasticity in response to altered sensory input. The temporal dynamics and cellular mechanisms underlying this plasticity are highly heterogeneous and seemingly specific to individual circuits. Excessive noise exposure leads to damage of peripheral auditory structures, such as cochlear hair cells and auditory nerve fibers, resulting in reduced afferent input to downstream structures and initiating a cascade of long-lasting compensatory changes in central auditory circuits. Among these changes, increased neuronal excitability, elevated spontaneous firing rates, and generalized enhancements in neural gain were reported in multiple structures from the cochlear nucleus to the auditory cortex. However, these findings have primarily involved neurons that are responsive to sound onset. In contrast, little is known about the impact of noise-induced hearing loss on neurons that are selectively activated by sound offset and predominantly driven by inhibitory synaptic input.

Methods: To address this gap, we investigated the effects of noise exposure on the intrinsic membrane properties, synaptic input patterns, and sound-evoked activity of neurons in the superior paraolivary nucleus (SPN)—a population of neurons specialized for encoding sound offset. We employed a combination of immunohistochemistry, in vitro whole-cell patch-clamp recordings from acute brain slices, and in vivo single-unit recordings to assess the mechanisms underlying offset response generation in SPN neurons following moderate noise exposure. The noise paradigm was designed to induce threshold shifts of up to 40dB, and neural responses were assessed at two time points: immediately after exposure (0 hours) and 24 hours post-exposure.

Results: Consistent with previous reports, we observed increased intrinsic excitability in SPN neurons at 24hrs following noise exposure. However, contrary to the prevailing hypothesis of reduced inhibition as a driver of central gain, we found that inhibitory input to SPN neurons was not diminished but rather enhanced. This observation was confirmed across multiple methodological approaches and was associated with preserved suprathreshold offset responses exhibiting spectral and temporal tuning properties comparable to those observed in control animals.

Conclusions: Together, these changes contribute to the recovery of suprathreshold sound-offset responses 24 hours after noise exposure. Notably, neurons in the lateral superior olive—which are anatomically close to the SPN and also receive glycinergic input from the medial nucleus of the trapezoid body—exhibited reduced mIPSC frequencies following noise exposure. This finding supports the idea of a circuit-specific compensatory mechanism that helps sound-offset (OFF) encoding in the face of peripheral auditory damage.

M62. Auditory Deficits Following Continuous Noise or Single Blast Exposure

Fernando Aguilera de Alba*¹, Isabella Huddleston¹, Elizabeth Jensen¹, Michael Heinz¹

¹*Purdue University*

Background: Service members are often exposed to harmful acoustic environments—from prolonged moderate-level noise (e.g., living and working on aircraft carriers) to brief high-intensity blasts (e.g., improvised explosive devices). Understanding how these different noise exposures affect auditory processing is critical. In this study, we investigated peripheral and central auditory functional deficits following continuous noise exposure simulating aircraft-carrier conditions or a single blast exposure simulating mild-to-moderate traumatic brain injury (TBI) using a chinchilla model.

Methods: For continuous noise, awake chinchillas were exposed for 1, 2, or 4 consecutive weeks (40 hours/week) at 87.5 dBA adjusting for cross-species middle-ear differences. For blast, anesthetized chinchillas were exposed to a single (1) blast at 150 kPa reflected peak overpressure with bilateral hearing protection (i.e., ear plugs). We employed a multi-metric auditory framework including tympanometry, wide-band middle-ear muscle reflex (WB-MEMR), otoacoustic emissions (OAEs; swept distortion product, DP; swept stimulus frequency, SF; transient evoked, TE), auditory brainstem response (ABR), and envelope frequency response (EFR) to amplitude-modulated stimuli. Electrophysiology (ABR and EFR) and blast exposures were performed under anesthesia using xylazine (2 mg/kg) and ketamine (20 mg/kg). Peripheral measures (tympanometry, WB-MEMR, and OAEs) were collected with fully awake but restrained animals.

Results: Continuous Noise Exposure (1, 2, or 4 weeks post-exposure): Reduced DPOAEs by 5–20 dB across all frequencies, SFOAEs decreased by 5-10 dB at mid-to-high frequencies, and diminished WB-MEMR strength as early as one week and remained up to four weeks. ABRs revealed mild-to-moderate (5–30 dB) threshold shifts across all frequencies while EFRs showed degraded temporal encoding occurs at high modulation frequencies as early as one week. However, ABR thresholds (1 and 2 kHz + click) and temporal encoding showed signs of recovery by week four. Single Blast Exposure (0.5, 2, 4, and 8 weeks post-exposure): No effects were observed for DPOAEs, SFOAEs, and WB-MEMR—as expected given bilateral protection with earplugs. Hearing thresholds were mostly unaffected except at 8 kHz with 5-10 dB shifts appearing until week four. Temporal encoding was degraded as early as three days post-exposure followed by hypersensitivity on week four that remained until week eight. Both continuous-noise and single-blast exposure showed mixed TEOAE effects across frequencies.

Conclusions: Together, these findings demonstrate continuous noise and single blast exposures have unique auditory deficits. Continuous noise at moderate levels caused persistent hearing loss and cochlear damage accompanied by transient temporal processing deficits. On the other hand, single blast exposure at intense levels led to minimal peripheral deficits but persistent temporal processing deficits. Our study shows the importance of a multi-metric auditory framework to highlight potential differences in auditory deficits that can be used to differentiate noise- and blast-induced hearing loss while helping to develop effective individualized treatment plans.

M63. Presynaptic Sodium Leak Channel NALCN at the Calyx of Held Synapse

Tianhao Wu^{*1}, Dainan Li¹, Maria Gurma², Tianyi Xiao¹, Youad Darwish¹, Lu-Yang Wang², Hai Huang¹

¹*Tulane University*, ²*University of Toronto*

Background: At chemical synapses, the invasion of an action potential activates voltage-gated Ca²⁺ channels, leading to highly localized, transient Ca²⁺ influx that triggers vesicle fusion and neurotransmitter release. Although the large Ca²⁺ transients are required for rapid phasic exocytosis, low concentrations of basal Ca²⁺ can modulate release via vesicle recruitment, priming and sensitization, and subtle changes in basal Ca²⁺ levels alone can profoundly alter neurotransmitter release and synaptic strength. The Ca²⁺ channels mediating action-potential triggered release have been extensively studied. However, the ion channels that set the resting Ca²⁺ levels in nerve terminals remain enigmatic.

Methods: Brain slices from wildtype (WT) and NALCN conditional knockout (cKO) mice were harvested for electrophysiological recordings, imaging, and immunohistochemistry.

Results: We found that NALCN is expressed in calyx of Held terminals, where it not only controls the resting membrane properties but also regulates cytosolic Na⁺ level to drive glutamate uploading into synaptic vesicles. Surprisingly, presynaptic NALCN, unlike that in its recombinant counterpart, exhibits previously unappreciated Ca²⁺ permeability. NALCN is tightly coupled with active zone proteins and occupies transsynaptic nanocolumns between postsynaptic glutamate receptors and presynaptic release sites, directly mediating Ca²⁺-dependent synaptic transmission. Pharmacological blockade of NALCN or selective genetic deletion of NALCN from nerve terminals ablates these effects, weakening synaptic strength and neurotransmission fidelity.

Conclusions: NALCN is a key contributor to the resting membrane properties of central mammalian nerve terminals. It regulates neurotransmitter release via two distinct pathways: by modulating presynaptic resting Na⁺ and Ca²⁺ concentrations, NALCN regulates vesicular glutamate transport and vesicle release probability, ultimately maintaining the fidelity of neurotransmission across the central synapses.

M64. From Compression to Periodicity: Cochlear Influences on Suprathreshold Neural Encoding

Pedro Andres Alba Diaz^{*1}, Anu Sreenivasan Nair¹, Sajana Aryal¹, Srikanta Mishra¹

¹*The University of Texas at Austin*

Background: The nonlinear mechanical properties of the cochlea, mediated by the outer hair cells, offer low-level amplification and mid-level compression of basilar membrane vibrations, which contribute to the broad dynamic range of human hearing. While these nonlinearities are often assumed to be uniform across normal-hearing listeners, there is increasing evidence for individual differences in both low-level gain and compressive growth. However, the extent to which these differences impact the neural encoding of sustained envelope periodicity, important for speech understanding, remains poorly understood. The envelope following responses (EFRs) serve as a reliable indicator of subcortical synchronization to amplitude modulation (AM). We hypothesize that cochlear compression will modulate EFRs measured at shallow modulation depths (e.g., 40% AM), making them more sensitive to individual differences than EFRs at deep

depths (100% AM). Specifically, individuals with weaker cochlear compression—indicated by steeper DPOAE input-output slopes—will exhibit stronger EFRs at shallow AM, while EFRs at deep AM remain robust and insensitive to compression. Studying the relationship between cochlear compression and EFRs could improve synaptopathy diagnosis by revealing how peripheral mechanical deficits influence neural encoding.

Methods: Envelope following responses and DPOAE were obtained from thirty normal-hearing adults (N=30; mean age=21.7 years, SD=3.6; 29 females). EFRs were elicited with a sinusoidally AM 4 kHz carrier at 101.56 Hz, with modulation depths of 40% and 100%. Wavelet analysis was used to derive EFR metrics, including signal-to-noise ratio (SNR) and phase-locking value (PLV). DPOAEs were obtained by varying the f2 level (L2) from 20 to 70 dB SPL and calculating the f1 level (L1) using the “scissor paradigm” ($L1=0.4 \times L2+39$). DPOAE I/O functions were fit with a two-segment piecewise linear regression model, obtaining slopes for the linear (S1) and compressive (S2) regions, as well as compression thresholds. Pearson's correlations were calculated between DPOAE slopes (S1, S2) and EFR metrics (SNR, PLV) across modulation depths.

Results: At shallow modulation depths (40%), the linear slope (S1) showed a significant positive correlation with PLV ($r=0.456$, $p=0.002$), but no correlation was observed at 100% modulation depth. For compressive slope (S2), a significant positive correlation was found with both SNR ($r = 0.326$, $p = 0.022$) and PLV ($r = 0.527$, $p < 0.001$) at 40%. However, no significant correlations were observed between S2 and PLV at 100% modulation depth. These findings revealed that cochlear compression contributes to subcortical envelope encoding at shallow modulation depths, while its influence is minimal at deep modulation depths.

Conclusions: Our findings demonstrate that individual differences in cochlear nonlinearities, particularly compressive gain, influence subcortical encoding of temporal envelopes at shallow modulation depths. These results indicate that EFRs reflect not only neural integrity but also peripheral cochlear mechanics, providing insight into the variability of envelope encoding among normal-hearing listeners.

M65. In Vivo Single-Cell Electroporation of Physiologically Identified Neurons in the Mouse Cochlear Nucleus

Yao-Hsin Huang*¹, Hsin-Wei Lu¹

¹*National Taiwan University*

Background: The cochlear nucleus (CN) serves as the initial station in the central ascending auditory pathway, processing acoustic information through its diverse cell types. Although single cell physiological and labeling studies provide extensive insights into structure-function relations of CN neurons, understanding the input-output transformation of individual neurons requires a comprehensive knowledge of connectivity map between single CN neurons and its presynaptic inputs. Single-cell initiated retrograde viral tracing from cells recorded in vivo offers a promising approach to address this question. The first step for this approach requires transfecting plasmids into a recorded neuron, achieved through in vivo single-cell electroporation or whole-cell recording. While this technique has been applied in several brain regions, its use in the auditory system remains unexplored. In this study, we investigate the feasibility of single-cell electroporation with simultaneous in vivo recordings in the mouse CN.

Methods: Anesthetized C57BL/6 mice (P35–P82), induced with zoletil-xylazine mixture (40/12 mg/kg), was used in this study. Lateral cerebellum was aspirated to expose the CN. A glass micropipette (tip resistance 5–8 MΩ) filled with an internal solution containing fluorescent protein plasmids (200ng/μL pAAV-CAG-GFP) was used for blind in vivo cell-attached recording. Sound stimuli consisted of pure tones, click trains, noises, AM tones, and harmonic complex tones to characterize single-neuron response to sounds. After recording, high-voltage pulses (–6 V, 0.5 ms, 50 Hz for 1 s) were applied through the same electrode, and the electrode was then carefully withdrawn. The mouse was allowed to recover for seven days before examination of transfection results.

Results: We found that single-cell electroporation provided more specific neuronal labeling than conventional biocytin labeling. GFP expression was observed in single CN neurons without apparent contamination due to pipette leakage. While consistent labeling remains a challenge, in cases where successful transfection is achieved, the soma and dendrites could be clearly labeled, and the axon could be traced for up to a several millimeters. In a few cases, the soma was absent despite successful labeling of dendrites and axon. Electrophysiological and morphological data could be integrated: for instance, a dorsal CN neuron responding with long first spike latency to its best frequency projects its axon through the dorsal acoustic stria, consistent with features of a fusiform cell. Both principal cells and interneurons could be labeled, including principal neurons such as octopus cells, fusiform cells, and interneurons such as vertical cells and cartwheel cells.

Conclusions: We demonstrate the feasibility of in vivo single-cell transfection with electrophysiological recordings in mouse CN neurons. Further refinement of the protocol, aimed at a more consistent transfection rate, will establish a foundation for single-cell initiated retrograde viral tracing to investigate the functional organization of the auditory brainstem in finer detail.

M66. A Comparison of Auditory Brainstem Responses to Diverse Stimulus Conditions in Rhesus Macaques

Alireza Karimi^{*1}, Reagan Whitaker², Aneesh Batchu¹, Swarat Kulkarni¹, Sarah Burkey², Colleen Le Prell³, Troy A Hackett², Ramnarayan Ramachandran²

¹*Vanderbilt University*, ²*Vanderbilt University Medical Center*, ³*University of Texas at Dallas*

Background: Nonhuman primates (NHPs) are a critical translational model for human hearing, with cochlear mechanics, brainstem and cortical organization similar to those of humans. Crucially, macaques have similar noise exposure susceptibility to humans, and support human-like perceptual and behavioral paradigms, enhancing the translation of both physiological and functional outcomes. In addition, NHPs permit controlled acoustic exposures and post-exposure intervals prior to histology. Together, these features make NHPs uniquely suited for auditory-system studies, particularly of noise injury and its brainstem correlates. However, normative non-invasive physiological measures spanning multiple stimulus classes are scarce in this species. To remedy this, we measured physiological responses to a wide range of stimuli.

Methods: Anesthetized young adult rhesus macaques (*Macaca mulatta*, age 4-7 years, n=16, 8 female, 8 males), were tested using non-invasive physiological assays, including auditory brainstem responses (ABRs) and Distortion Product Otoacoustic Emissions (DPOAEs) in a sound-treated

RF-shielded booth. Anesthesia was induced with ketamine and midazolam and maintained with isoflurane. Eight physiological tests are reported: DPOAEs (1-32 kHz), tones (0.5–32 kHz), chirps and clicks presented at various rates (27.7-200 /s), click and chirp pairs with varying inter-stimulus intervals (1-10 ms). For each, we extracted standard wave metrics (Waves I/II/IV amplitudes and latencies) and quantified ear-wise asymmetries.

Results: Thresholds to tones showed the expected U-shaped frequency dependence, with no sex-related differences. Click and chirp thresholds also showed no sex related differences. Inter-ear threshold differences were ≤ 10 dB SPL for most subjects, with no significant sex- or frequency-related bias. Paired-stimuli conditions exhibited canonical temporal-recovery signatures: reduced response amplitudes and prolonged latencies compared to the first stimulus response at short inter-stimulus intervals, with responses more similar to the first stimulus at longer intervals. Rate-manipulation experiments produced rate-dependent reductions in amplitude and latency increases at higher stimulus rates. Across ears, per-wave response amplitude correlations were stronger for closer tone frequencies and for chirp–click comparisons. Latency correlations were weaker and sparser than amplitude correlations.

Conclusions: Together, these results provide a comparative reference for macaque ABRs across complementary stimulus classes—covering thresholds, ear asymmetries, and temporal-recovery functions—and furnish benchmarks to support longitudinal studies of auditory brainstem physiology in a translational primate model. These data form pre-exposure baselines for chronic noise exposure in the same cohort. By spanning complementary stimulus classes and including DPOAE, this baseline enables sensitive detection of exposure-related changes, including subtle synaptic / neural deficits that may precede threshold shifts, through shifts in wave-I/II/IV amplitudes and latencies, altered temporal recovery functions, and rate-dependent modulation.

M67. Neurons of the Small Cell Cap

James Baldassano*¹, Catherine Weisz¹

¹*National Institutes of Health*

Background: Auditory processing requires the brain to extract a wide breadth of information from acoustic signals. This is accomplished in part by heterogeneity of neurons in the cochlear nucleus (CN), an obligatory relay point of auditory nerve activity. Heterogeneity of auditory neurons is necessary to extract specific features, such as sound intensity, from cacophonous auditory nerve activity. Therefore, it is critical to understand the role of each type of neuron in CN processing to understand how sound features are initially represented in neuronal activity. In vivo recordings from the small cell cap (SCC), a region just ventral to the granule cell domain, showed that these neurons encode amplitude modulations and sound intensity with higher fidelity than other CN neurons. However, little is known about the intrinsic properties of these neurons, nor what function they provide within the circuit. SCC receives exclusively high threshold/low spontaneous rate inputs thought to be of particular importance in human speech processing. To investigate the function of these neurons, we used a mouse line that labels a subset of neurons in the small cell cap and performed patch-clamp electrophysiological recordings from labeled neurons.

Methods: Jing et. al (2025) used FISH to demonstrate that Penk was expressed in SCC neurons. Therefore, we crossed Penk-Ires-Cre mice with Ai14-TdTomato reporter mice to label a subset

of neurons in SCC. Next, we performed immunohistochemistry on Penk-Cre/TdTomato mice in brainstem slices to confirm that the expression was in the expected region of CN. For electrophysiology experiments, we collected sagittal brain slices containing SCC. We performed patch-clamp recordings from individually identified neurons in both current-clamp and voltage-clamp. Gap-free recordings were performed to collect spontaneous synaptic events. Series of either voltage steps or current steps were used to measure membrane and electrophysiological properties such as input resistance, capacitance, firing rate, and characterize voltage-gated currents.

Results: Recordings from Penk+ neurons in SCC indicate that these neurons have a high input resistance ($\sim 1.02 \pm 0.28$ G Ω), low capacitance (9.3 ± 2.1 pF), and are very excitable, consistently able to be excited with current injections as low as 5 pA. Voltage-clamp recordings revealed two different distinct types of outward currents, with one producing a flat, constant current ($n=4$) and the other displaying an inactivating current ($n=10$). All of these neurons displayed a voltage-dependent I_h current, with an activation voltage beginning at ~ -84 mV and becoming more prominent at more negative voltages.

Conclusions: Here, we used the Penk-Ires-Cre mouse line to target neurons in the small cell cap. Using patch-clamp electrophysiology, we demonstrate that these neurons have several unique properties, including a high input-resistance, a prominent I_h current, and a low rheobase. To understand the role of these neurons in auditory processing, further experiments manipulating their synaptic inputs and post-synaptic targets will be required.

M68. Modeling of Dorsal Cochlear Nucleus Reveals Connectivity Underlying Response Profiles

Katherine Doxey^{*1}, Sharon Crook¹, Timothy Balmer²

¹Arizona State University, School of Mathematical and Statistical Sciences, ²Arizona State University, School of Life Sciences

Background: The dorsal cochlear nucleus (DCN) plays a critical role in auditory processing, including contributing to sound source localization, suppression of self-generated sounds, and transformation of complex spectral patterns (Oertel and Popper 2002, Young and Davis 2002, Singla et al. 2017). Data-driven computational modeling provides a powerful framework for investigating these functions, informing the understanding of experimental results and guiding future experimental studies.

Methods: We develop biophysically realistic cell and network models to investigate how connectivity within the DCN modulates representations of auditory stimuli. Using the CNModel platform (Manis and Campagnola 2018), we simulate a fusiform cell receiving synaptic input from excitatory auditory nerve fibers and inhibitory D-stellate and tuberculoventral cells. Auditory nerve inputs are driven by an auditory periphery model (Zilaney et al. 2014) that generates spike trains in response to pure tone stimuli.

Results: We explore the dynamical behaviors of a fusiform cell model by generating response maps that represent the evoked firing rate in response to model auditory stimuli of varying frequencies and sound levels. We demonstrate that distinct type III and IV response profiles emerge from different combinations of excitatory and inhibitory synaptic strengths.

Conclusions: These results highlight how subtle variations in network connectivity can shape neuronal response properties and provide a mechanistic framework for understanding functions of the DCN. Additionally, we model high frequency hearing loss by simulating hair cell impairment in the auditory periphery model and explore how altered connectivity patterns could contribute to the emergence of tinnitus.

M69. Open Board

M70. Contactin-2 (CNTN2) Expression in Developing Chick Inner Ear Neurons

Jennifer Rowsell*¹, Makenna Schroeder¹

¹*Saint Mary's College*

Background: During development of the inner ear, neuron progenitors extend projections from their soma centrally toward the brain and peripherally toward the inner ear organs. Neuronal projections rely on cues from their environment to navigate correctly to their targets. Cell adhesion molecules (CAMs) have been shown to play a role in axonal pathfinding processes, including an immunoglobulin super-family CAM, Contactin-2 (CNTN2).

Methods: To explore whether CNTN2 might play a role in axonal pathfinding of inner ear neurons, we characterized the spatiotemporal expression in chick auditory and vestibular neurons, by performing immunohistochemistry from E3-E7. CNTN2 expression was compared to the well-known neuronal label, TuJ1 as well as additional labels NCAM (Neuronal CAM), GATA3 (auditory neurons), and Myosin VIIa (vestibular neurons).

Results: CNTN2 was expressed in auditory and vestibular neuron soma and projections at all ages that were observed.

Conclusions: These data show that CNTN2 was present during the developmental stages when pathfinding is taking place, suggesting a role for CNTN2 in the pathfinding process of inner ear neurons.

M71. The Function of CaMKIV in Spiral Ganglion Neuron Development

Muthu Malavika Sugumar*¹, Zhirong Wang¹, Thomas Coate¹

¹*Georgetown University*

Background: Spiral ganglion neurons (SGNs) are the primary auditory neurons that form synaptic connections with hair cells in the cochlea and transmit auditory information to the brainstem. SGN-hair cell contacts are critical for hearing and are lost in various forms of hearing loss. In this research, we have focused our attention on activity-dependent aspects of SGN development, an area that is not well understood.

Ca²⁺/calmodulin-dependent protein kinase IV (CaMKIV) is crucial for aspects of neuron function, such as gene expression and neurotransmitter release, and is a target gene for autism spectrum disorders in humans. CaMKIV was shown by others to facilitate SGN survival and neuron branch dynamics in vitro. In previous studies (manuscript in preparation), we found that CaMKIV is a downstream effector of the purinergic receptor P2RX3: developing SGNs lacking

P2rx3 showed increases in SGN activity and levels of activated CaMKIV. In this present study, we addressed the hypothesis that CaMKIV is a downstream effector of SGN activity and that CaMKIV is an important regulator of SGN differentiation and survival.

Methods: We performed immunohistochemistry on P2rx3 knockout mice and cochlear cultures treated with MRS2500 to investigate CaMKIV levels in the context of high vs. low SGN activity. We also performed immunohistochemistry on CaMKIV knockout mice to characterize the role of CaMKIV in SGN subtype differentiation and its interaction with pCREB in the cochlea at different developmental stages.

Results: CaMKIV protein levels were increased in the nuclei of the SGNs from mice lacking P2RX3 (P2rx3 knockout mice). The increased CaMKIV levels coincided with increased pCREB activation, SGN branch arborization, and a brief increase in spontaneous activity. Our data also show a decrease in CaMKIV protein levels in samples treated with MRS2500 (low activity model). Collectively, these data suggest CaMKIV responds to changes in SGN synaptic activity. In addition, we observed decreased pCREB levels in neonatal mice lacking CaMKIV (camk4 knockout mice), suggesting a direct relationship between CaMKIV and pCREB. Furthermore, adult mice lacking CaMKIV showed an increase in the number of 1c SGNs and an increase in pCREB levels, indicating a role for CaMKIV in SGN differentiation and pCREB regulation.

Conclusions: CaMKIV expression is dependent on activity in the cochlea. Our data indicate a relationship between CaMKIV and pCREB in the cochlea during development. Our data also indicates that CaMKIV plays a role in SGN differentiation. These data provide insight into activity-dependent mechanisms associated with SGN development. In current research, we are investigating other functions of CaMKIV in SGNs during development, like branch refinement and survival.

M72. From Alzheimer's Disease to Hearing Loss: The Role of APOE in SGN-Hair Cell Connectivity

M. Alp Demirhan*¹, Thomas Coate¹

¹*Georgetown University*

Background: Hearing loss and Alzheimer's Disease prevalence in the US is astounding, with each affecting over 10% of the population. Recently "sensorineural hearing loss" (the most common form of hearing loss) was found to be a risk factor for Alzheimer's Disease.
